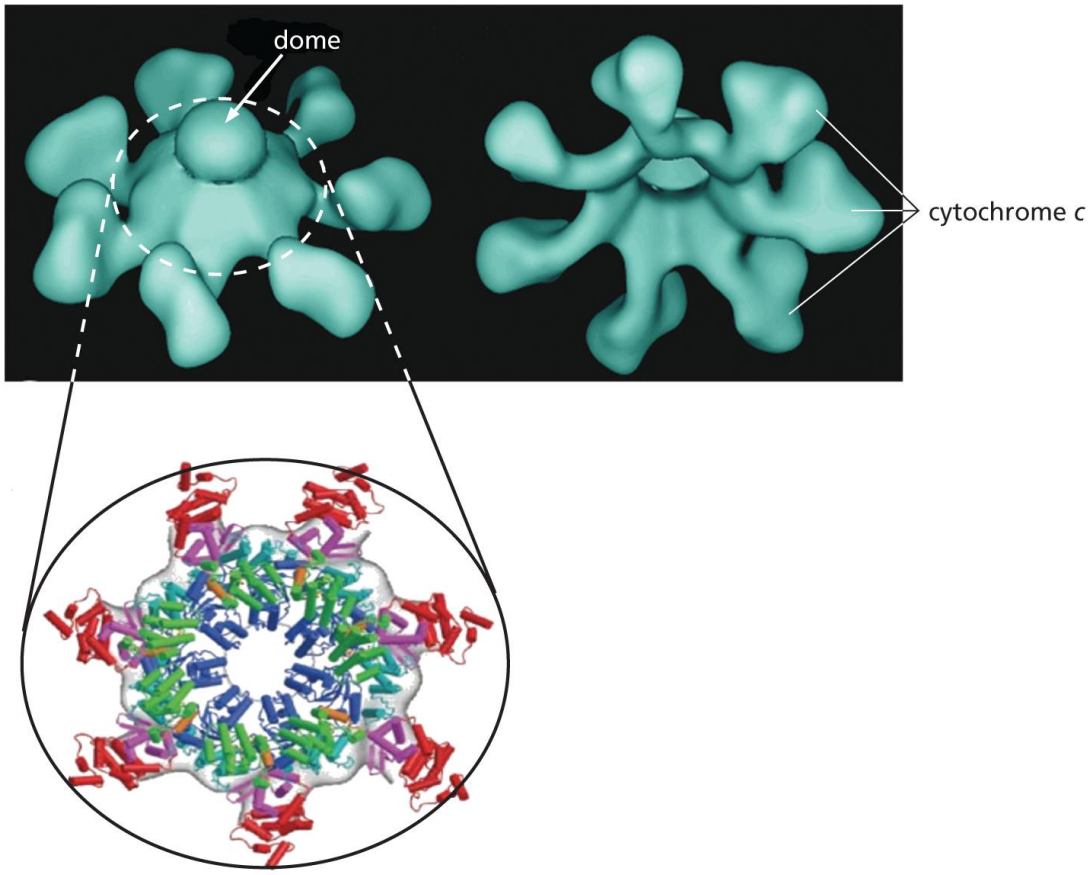
Figure 9.25 Pro-apoptotic signals acting through various Bcl-2–related proteins (A) The rationale for the multiplicity of Bcl-2–like proteins is that various cell-physiological stresses operate through different pro-apoptotic proteins to antagonize anti-apoptotic proteins such as Bcl-2 and Bcl-X_L (*green*). The latter are thereby prevented from neutralizing Bax and Bak (*red*), the dominant pro-apoptotic proteins that function to release cytochrome *c* from the mitochondrial membrane. The caspases that are activated downstream in the apoptotic pathway (see Figure 9.27) can also activate the pro-apoptotic function of Bid by proteolysis (cleaving it to truncated Bid, or tBid). This action amplifies the apoptotic response, as indicated in panel B. (B) The activities of pro-apoptotic BH3-only proteins are controlled in multiple ways. Bim is regulated at the transcriptional level (*not shown*) and post-translationally via phosphorylation by Erk, which results in its ubiquitylation and degradation. Phosphorylation of Bad by anti-apoptotic kinases, such as Akt/PKB and Raf, leads to its sequestration by the 14-3-3 protein and loss of its ability to bind the anti-apoptotic Bcl-2 and Bcl-X_L proteins. The pro-apoptotic Bid protein is liberated from its inhibitory domain by the actions of proteases, such as caspases that are activated downstream in the apoptotic cascade and the granzymes released by cytotoxic cells, the latter described in Chapter 15. (C) Each member of the Bcl-2 family of proteins has its own set of opposing partners. At the center of this network lie the anti-apoptotic (i.e. pro-survival) proteins Bcl-2, Bcl-X_L, Bcl-W, Mcl-1, and A1 (*green rectangles*). Each has its own set of antagonistic, pro-apoptotic partners (*pink rectangles*). For example, Bcl-2, Bcl-X_L, and Bcl-W are opposed by the pro-apoptotic Bad protein. At the bottom of this network lie the pro-apoptotic Bax and Bak proteins; if unopposed, they will promote apoptosis by opening the mitochondrial outer membrane channel. Not all members of the Bcl-2 family of proteins (see Figure 9.23A) are indicated here. (D) In wild-type ($Bim^{+/+}$) mice, a cavity is excavated in the solid tip (terminal end bud) of an elongating mammary duct in order to form the lumen of the future duct (*left*). However, in $Bim^{-/-}$ mice, mammary epithelial cells persist, preventing normal lumen formation (*right*) and suggesting that lumen formation normally depends on anoikis of cells that failed to establish anchorage to the basement membrane that lies immediately outside of the myoepithelial cells (*not visualized*). p63, marker of basal myoepithelial cells (*red*); mucin1, marker of secretory luminal cells (*green*); cell nuclei (*blue*). (A, courtesy of J. Adams; adapted from S. Cory et al., *Oncogene* 22:8590–8607, 2003. With permission from Nature. B, adapted from S. Cory and J.M. Adams, *Nat. Rev.*

Cancer 2:647–656, 2002. C, courtesy of D.C.S. Huang. D, from A.A. Mailleux et al., *Dev. Cell* 12:221–234, 2007. With permission from Elsevier.)

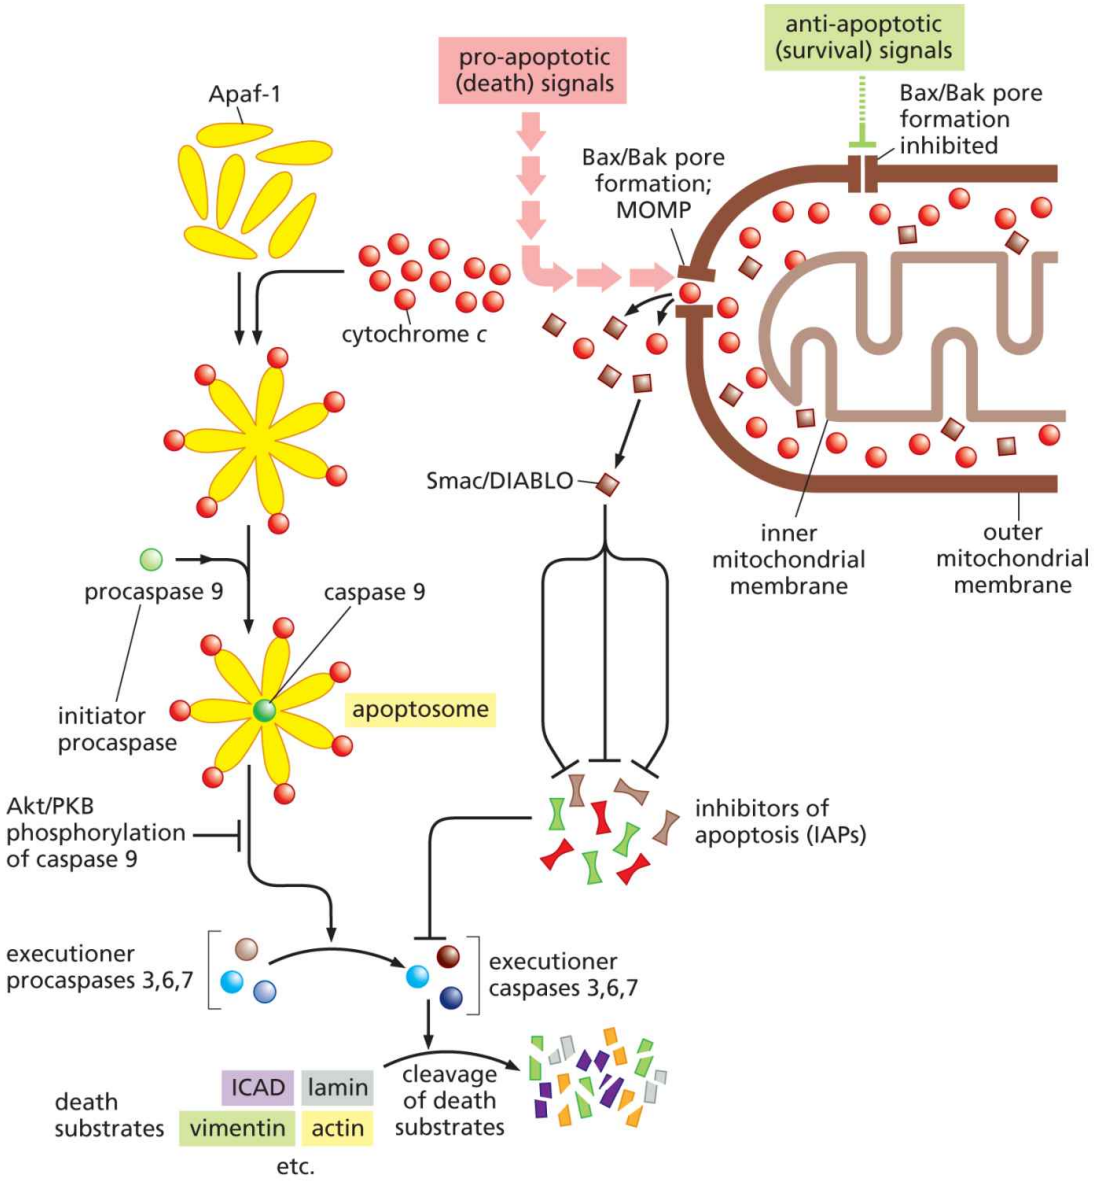
In addition, the various pro- and anti-apoptotic members of the Bcl-2 family of proteins each has its own opposing partner or partners (Figure 9.25C). Each of these proteins also functions to trigger apoptosis in specific cell types; for example, Figure 9.25D shows the key role that Bim-dependent anoikis plays in eliminating cells in the developing mammary gland, allowing lumina to form in the ducts. Finally, these Bcl-2–related proteins can be regulated in different, complex ways: the actions of the BH3-only proteins of the Bcl-2 family (see Figure 9.23A), for example, can be controlled by modulating their expression, their intracellular localization, proteolytic cleavage, or phosphorylation (Figure 9.25B).

Once individual cytochrome *c* molecules have leaked out of mitochondria into the cytoplasm, they associate with seven copies of the Apaf-1 protein with which they form the structure called the apoptosome (**Figure 9.26** and **Figure 9.27**). The resulting apoptosome complexes then proceed to activate a normally latent cytoplasmic protease termed procaspase 9, converting it into active caspase 9, which has catalytic activity that is at least one thousand-fold higher than the procaspase (see Figure 9.27). Caspase 9 is just one member of a family of **c**ysteine **asp**artyl–specific prote**ases**; the human genome carries 12 genes that encode members of this protease family.



Two views of the wheel of death. An apoptosome looks like a flower with seven lumpy petals and a bulbous dome at the point where the flower would connect to the stem. At the tip of each petal is a cytochrome c. A ribbon diagram is also shown.

Figure 9.26 The wheel of death The apoptosome—essentially a wheel of death—is assembled in the cytosol when cytochrome *c* molecules are released from mitochondria and associate with Apaf-1 monomers. Cytochrome c molecules and Apaf-1 monomers assemble to form the assembly of a seven-spoked wheel, in which Apaf-1 monomers form the spokes and cytochrome *c* molecules form the tips of the spokes (*above*), visualized here by electron cryomicroscopy. Procaspase 9 is attracted to the hub of the wheel ("dome"), where it is converted into active caspase 9. The more detailed structure of the inner circle of the apoptosome (*below*), formed from seven Apaf-1 subunits, is illustrated in the molecular model determined by X-ray crystallography. The *blue* helices in the center interact with procaspase 9 to convert it into caspase 9, which then triggers the apoptotic cascade. (Top, from D. Acehan et al., *Mol. Cell* 9:423–432, 2002. With permission from Elsevier. Bottom, from S.J. Riedl et al., *Nature* 434:926–933, 2005. With permission from Nature.)



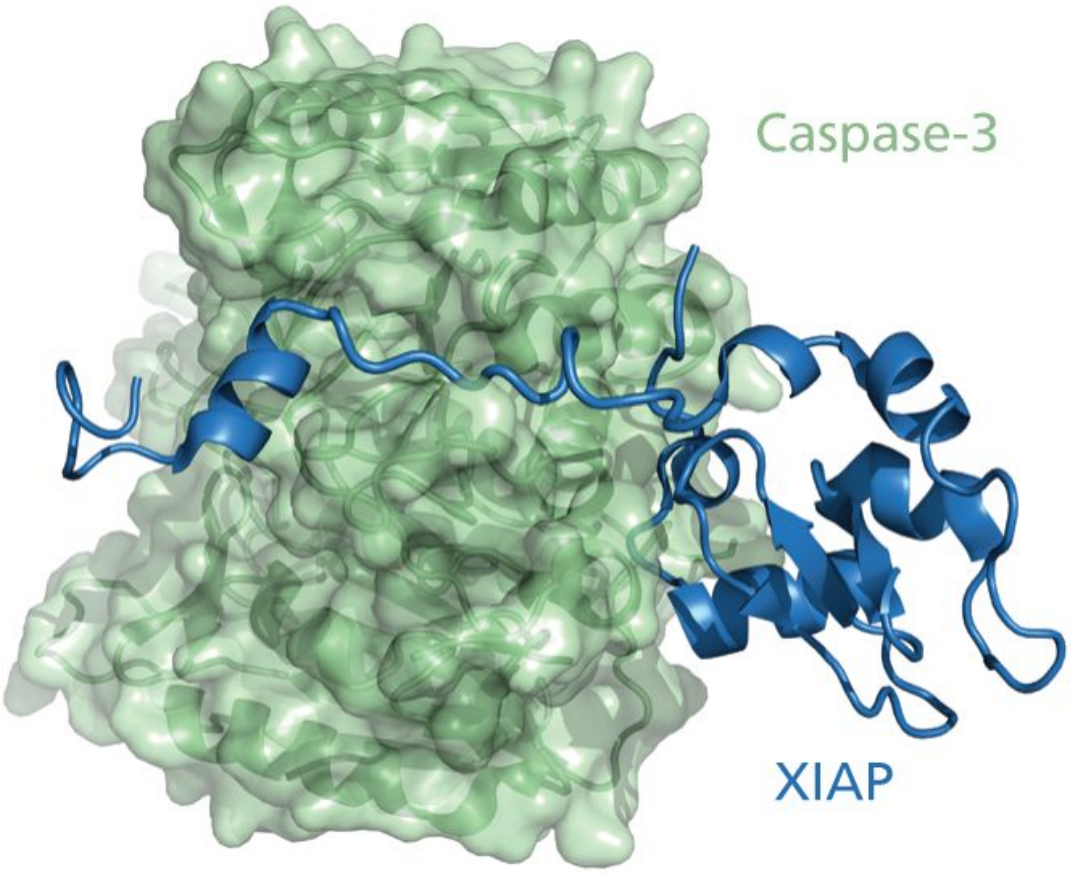
The apoptotic caspase cascade. So long as anti-apoptotic (survival) signals inhibit Bax Bak pore formation in the outer membrane of a mitochondrion, cytochrome c molecules and S m a c DIABLO molecules remain contained between the inner and outer membranes. But when pro-apoptotic (death) signals promote pore formation–that is, mitochondrial outer membrane permeabilization–cytochrome c and S m a c DIABLO molecules leak out into the cytoplasm. Seven cytochrome sees join with seven Apaf ones to form the spokes of an apoptosome. An initiator procaspase, procaspase 9, attaches to the center of the structure as caspase 9 to complete the apoptosome. Unless inhibited by A k t P K B phosphorylation of caspase 9, the apoptosome facilitates the transformation of executioner procaspases 3, 6, and 7 into executioner caspases 3, 6, and 7. With S m a c DIABLO blocking inhibitors of apoptosis that would interfere with the action of

the executioner caspases, the executioner caspases engage in cleavage of death substrates such as I C A D, lamin, vimentin and actin.

Figure 9.27 The apoptotic caspase cascade Various anti-apoptotic signals promote MOMP (see Figure 9.23). Important mitochondrial molecules that may be released into the cytosol by MOMP are cytochrome *c* (*red circles*) and Smac/DIABLO (*brown squares*). Cytochrome *c* molecules proceed to aggregate with Apaf-1 to form the seven-spoked apoptosome (*left*; see Figure 9.26). Once assembled, the apoptosome attracts and converts procaspase 9 into active caspase 9 (*green circle*), which in turn cleaves and activates procaspases 3, 6, and 7 (*bottom left*), converting them into executioner caspases, which then cleave various "death substrates" whose products create the apoptotic cell phenotype. Normally, a number of inhibitors of apoptosis (IAPs; *lower right*) attach to and inactivate caspases. However, the Smac/DIABLO that is also released from mitochondria during the triggering of apoptosis antagonizes these IAPs, thereby protecting caspases from IAP inhibition and setting the stage for full activation of the apoptosis program. Acting in the opposite direction, as part of its anti-apoptotic actions, the Akt/PKB kinase can phosphorylate and thereby inactivate already-activated caspase 9 (*lower left*).

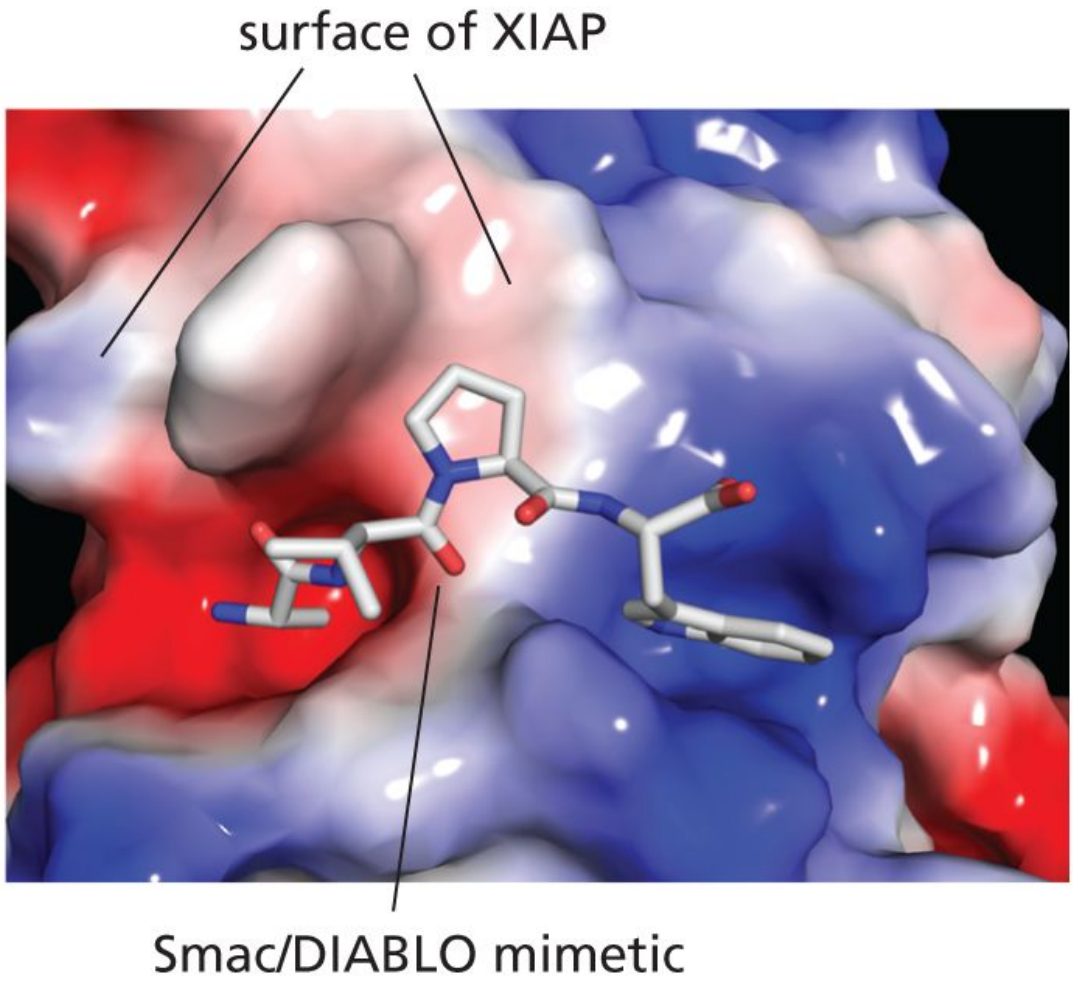
Having been converted into an active protease by the apoptosome, caspase 9 then cleaves procaspase 3, thereby activating yet another related protease; caspase 3 then proceeds to cleave and activate yet another procaspase, and so on down the line (see Figure 9.27). This sequence of cleavages constitutes a signaling cascade in which one protease activates the next one in the series by cleaving it. Such behavior is reminiscent of the organization of kinase cascades that we read about earlier (see Section 6.5), in which a group of Ser/Thr kinases activate one another in a linear sequence. Because each of these caspases acts catalytically, a relatively minor initiating signal at the top of the cascade can be amplified to yield a large number of activated caspases at the bottom. Interestingly, one of the functionally important proteins phosphorylated by the anti-apoptotic Akt/PKB kinase is caspase 9. As might be anticipated from the role that Akt/PKB has in inhibiting apoptosis, the phosphorylation of caspase 9 inhibits this protease.

At the same time as cytochrome *c* in the cytosol serves to activate the caspases, Smac/DIABLO—another protein that is released from mitochondria together with cytochrome *c*—inactivates a group of anti-apoptotic proteins termed IAPs (inhibitors of apoptosis proteins; see Figure 9.27). These IAPs normally block caspase action in two ways: first, they bind to caspases directly and thereby inhibit their proteolytic activity (**Figure 9.28**); in certain cases, they can also mark caspases for ubiquitylation and degradation. Once the restraining influences of IAPs have been minimized, caspases are free to initiate the proteolytic cleavages that result ultimately in apoptosis.



A space-filling surface model of caspase 3 combined with a ribbon diagram of X I A P.

(A)



An S m a c DIABLO mimetic in stick model form attached to a space filling surface model of X I A P.

(B)

Figure 9.28 Structure and function of an inhibitor of apoptosis IAPs function by binding and inhibiting various caspase molecules, thereby preventing inadvertent activation of the caspase cascade and the triggering of apoptosis. (A) Shown here is the molecular structure of the complex formed by the BIR3 domain of the IAP molecule termed XIAP with caspase 3. The peptide backbone of XIAP is shown (*blue*) in contrast to the space-filling surface model of caspase 3 (*light green*). The BIR3 domain of XIAP binds to the substrate-binding groove of the caspase, thereby blocking its function. (B) Like the naturally occurring Smac/DIABLO molecule, chemically synthesized Smac/DIABLO mimetics can promote apoptosis by keeping IAP molecules from inhibiting caspase action. Here a tetrapeptide Smac/DIABLO mimic is shown binding to the groove in the surface of XIAP that normally binds Smac/DIABLO. Chemical derivatives of this

tetrapeptide function as potent apoptosis-inducing drugs. Negatively charged surface (*red*); positively charged surface (*blue*). (A, from P.D. Mace, S. Shirley and C.L. Day, *Cell Death Differ.* 17:46–53, 2010. With permission from Nature. B, from K. Zobel et al., *ACS Chem. Biol.* 1:525–533, 2006. With permission from American Chemical Society.)

The cascade of caspase activations, once initiated, proceeds until the final caspases in the cascade cleave "death substrates," that is, proteins whose degradation creates the diverse cellular changes that one associates with the apoptotic death program (see Figure 9.27). The specialized roles of these various caspases have led to their classification into two functional groups: the initiator caspases, which trigger the onset of apoptosis by activating the caspase cascade, and the downstream executioner caspases, which undertake the actual work of destroying critical components of the cell.

A number of key cellular components are cleaved by caspases 3, 6, and 7, which function as the executioner caspases. The degradation of these components causes the profound morphological transformations that accompany the death throes of apoptotic cells. Cleavage of lamins on the inner surface of the nuclear membrane is involved in some fashion in the observed chromatin condensation and nuclear shrinkage, or pyknosis, that is characteristic of the apoptotic program. Cleavage of the inhibitor of caspase-activated DNase (ICAD) liberates this nuclease, which then fragments the chromosomal DNA. Caspase-mediated cleavage of cytoskeletal proteins such as actin, plectin, vimentin, and gelsolin leads to collapse of the cytoskeleton, the formation of blebs protruding from the plasma membrane, and the production of apoptotic bodies—the condensed hulks of cells that remain after all this destruction has occurred (see Figure 9.19).

The executioner caspases even extend their reach back to the mitochondria, where the apoptotic program is initiated: one of their substrates is a protein that is part of the mitochondrial electron transport chain. Its cleavage by caspases leads to disruption of electron transport, loss of ATP production, release of reactive oxygen species (ROS) from the mitochondria, and the loss of mitochondrial structural integrity, thereby amplifying an already-initiated apoptotic program. In addition, as cytochrome *c* and other components of the mitochondrial intermembrane space leak out into the cytoplasm, a variety of mitochondrial functions are severely compromised.

The efficient execution of many of the steps of the apoptotic program is also enabled by changes in signaling that further amplify the signals initiating apoptosis. For example, cleavage of the Rel subunit of NF-κB—a transcription factor driving expression of anti-apoptotic genes such as *Bcl-2* (see Figure 6.22A) —shifts the regulatory balance further in favor of apoptosis. Some researchers estimate that 400 to

1000 distinct cellular proteins undergo cleavage during apoptosis, but it remains unclear how many of these are active participants in the apoptotic program and how many are victims of the collateral damage that occurs as cells are disassembled from within.

OceanofPDF.com

Glossary

necrosis
: A non-programmed form of cell death triggered by the collapse of cellular energy production, involving the breakdown of a cell's constituents through steps that are distinct from those in the neocroptosis and apoptotic death programs. *See* **necroptosis**, **apoptosis**.

oxidative phosphorylation
: The process of generating ATP from ADP driven by electron gradients in the mitochondrion.

anoikis
: Form of apoptosis that is triggered by the failure of a cell to establish anchorage to a solid substrate, such as the extracellular matrix, or by loss of such anchorage.

apoptosome
: Multiprotein complex that consists of cytochrome *c* molecules and Apaf-1 and helps to initiate apoptosis by activating procaspase 9 into caspase 9. *See also* **caspase**.

initiator caspases
: A family of proteases (including caspase 2, 8, 9, and 10) that become activated by upstream activating signals in the apoptotic pathway and functions to activate other downstream members of the caspase family (so-called executioner caspases), which proteolytically cleave a number of cellular target proteins. *See also* **caspase**.

executioner caspases
: A family of proteases (including caspases 3, 6, and 7) that become activated by initiator caspases through proteolytic cleavage and subsequently cleave a number of cellular target proteins, leading to cell death. *See also* **caspase**.

OceanofPDF.com

9.14 Both intrinsic and extrinsic apoptotic programs can lead to cell death

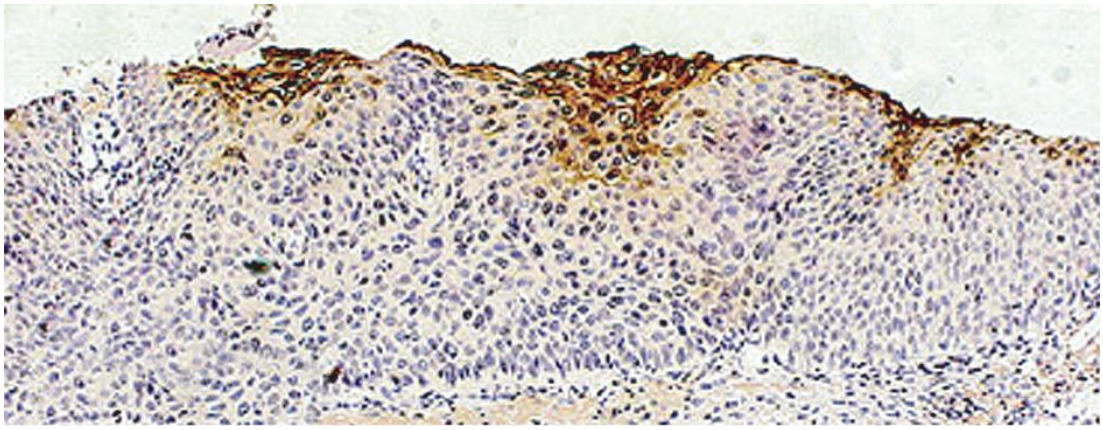
This series of events described above is sometimes termed the *intrinsic apoptotic program*, because the signals that trigger it originate within the cell; it is also known as the *stress-activated* apoptotic pathway. While p53 often plays a prominent role in triggering the intrinsic apoptosis program, other types of intracellular signals can also cause the mitochondria to release cytochrome *c* without involving p53 (see Figure 9.25A). Included in this category are stresses such as a buildup of calcium within the cell, excessive oxidants, certain types of DNA-damaging agents, and agents that disrupt the microtubules—key components of the cytoskeleton and mitotic spindle. Infections by various tumor viruses may also trigger apoptosis. Interestingly, these viruses generally take great pains to ensure that the intrinsic apoptotic program is not initiated, lest their cellular hosts die before their infectious cycles reach completion (**Sidebar 9.5**).

Sidebar 9.5 Why do DNA tumor viruses seek to inactivate p53?

As described previously (see Section 8.5), a diverse group of DNA tumor viruses specify oncoproteins that are designed to inactivate pRb. In addition, they undertake to inactivate p53 activity (see Table 9.1), raising the question why both host-cell proteins must be inactivated by these viruses. Because these agents are called “tumor viruses,” we might conclude that they must create tumors in order to propagate themselves and that pRb and p53 inactivation is central to this goal. However, careful examination of the life cycles of these viruses indicates that cell transformation is only an inadvertent side effect of their replication. Like all other viruses, these viruses have evolved to optimize only one outcome—their efficient multiplication in tissues of infected hosts. This realization forces a restatement of the question: Why is inactivation of both tumor suppressor proteins critical to viral replication?

DNA tumor viruses parasitize the host-cell DNA replication machinery to replicate their own genomes; this machinery is available only in the late G_1 and S phases of the cell cycle. Consequently, these viruses must inactivate pRb, as well as the two pRb-related proteins p107 and p130, to allow initially quiescent, infected host cells to advance into S phase. (Certain herpesviruses achieve the same end by expressing potent virus-encoded D-type cyclins.) The situation is slightly different in the case of

human papillomaviruses (HPVs): they infect replicating cells in the cervical epithelium and block the normally occurring exit from the active cell cycle into a post-mitotic state that takes place as these cells differentiate (**Figure 9.30**).



A histology image of cervical epithelium. Most of the tissue is the usual pink with blue nuclei, but parts of the surface of the tissue are stained rust brown.

Figure 9.30 Human papillomavirus and the pathogenesis of cervical carcinomas This histological section of cervical epithelium infected with a human papillomavirus (HPV) reveals, through immunostaining with an anti-HPV antibody stain (*brown*), clusters of HPV-infected cells in dysplastic areas of the epithelium, termed high-grade squamous intraepithelial lesions (HSILs). The dysplastic cells arise, in large part, from the ability of the HPV E7 oncoprotein to inactivate pRb and thereby block their entrance into a post-mitotic state and the ability of the viral E6 oncoprotein, which targets the cells' p53 protein for destruction, to suppress apoptosis. The resulting lesions progress with a low but significant frequency to cervical carcinomas. Unlike epithelial cells in normal cervical epithelium, these virus-infected cell populations harbor a significant proportion of proliferating, Ki67-positive cells (*not shown*). (From K. Middleton et al., *J. Virol.* 77:10186–10201, 2003. With permission from American Society for Microbiology.)

The cells infected by these various viruses respond to pRb inactivation by activating their p53 alarm systems. This response occurs due to the excessive activity of E2Fs that results from the functional inactivation of pRb (see Figure 9.14B); in addition, other, poorly understood virus-induced changes in cells may trigger p53 activation. Such p53 activation threatens to kill the infected host cells through apoptosis long before the viruses have had a chance to multiply and produce progeny. So these viruses proceed to eliminate p53 function. The SV40 large T antigen binds and sequesters p53 (in addition to binding pRb); HPV uses its E6 protein, which functions

like Mdm2 to mark p53 for destruction via ubiquitylation (see Figure 9.14A). Adenovirus uses one of its E1B proteins to bind to p53 and pRb, and it deploys a second E1B-encoded protein, which is related to Bcl-2, to antagonize two important pro-apoptotic proteins, Bax and Bak (see Figure 9.25A).

Interestingly, at least one human RNA tumor virus—the HTLV-I retrovirus—takes the trouble to inactivate many of the same host-cell pathways. Perhaps the active transcriptional machinery of rapidly dividing cells confers some advantage on this virus, whose multiplication does not depend on the DNA replication of its host (see Figure 3.12).

In fact, these diverse intracellular stressors, when taken together, still do not encompass all of the triggers of apoptosis, since this death program can also be triggered through an alternative route—one that is initiated *outside* the cell. This pathway operates in part via the activation of pro-apoptotic cell surface receptors. These transmembrane proteins are often termed death receptors to reflect their ability to activate the apoptotic program. Thus, after binding their cognate ligands in the extracellular space, the death receptors activate a cytoplasmic caspase cascade that converges rapidly on the intrinsic apoptotic pathway described above, thereby triggering an apoptotic response similar to the one seen following activation of the intrinsic apoptotic program (see Figure 9.27). Because the signals that activate the death receptors originate from outside the cell, the apoptotic program initiated by these receptors has been called either the *extrinsic apoptotic* program or the *receptor-activated* apoptotic pathway.

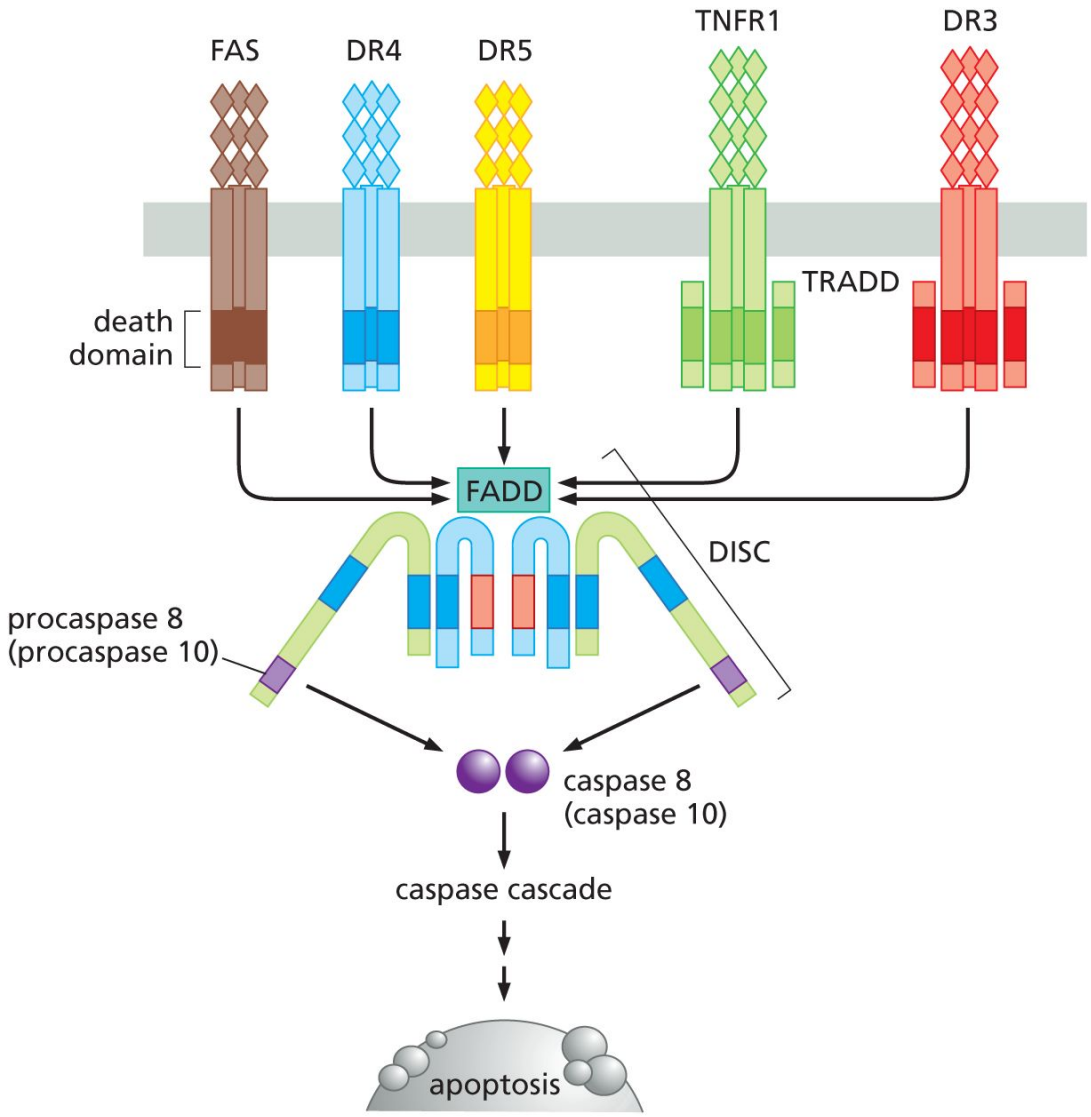
The ligands of the death receptors are members of the tumor necrosis factor (TNF) family of proteins. TNF-α was first identified and studied because of its ability to cause the death of cancer cells. Subsequently, this group of protein ligands was found capable of causing the death of a wide variety of normal cell types that display appropriate receptors on their surfaces. Similar to growth factors and their receptors, each of these TNF-like proteins binds to its own cognate death receptor (**Table 9.3**). Six members of a superfamily of TNF-like receptors are involved in triggering apoptosis.

Table 9.3 Death receptors and their ligands

Alternative names of receptors	**Alternative names of ligands**
FAS/APO-1/CD95	FasL/CD95L

Alternative names of receptors	Alternative names of ligands
TNFR1	TNF-α
DR3/APO-3/SWL-1/TRAMP	APO3L
DR4/TRAIL-R1	APO2L/TRAIL
DR5/TRAIL-R2/KILLER	APO2L/TRAIL

Once activated by ligand binding, members of the death receptor family assemble a death-inducing signaling complex (DISC) that triggers the cleavage and activation of caspases 8 and 10 (**Figure 9.29A**). These initiator caspases then cleave and activate the executioner caspases 3, 6, and 7, thereby converging on the signaling pathway through which the intrinsic apoptotic program operates (see Figure 9.27). Caspase 3 can also cleave and activate the Bcl-2–related protein Bid (see Figure 9.23A), which then initiates MOMP, further amplifying the pro-apoptotic signals of the extrinsic apoptotic program by recruiting elements of the intrinsic program into the process (**Figure 9.31**). In addition, as this figure illustrates, the attack and killing of cancer cells by cytotoxic cells of the immune system, such as the CD8 and NK lymphocytes described in Chapter 15, can be provoked through their ability to inject the granzyme B protease into the cytoplasm; once in the cytosol, the injected protease then proceeds to cleave and activate executioner caspases.



A diagram with five different receptors across the top, all traversing a plasma membrane. From left to right, they are F A S, D R4, D R5, T N F R1, and D R3. The first three have a domain labeled death domain on the cytoplasmic side. The last two have more complex tails with domains labeled T R A D D. All five tails act via the F A D D-associated death domain protein to assemble a death-inducing signaling complex with two arms that each have procaspase 8 or 10 at the end, which is released as caspase 8 or 10, which begins a caspase cascade that leads to apoptosis.

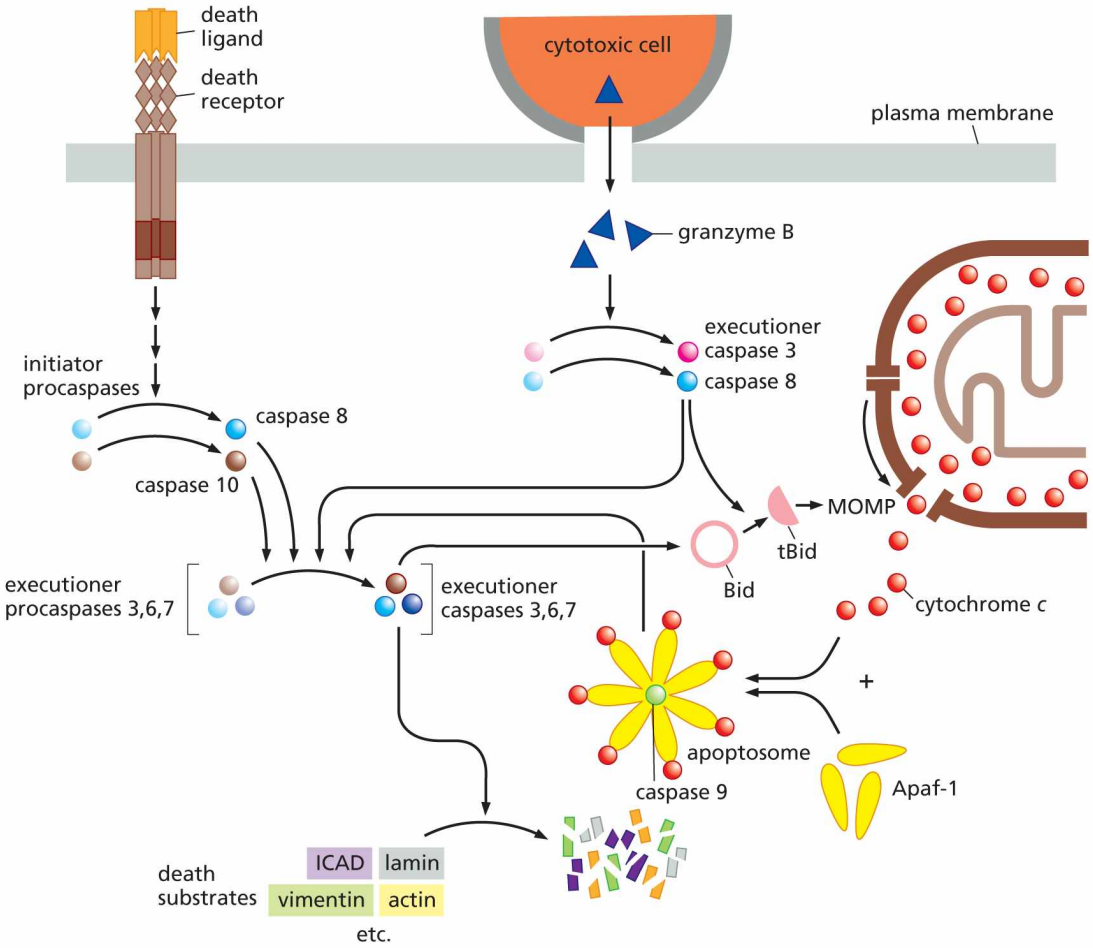
(A)

An electron micrograph of a cytotoxic T lymphocyte attacking a cancer cell that is covered with spherical blisters.

(B)

Figure 9.29 Death receptors (A) Five families of “death receptor” proteins are displayed on the surfaces of various types of mammalian cells. For example, the FasL and APO2L/TRAIL ligands bind to the FAS, DR4, and DR5 death receptors

(*top left*). The cytoplasmic tails of these receptors act via the FAS-associated death domain (FADD) protein to assemble a death-inducing signaling complex (DISC), and the latter proceeds to convert procaspases 8 and 10 into their respective active caspases. These then converge on the caspase cascade that is activated through the intrinsic apoptotic program. A similar sequence of events occurs following the activation of the TNFR1 and DR3 receptors (*top right*). These death receptors differ from receptor tyrosine kinases (and their ligand-induced dimerization) in that the ligand complexes, sometimes called “death ligands,” are homotrimers and appear to work by causing receptor trimerization. [Compare these ligands with the ligands of growth factor receptors (see Figure 5.11A), which drive receptor dimerization.] (B) Death receptor ligands, notably FasL, are frequently used by cytotoxic T lymphocytes (CTLs) to kill cancer cells, which display the FAS receptor on their surfaces. (In addition, granzymes may be injected by CTLs into target cells; see Figure 9.31.) In this colorized scanning electron micrograph, a CTL (*orange*) is attacking a cancer cell, which is in the throes of apoptosis, as evidenced by the numerous blebs on its surface. (A, adapted from A. Ashkenazi, *Nat. Rev. Cancer* 2:420–430, 2002. With permission from Nature. B, from Dr. Andrejs Liepins /Science Source.)

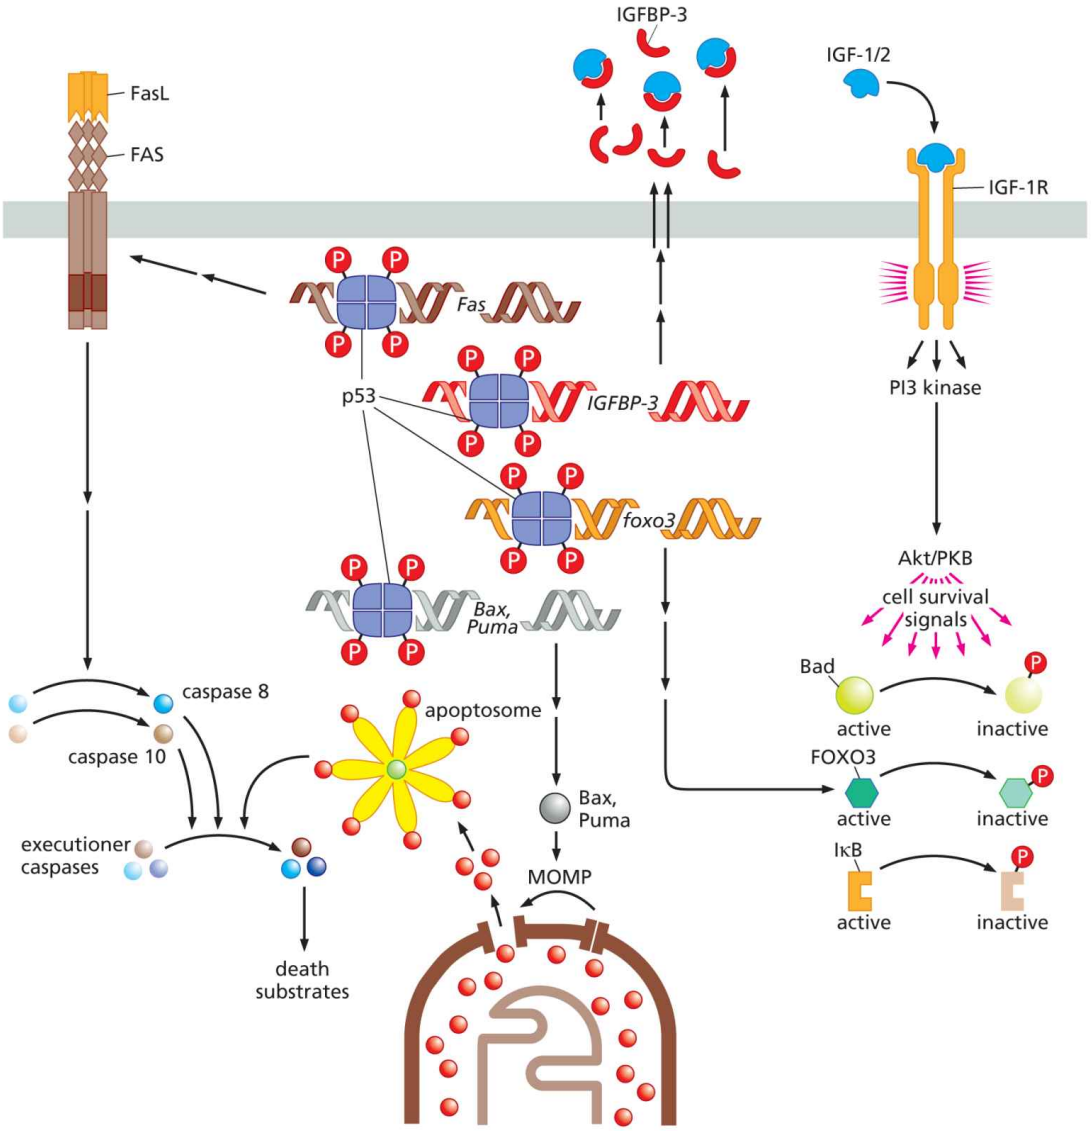


A cascade that begins with two things happening in parallel. In one pathway, a death ligand binding to a death receptor in a cell's plasma membrane causes initiator procaspases in the cytoplasm to become caspases 8 and 10. In the other pathway, another cell, which is cytotoxic, to inject granzyme B through the plasma membrane, which causes initiator procaspases in the cytoplasm to become caspase 8 and executioner caspase 3. These two caspases produce t Bid from Bid. The t Bid initiates M O M P on a mitochondrion, releasing cytochrome sees. These combine with Apaf 1 and caspase 9 to form apoptosomes. The apoptosome, caspase 8 and caspase 10 all contribute to the conversion of executioner procaspases 3, 6 and 7 into executioner caspases 3, 6 and 7. These, finally, cleave and degrade death substrates such as I CAD, lamin, vimentin, and actin.

Figure 9.31 Convergence of intrinsic and extrinsic apoptotic pathways After a death receptor activates procaspase 8 or 10, or both, into the corresponding active caspases (*top left*), the latter converge on the intrinsic apoptotic cascade by cleaving and activating the executioner caspases (*middle left*). In addition, after procaspases 3 and 8 have been activated into caspases 3 and 8, the latter cleave and activate Bid, a Bcl-2–related protein (*center, pink circle*). The resulting

activated tBid moves from its cytosolic location to the mitochondrion, where it initiates MOMP, further amplifying the apoptotic cascade by promoting the formation of new, activated apoptosomes (*lower right center*). A second, alternative form of the extrinsic apoptotic pathway is initiated by cytotoxic cells that are dispatched by the immune system (*top middle*) and attach to the surfaces of targeted cells, into which they introduce granzyme B molecules; these cleave and thereby activate procaspases 3 and 8 (see also Figure 9.25).

Mapping the intrinsic and extrinsic apoptotic cascades has enriched our understanding of how p53 succeeds in evoking apoptosis (**Figure 9.32**). To begin, p53 induces expression of the genes encoding Bax and PUMA proteins (see Figure 9.25A) that are directly involved in MOMP and the initiation of apoptosis at the mitochondrial membrane. In addition, p53 activates expression of the death receptor FAS and a protein called IGFBP-3. The FAS receptor, once expressed at the cell surface, increases a cell's responsiveness to extracellular death ligands, specifically the Fas Ligand (FasL). IGFBP-3, an IGF-binding protein, when released from the cell, sequesters IGF-1/2 (insulin-like growth factors-1/2), growth factors that provide cells with trophic (survival) signals. Because many cells depend on continuous exposure to trophic signals to remain viable, reducing the survival signals induced by IGF-1 places them in grave danger of succumbing to apoptosis, a process that has been called "death by neglect." This explains why many cancer cells find ways of maintaining high concentrations of IGFs in the microenvironments that surround them. Apart from simply secreting abnormally high amounts of IGF-1 or the related IGF-2, cancer cells may reduce the levels of IGFBPs—either by methylating *IGFBP* gene promoters or by increasing the synthesis and secretion of matrix metalloproteinases (MMPs) that cleave and thereby inactivate IGFBP molecules.



A diagram shows the activation of apoptosis by p53, via a complex, interconnected set of pathways. Phosphorylated p53 induces expression of the F a s gene which promotes display of the F A S receptor on the cell's surface. When this binds with the F a s L ligand, it causes initiator procaspases in the cytoplasm to become caspases 8 and 10. At the same time, p53 induces expression of the Bax and Puma genes, which initiative M O M P on a mitochondrion, releasing cytochrome sees. These go to form apoptosomes. The apoptosomes, caspase 8 and caspase 10 all contribute to the conversion of executioner procaspases into executioner caspases that act on the death substrates. Separately from all this, p53 induces expression of the I G F B P 3 and foxo 3 genes. The foxo 3 protein is pro-apoptotic, along with Bad and I kappa B. At the same time, the I G F B P 3 protein passes through the plasma membrane and, outside the cell, binds I G F-1 slash 2, preventing the latter from binding to the I G F-1R receptor whose P I 3 kinase tail

would otherwise trigger A k t P K B produced cell-survival signals that phosphorylated and thereby deactivated foxo 3, Bad and I kappa B.
Figure 9.32 Activation of apoptosis by p53 p53 employs multiple signaling pathways in order to activate the apoptotic program. By inducing expression of the gene encoding the FAS receptor, p53 promotes display of this death receptor at the cell surface (*brown*, *top left*), thereby sensitizing the cell to any Fas ligand (FasL) that may be present in the extracellular space. Activated p53 also drives expression of the FOXO3 pro-apoptotic transcription factor, as well as Bax (*center*), the pro-apoptotic, Bcl-2–related protein; Bax homo-oligomerization triggers MOMP, promoting the release of cytochrome *c* and other pro-apoptotic proteins from the mitochondria (*bottom center*). In addition, p53 induces expression of IGF-binding protein-3 (IGFBP-3, *red*); when this protein is released into the extracellular space, it binds and sequesters IGF-1 and IGF-2 (*blue*, *top center*), the pro-survival, anti-apoptotic ligands of the IGF-1 receptor (IGF-1R). In the absence of IGFBP-3, IGF-1 would bind to its receptor (*top right*), causing the activation of PI3 kinase and the subsequent generation of anti-apoptotic signals in the cell, including those leading to the inactivation of the pro-apoptotic proteins Bad (related to Bcl-2), FOXO3, and IκB (antagonist of NF-κB). However, the sequestration of IGF-1/2 by IGFBP-3 prevents it from exerting its critical anti-apoptotic functions (*right*). p53 also inactivates several other anti-apoptotic agents (*not shown*).

We will return to the extrinsic apoptotic program in Chapters 15 and 16, because it can play two important roles in the complex interactions between cancer cells and the immune system. On the immune front, cells of the immune system may release death ligands (such as FasL) in an attempt to trigger apoptosis in cancer cells that they have targeted for elimination (Figure 9.29B). Working in the opposite direction, cancer cells may display or release death ligands that they deploy to kill immune cells that have approached too closely and threaten their survival.

The complexity of the signals flowing through apoptotic pathways underscores the fact that the decision for or against apoptosis is achieved by altering the *balance* of complex arrays of pro- and anti-apoptotic proteins that influence the ultimate decision whether or not to flip the “apoptotic master switch.”

OceanofPDF.com

Glossary

death receptor
: A family of mammalian transmembrane receptors that function at the cell surface to initiate apoptosis through the extrinsic apoptotic program following binding of their cognate ligands. Examples of death receptors are TNFR1, FAS, DR3, DR4, and DR5.

trophic
: Aiding in or supporting cell growth, proliferation, or survival.

OceanofPDF.com

9.15 Cancer cells deploy numerous ways to inactivate their apoptotic machinery

As emphasized earlier, cells advancing down the long road toward neoplasia encounter a number of physiological stressors that threaten their existence. Each of these stressors has the ability to trigger apoptosis, which explains why most, if not all, types of cancer cells inactivate key components of their apoptosis-inducing machinery (**Table 9.4**). We can also view these changes from the perspective of the organism as a whole: virtually all human cancer cells employ anti-apoptotic strategies, which suggests that the apoptotic machinery integrated into all normal cells is held in active reserve as an anti-neoplastic mechanism that can be rapidly deployed, when needed, to obstruct tumor progression.

Table 9.4 Examples of anti-apoptotic alterations found in human tumor cells

Alteration	**Mechanism of anti-apoptotic action**	**Types of tumors**
CASP8 promoter methylation	inactivation of extrinsic cascade	SCLC, pediatric tumors
CASP3 repression	inactivation of executioner caspase	breast carcinomas
Survivin overexpression[a]	caspase inhibitor	mesotheliomas, many carcinomas
ERK activation	repression of caspase 8 expression	many types

Alteration	**Mechanism of anti-apoptotic action**	**Types of tumors**
ERK activation	protection of Bcl-2 from degradation	many types
Raf activation	sequestration of Bad by 14-3-3 proteins	many types
PI3K mutation/activation	activation of Akt/PKB	gastrointestinal
NF-κB constitutive activation[b]	induction of anti-apoptotic genes	many types
p53 mutation	loss of ability to induce pro-apoptotic genes	many types
p14^{ARF} gene inactivation	suppression of p53 levels	many types
Mdm2 overexpression	suppression of p53 levels	sarcomas
IAP-1 gene amplification	antagonist of caspases 3 and 7	esophageal, cervical
APAF1 methylation	loss of caspase 9 activation by cytochrome *c*	melanomas

Alteration	**Mechanism of anti-apoptotic action**	**Types of tumors**
BAX mutation	loss of pro-apoptotic protein	colon carcinomas
Bcl-2 overexpression	closes mitochondrial channel	~½ of human tumors
PTEN inactivation	hyperactivity of Akt/PKB kinase	glioblastoma, prostate carcinoma, endometrial carcinoma
IGF-1/2 overexpression	activates PI3K	many types
IGFBP repression	loss of anti-apoptotic IGF-1/2 antagonist	many types
Casein kinase II overexpression	activation of NF-κB	many types
TNFR1 methylation	repressed expression of death receptor	Wilms tumor
FLIP overexpression	inhibition of caspase 8 activation by death receptors	melanomas, many others

Alteration	Mechanism of anti-apoptotic action	Types of tumors
Akt/PKB activation	phosphorylation and inactivation of pro-apoptotic Bcl-2-like proteins	many types
USP9X overexpression	deubiquitylates Mcl-1	lymphomas
STAT3 activation	induces expression of Bcl-X_L	several types
TRAIL-R1 repression	loss of responsiveness to death ligand	small-cell lung carcinoma
FAP-1 overexpression	inhibition of FAS receptor signaling	pancreatic carcinoma
XAF1 methylation[c]	loss of inhibition of anti-apoptotic XIAP	gastric carcinoma
Wip1 overexpression[d]	suppression of p53 activation	breast and ovarian carcinomas, neuroblastoma

Arguably the most important and widely exploited strategy has already been noted: inactivation of the p53 pathway. The *p53* gene is altered in almost half of all human cancer cell genomes, and in a substantial proportion of others, ARF is no longer expressed. This repression is often achieved through outright deletion of the ARF-encoding gene or by promoter methylation, the latter resulting in the

silencing of transcription (see Section 1.8). A small percentage of human tumors (mostly sarcomas) will overexpress Mdm2. All of these mechanisms affecting ARF or Mdm2 expression serve to drive down levels of p53 protein in cells. Finally, in some human tumor cells, p53 appears to be inappropriately localized, that is, it is sequestered in the cytoplasm, where it cannot carry out its main task, transcriptional activation.

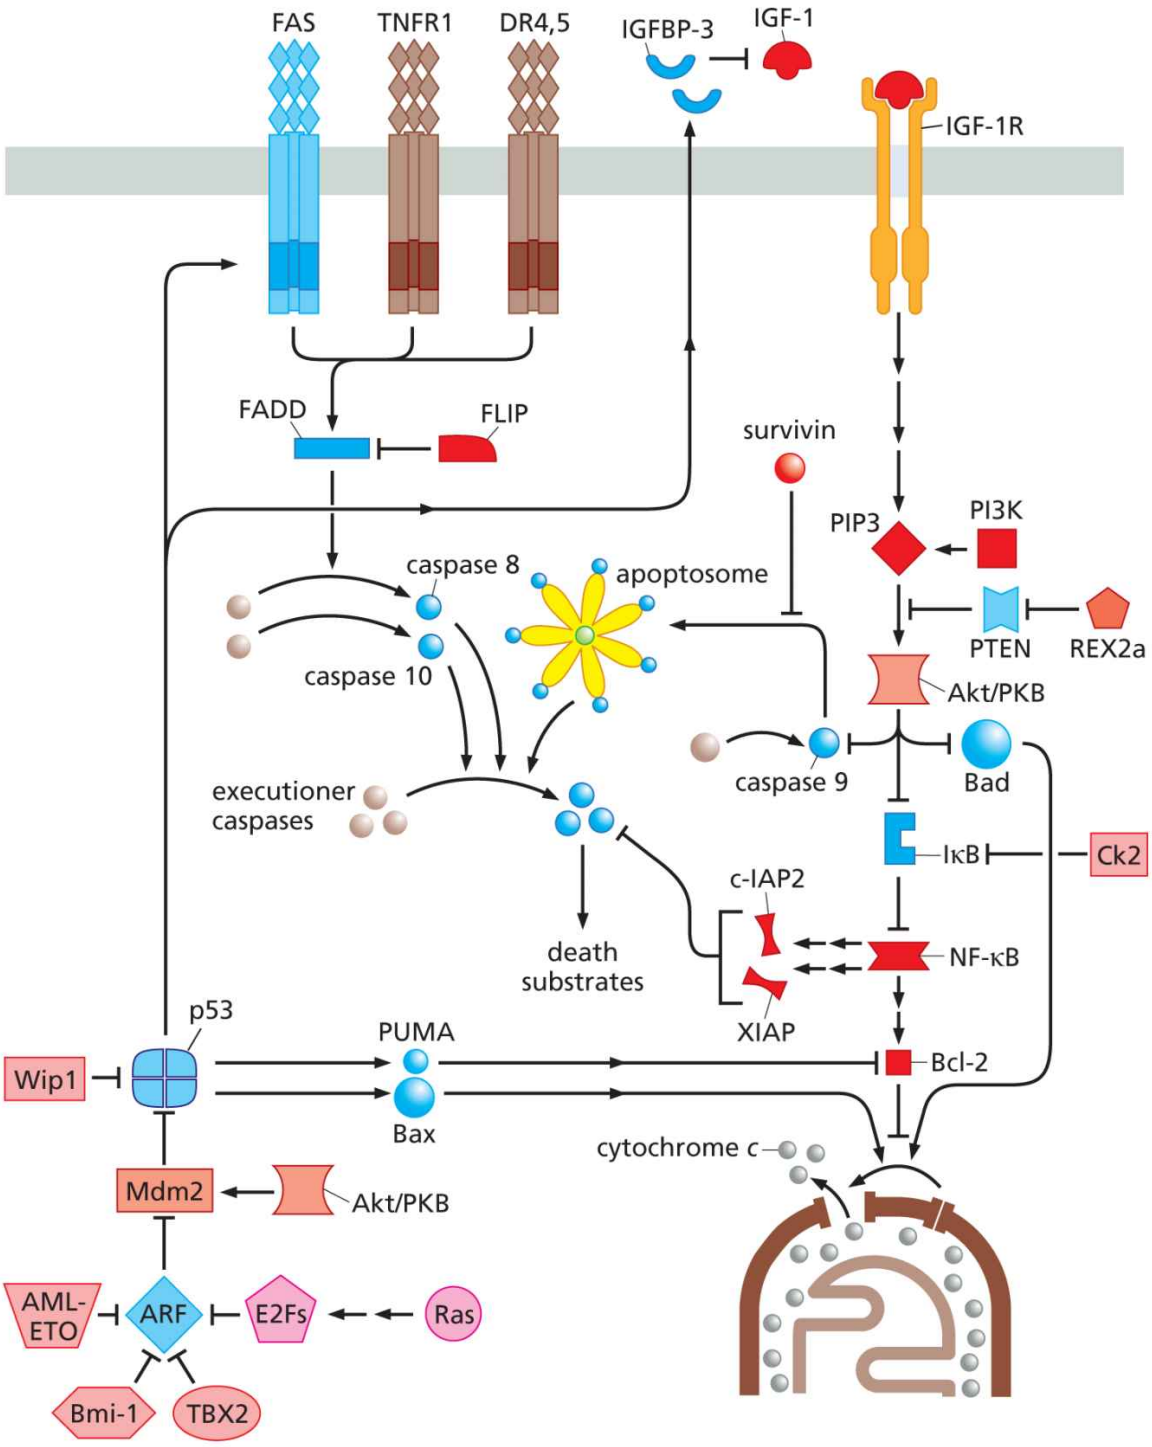
Still, this elimination of p53 function does not seem to suffice for many types of human tumors, which strive to subvert additional components of the apoptotic machinery. For example, many melanoma cells exhibit methylation and thus functional inactivation of the promoter of the *APAF1* gene, which encodes the cytosolic protein that assembles with released cytochrome *c* to form the apoptosome and activate caspase 9 (see Figure 9.27). The pro-apoptotic *Bax* gene (see Table 9.4) is inactivated by mutation in more than half the colon cancers that show microsatellite instability as described in Chapter 12. Deregulated overexpression of *BCL2* (the human version of *Bcl-2*) is found in follicular B-cell lymphomas, and *BCL2* expression is elevated in large numbers of human tumors of diverse tissue origins; by some estimates, at least half of all human tumors show elevated *BCL2* expression.

Yet another highly effective strategy for acquiring resistance to apoptosis derives from hyperactivation of the PI3K → Akt/PKB pathway (see Section 6.6). Activation of this pathway can be achieved through the collaborative actions of tyrosine kinase receptors and the Ras oncoprotein, both of which activate PI3K; the result is an increased level of PIP3 and activation of Akt/PKB (see Figure 6.14A). Inactivation of the gene encoding PTEN, the phosphatase that breaks down PIP3, has a similar effect. Once Akt/PKB has been activated by the accumulated PIP3, it can phosphorylate and thereby inhibit pro-apoptotic proteins such as Bad and caspase 9, and at the same time phosphorylate and activate Mdm2, the key antagonist of p53.

A diverse collection of cancer cell types, ranging from leukemias to colon carcinomas, have been found to resort to yet another mechanism to protect themselves against apoptosis: they activate expression of NF-κB. This transcription factor is usually sequestered in an inactive form in the cytoplasm and, in response to certain physiological signals, is liberated and translocates to the nucleus, where it activates a large constituency of target genes (see Section 6.12). A number of these genes are involved in pro-inflammatory and angiogenic functions, and a significant cohort function as apoptosis antagonists, blocking both the intrinsic and extrinsic apoptotic programs. The list of NF-κB targets is

expanding rapidly, and it is likely that the overexpression of some of these anti-apoptotic genes (and encoded proteins) seen in many types of human cancer cells will be traced directly to activation of NF-κB.

Yet another strategy for avoiding apoptosis is evident in childhood neuroblastomas, in which amplification of the N-*myc* gene normally indicates aggressive tumor growth and short life expectancy. On its own, this amplification actually *threatens* the proliferation of neuroblastoma cells because, as mentioned earlier, the actions of the *Myc* oncogene (and those of its N-*myc* cousin) release potent mitogenic signals, but at the same time are strongly pro-apoptotic. Many neuroblastoma cells that have overexpressed N-*myc* through gene amplification seem to solve this problem, at least in part, by inactivating the gene encoding caspase 8 (**Figure 9.33**), doing so through methylation or deletion.



A pathway diagram of Anti-apoptotic strategies used by cancer cells. In the lower left corner, several proteins inhibit the pro-apoptotic action of p53. Wip 1 and M d m2 do this directly, and A k t P K B enhances the action of M d m 2. In addition, A M L E T O, Bmi-1, T B X2, and E2 effs promoted by R a s inhibit A R F, blocking it from inhibiting M d m 2. Elsewhere, F L I P inhibits

F A D D, blocking it from setting off the chain of caspase production that leads to the degradation of death substrates. c-I A P2 and X I A P also inhibit the action of those caspases. These last two proteins are the products of a long pathway that begins with the binding of an I G F-1R receptor by a I G F-1 ligand.

Figure 9.33 Anti-apoptotic strategies used by cancer cells Cancer cells resort to numerous strategies in order to decrease the likelihood of apoptosis. This diagram indicates that in various cancer cell types, the levels or activity of important pro-apoptotic proteins are decreased (*blue*). Conversely, the levels or activity of certain anti-apoptotic proteins may be increased (*red*). (Some of these, because they are downstream of master regulators that are known to be altered in cancer cells, are affected by known changes in their upstream regulators.)

The involvement of caspase 8, as cited above, reveals that the actions of the extrinsic apoptosis-inducing pathway are also relevant for the evolution of certain types of cancer cells. Others deploy a protein termed FLIP (FLICE-inhibitory protein) that can interfere with the activation of the extrinsic apoptotic cascade by binding to the death domain proteins that associate with death receptors, thereby blocking the activation of the initiator caspase 8. Yet other tumor cells suppress expression of their TNF receptors by methylating the promoter of the encoding *TNFR1* gene. A selection of the mechanisms that disable apoptosis is outlined in Figure 9.33.

These maneuvers provide clear evidence that cancer cells can gain survival advantage by inactivating the extrinsic pathway. This observation leads, in turn, to the speculation that cells of the immune system often besiege cancer cells and attempt to kill them through the release of TNF-like factors that can initiate the extrinsic apoptotic program. Given the complex wiring diagram of the circuitry controlling apoptosis, it is virtually certain that many additional anti-apoptotic strategies will be uncovered in various types of human cancer cells.

9.16 p53 inactivation provides an advantage to incipient cancer cells at a number of steps in tumor progression

As we will learn in Chapter 11, the formation of a malignant human cell involves more than half a dozen distinct steps that usually occur over many years' time. An early step in the formation of a cancer cell often involves activation of an oncogene through some type of mutation. Such oncogene activation can put a cell at great risk of p53-induced senescence or apoptosis. Recall, for example, that a *Myc* oncogene can, on its own, trigger p53-dependent apoptosis. Hence, cells that have acquired such an oncogene can accrue additional growth advantage by shedding p53 function.

Later in tumor development, a growing population of tumor cells may experience hypoxia because cells toward the center of a developing tumor may lack an adequate network of vessels to provide access to blood-borne oxygen. Although normal cells would die from oxygen deprivation, tumor cells may survive because their ancestors managed to inactivate the *p53* gene during an earlier stage of tumor development (having done so initially for a quite different reason). Hypoxia itself could provide a sufficient stress to select for p53-mutant cells.

During much of this long, multi-step process of tumor progression, the absence of p53-triggered responses to genetic damage will permit the survival of cells that are accumulating mutations at a greater-than-normal rate. Such increased mutability increases the rate at which oncogenes become activated and tumor suppressor genes become inactivated; the overall rate of evolution of premalignant cells to a malignant state is thereby accelerated. Telomere collapse, another danger faced by evolving, premalignant cells (see Chapter 10), also selects for the outgrowth of those cells that have lost their p53-dependent DNA damage response.

The advantages to the incipient tumor cell of shedding p53 function do not stop there. One of the important target genes whose expression is increased by p53 is the *TSP-1* gene, which specifies thrombospondin-1. As we will see in Chapter 13, Tsp-1 is a secreted protein that functions in the extracellular space to block the development of new blood vessels. Consequently, a reduction of Tsp-1 expression following p53 loss removes an obstacle that otherwise would prevent clusters of cancer cells from developing an adequate blood supply during the early stages of tumor development. Loss of p53 can also affect major metabolic pathways in cells, stimulate changes in the tumor microenvironment, and promote cell motility and invasion—all of which can favor tumor progression.

Together, these diverse consequences of p53 pathway inactivation illustrate, once again, how the malfunctioning of a small number of key components of the alarm response circuitry permits cancer cells to acquire multiple alterations and survive under conditions that usually lead to the death of normal cells. These multiple benefits accruing to cancer cells explain why the p53 pathway is disrupted in most if not all types of human tumors.

In almost half of these tumors (see Figure 9.3), functioning of the p53 protein itself is compromised by mutations in the *p53* gene on numerous occasions as cited earlier. In many of the remaining tumors, the ARF protein is missing or the Mdm2 or MdmX proteins are overexpressed. In addition, p53 function may be compromised by defects in the complex signaling network in which p53 and its antagonist, Mdm2, are embedded. This network includes the *p53*-related genes *p63* and *p73*, which carry distinct but overlapping functions with p53 (**Sidebar 9.6**). There are reasons to suspect that other, still-undiscovered genetic mechanisms subvert p53 function. Although the organism as a whole benefits greatly from the p53 being stationed in its myriad cells, it suffers grievously once p53 function is lost in some of them, because the resulting p53-negative cells are now free to begin the long, multi-step march toward malignancy.

Sidebar 9.6 p53 has interesting cousins

As is often the case with important regulatory proteins, both p53 and Mdm2 have relatives in the cell; we have already encountered Mdm2’s cousin,

Mdm4 (also known as MdmX; see Section 9.8). In many situations, the ability of Mdm2 to drive down p53 concentrations may depend on its ability to do so as part of multi-protein complexes formed with Mdm4.

p53, for its part, actually has two cousins, p63 and p73. These two have quite different functions in cells. For example, although *p53*-null mice (created by germ-line gene inactivation; see **Supplementary Sidebar 7.2**) are largely normal at birth, *p63*-null mice have severe developmental defects involving epithelial cell differentiation and die shortly after birth. *p73*-null mice show yet other developmental abnormalities that affect primarily the nervous and secretory tissues. Moreover, like $p53^{+/-}$ mice, $p63^{+/-}$ and $p73^{+/-}$ heterozygous mice show predispositions to cancer, although these phenotypes are not as strongly penetrant as those of *p53* mutants.

These two cousins are important for p53-dependent apoptosis, because mouse embryo fibroblasts that have been deprived of both copies of both genes (that is, are of a $p63^{-/-}p73^{-/-}$ genotype) are no longer able to induce expression of many pro-apoptotic genes and fail to execute p53-dependent apoptosis. The tendency of excessive E2F1 to trigger apoptosis, as described in Section 9.9, may result in part from its ability to induce expression of p73, which then functions as a pro-apoptotic partner of p53. Loss of the *p63* and *p73* genes does not, however, affect the ability of p53 to inhibit proliferation (mediated by $p21^{Cip1}$ induction) or p53's ability to induce Mdm2 expression.

A final dimension of complexity comes from naturally occurring variant forms of these proteins. For example, full-length p63 and p73 function with p53 to promote apoptosis, whereas shorter, N-terminally truncated versions of p63 and p73—both products of alternative splicing—inhibit p53-induced apoptosis. Nonetheless, inactivation of either the *p63* or the *p73* gene in the mouse germ line leads to increased tumor incidence and places these two genes squarely in the camp of TSGs.

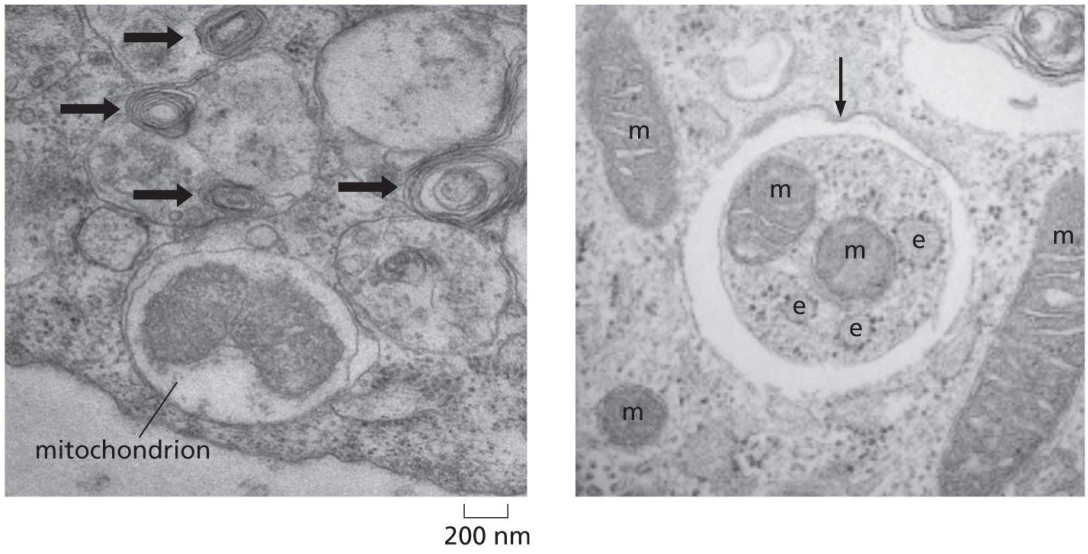
9.17 Additional forms of cell death may limit the survival of cancer cells

Although much of this chapter has focused on apoptosis as a major obstacle to cancer cell survival, alternative fates may befall a cell en route to full-fledged neoplastic growth. One such fate has already been mentioned, albeit in passing: necrosis. In complex metazoa like ourselves, the cells within our tissues are usually guaranteed access to reasonably constant levels of essential nutrients, such as glucose and amino acids. Cancer cells, however, often lack such access. In the early stages of tumor growth, tumor-directed angiogenesis—the formation of new blood vessels—is not fully activated, as we discuss in Chapter 13. Later in tumor progression, many vessels are malformed. In both cases, cancer cells may become nutrient- and oxygen-starved. This ischemia can trigger bioenergetic collapse and necrosis. The necrotic cores of many tumors are testimonials to the important role of necrosis in limiting tumor growth. Although the overall size of a tumor often yields the impression of a large and actively growing mass, the bulk of most tumors is actually inert, necrotic tissue that has never been eliminated.

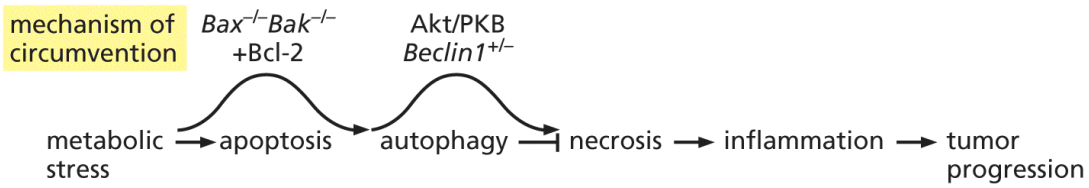
As indicated in Table 9.2, necrotic cell death differs in many respects from apoptosis and results in the lysis of the cells rather than the production of apoptotic bodies. The resulting cell lysis can trigger localized inflammation, as the surrounding tissues become exposed to the intracellular contents of the necrotic cell. Interestingly, if the apoptotic response is blocked through one of the mechanisms described earlier, exposing the cell to a death receptor ligand may instead trigger necrosis.

Before nutrient starvation drives a cancer cell into necrosis, the cell may resort to an alternative strategy to stave off the irreversible collapse of metabolism that triggers necrotic cell death: it may activate a program called autophagy, which allows it to cannibalize its own organelles as a means of recycling their contents (**Figure 9.34A**). The recycled molecules can then be used to generate the energy and intermediary metabolites that are required to maintain cell viability, permitting the nutrient-starved cell to survive for an extended period of time.



Two electron micrographs. The one on the left shows a mitochondrion enclosed within a round structure. Above it, indicated by arrows, are four structures with concentric layers, like an onion. The electron micrograph on the right shows a white ring-like structure. Within the structure are two generally round structures labeled m and three smaller round structures labeled e. Outside the ring are three more structures labeled m. Two of them are elongated and are obviously mitochondria.

(A)

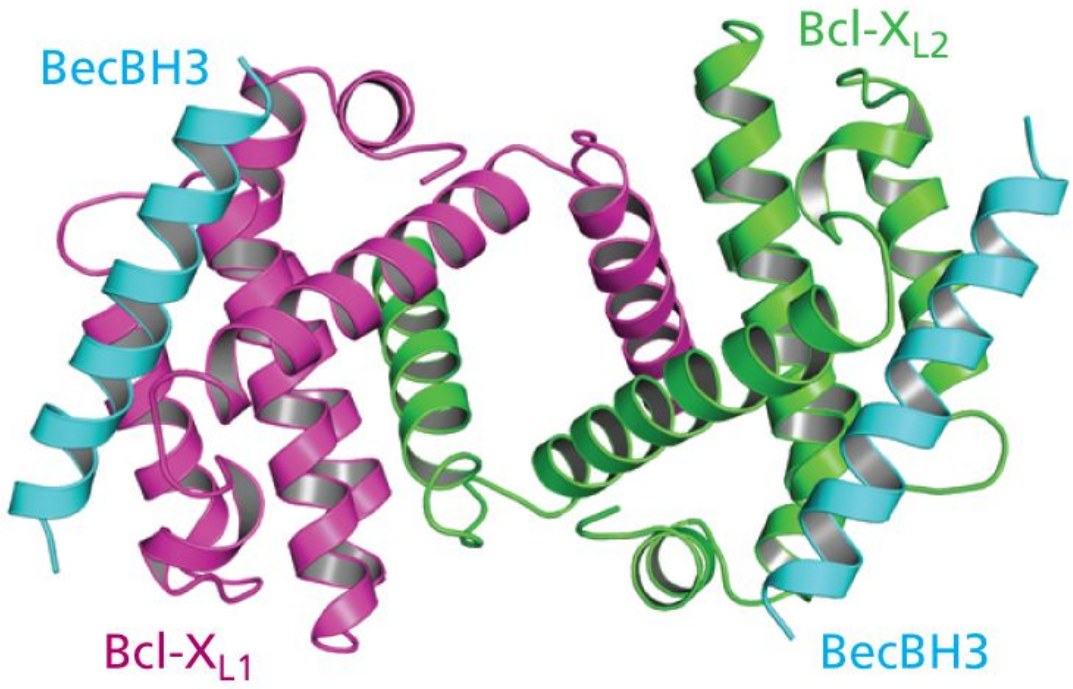


Several possible sequences of events in a single diagram. Metabolic stress normally leads to apoptosis. However, this can be circumvented, by a mechanism that involves Bax minus minus and Bak minus minus, plus B c l-2. Then the natural result is autophagy, which would normally block necrosis. However, this, too, can be circumvented, by a mechanism that involves A k t P K B and Beclin1 plus minus. Then the result is necrosis, which leads to inflammation, which leads to tumor progression.

(B)

A micrograph in which gray-blue necrotic cells are surrounded by yellow healthy stroma, and in between the two is a layer of dark brown cells.

(C)



A ribbon diagram showing Bec B H3 bound to B c l-X L1 and Bec B H3 bound to Bcl-XL2.

(D)

Figure 9.34 Autophagy and necrosis (A) In a cell undergoing autophagy, an entire mitochondrion has been engulfed in a digestive compartment called an autophagosome (electron micrograph, *left*); the *arrows* indicate structures that have the multilayered appearance of autophagosomes. The *right* panel shows an autophagosome (*arrow*) surrounding mitochondria (m) and fragments of endoplasmic reticulum (e). (B) Under some circumstances, cancer cells may respond to metabolic stress, such as nutrient deprivation, by activating apoptosis. If apoptosis is circumvented experimentally (*curved arrow*) by inactivating pro-apoptotic genes *(Bax* and *Bak*) and by expressing an anti-apoptotic protein (Bcl-2), these cells may activate autophagy. If autophagy is then inhibited by expressing the Akt/PKB kinase (which blocks autophagy) plus inactivating one of the two copies of the *Beclin* gene (whose protein product is a master regulator of autophagy), such cells will enter into necrosis. Necrosis may in turn promote localized inflammation, which often serves to promote tumor progression, as discussed in Chapter 11. (C) A subtype of ductal carcinoma *in situ* (DCIS) of the breast, termed comedo carcinoma, shows a rim of viable cells (C) that are expressing high levels of Beclin-1 (*brown*), the master regulator of autophagy, surrounding a central core of necrotic cells (N, *light blue*). The *Beclin*$^{+}$ cells have activated autophagy, apparently in response to the limited nutrients available to

them from the nearby surrounding stroma (S). Of note, this subtype of DCIS has a worse prognosis than the more common subtypes, in which intraductal necrosis is not seen; indeed, the *Beclin*$^{+}$ cancer cells seen here are close to becoming actively invasive. (D) The complex interactions between the apoptosis and autophagy programs are highlighted by the fact that Beclin can be bound directly by either Bcl-2 or Bcl-X_L, two potent anti-apoptotic proteins; this binding prevents Beclin from causing autophagy. Seen here is a crystallographic structure of a complex of two molecules of the BH3 domain of Beclin bound to two molecules of the BH3 domain of Bcl-X_L. (A, left, courtesy of E.M. Haley, B.A. Lund, M.E. Bisher and H.A. Coller; right, from N. Mizushima and B. Levine, *Nat. Cell Biol.* 12:823–830, 2010. With permission from Nature. B, from K. Degenhardt et al., *Cancer Cell* 10:51–64, 2006. With permission from Elsevier. C, from V. Espina and L.A. Liotta, *Nat. Rev. Cancer* 11:68–75, 2011. With permission from Nature. D, from A. Oberstein, P.D. Jeffrey and Y. Shi, *J. Biol. Chem*. 282:13123–13132, 2007. © 2007 ASBMB. This article is available under the terms of the Creative Commons Attribution 4.0 license.)

In the case of cancer cells, this survival may allow them to avoid necrosis altogether if they subsequently succeed in obtaining access to nutrients (Figure 9.34B–D). Under conditions of nutrient deprivation, some cancer cells have been seen to consume two-thirds of their own mass and still remain viable, retaining the ability to return to full size and to a state of active proliferation once nutrients are eventually procured. Importantly, excessive, deregulated autophagy may lead a cell to cannibalize too many of its own constituents, leading to its death by specialized death program termed autophagic cell death.

In recent years, a number of additional forms of regulated cell death have been described. They can be distinguished by a combination of the morphological changes that accompany the death process and by the genetic and biochemical pathways that are implicated in their execution. One of these, necroptosis, exhibits certain morphological features of necrosis (for example, cell lysis), but unlike necrosis, this form of cell death is orchestrated by specific biochemical pathways. In particular, death receptors, such as the TNF receptor, and the kinases RIPK3 and RIPK1 are implicated in necroptosis. Following activation of this pathway by upstream signals, the protein MLKL is phosphorylated by RIPK3 and undergoes oligomerization and translocation to the plasma membrane, leading to membrane rupture and cell lysis. The importance of the MLKL executioner in this pathway has been confirmed via mouse knockout experiments. Thus, although *Mlkl*$^{-/-}$ mice survive and show no obvious defects, their cells are resistant to the induction of necroptosis.

Pyroptosis derives its name from a form of cell death that is associated with inflammation. Indeed, pyroptosis operates in the context of infection of cells by intracellular pathogens, including viruses and bacteria. In the context of cancer, this program can be induced by exposure of cancer cells to a variety of cytotoxic therapeutic drugs. Once activated, the programmed release of a variety of pro-inflammatory cytokines together with the rupture of the plasma membrane results in the recruitment of several types of cells of the innate immune system, amplifying the host response to these various noxious agents. It is thought that induction of pyroptosis involves several caspases, including caspase 1, which activates the pro-inflammatory cytokine IL-1β, as well as the pore-forming protein gasdermin D (GSDMD). Cleavage of the latter by caspase 1 or other inflammatory caspases leads to the release of its N-terminal domain, which forms pores in the cell membrane and induces cell lysis. These processes explain why cells lacking GSDMD are protected against pyroptosis provoked by certain agents.

Finally, a form of regulated cell death known as ferroptosis is associated with iron availability and intracellular lipid peroxidation. Ferroptosis is inhibited by the lipid peroxidase GPX4, and inhibition of this enzyme can lead to induction of this death program. Because ferroptosis depends on iron, various iron chelators also inhibit ferroptosis. This program may be important in the cellular response to certain anti-cancer agents. In addition, carcinoma cells that have moved from an epithelial to a more mesenchymal phenotype (as described in Chapter 14) exhibit a significantly increased susceptibility to induced ferroptosis. Interestingly, recent evidence points to p53 as a positive regulator of ferroptosis, adding to the list of its potential tumor-suppressing mechanisms.

As is true for apoptosis, the genes and pathways that control these other forms of cell death may be the target of mutation or silencing during tumor development, enabling cancer cells to survive in the face of multiple insults and challenges. As an example, expression levels of the genes encoding RIPK and MLKL are lower in certain cancers compared with corresponding normal tissues, implicating suppression of necroptosis as a pro-tumorigenic strategy. Moreover, investigations of these various cell death pathways, undertaken in order to reveal new strategies for eliminating neoplastic cells, represents an active area of investigation.

OceanofPDF.com

Glossary

ischemia
: State within a tissue caused by inadequate access to circulating blood, resulting in hypoxia, decreased pH, and inadequate supply of nutrients.

autophagy
: A catabolic process whereby selected intracellular organelles and molecules are degraded by engulfment in autophagosomes that proceed to fuse with lysosomes in which degradation occurs, yielding metabolites that can be recycled for biosynthetic reactions.

autophagic cell death
: A form of cell death associated with autophagy in which dying cells sequester large portions of their cytoplasmic contents in autophagosomes. This form of cell death lacks the characteristic chromatin condensation seen in apoptosis. *See* **autophagosome, autophagy**.

necroptosis
: A programmed form of necrosis that leads to cell death and the release of cellular debris that may persist and trigger local tissue inflammation. *See also* **apoptosis**, **ferroptosis**, **pyroptosis**.

pyroptosis
: A cell death program that is often provoked by infection by intracellular pathogens and results in cell death and the release of pro-inflammatory cytokines. Pyroptosis can also be induced following exposure to certain chemotherapeutic agents.

ferroptosis
: A form of programmed cell death that depends on iron and the formation of lipid peroxides and is distinct from other forms of cell death such as apoptosis. *See also* **apoptosis, necroptosis, pyroptosis**.

9.18 Synopsis and prospects

In the early chapters of this book, we concentrated on the molecular mechanisms that propel cell proliferation forward or hold it back. Most of these regulators—the products of (proto-) oncogenes and tumor suppressor genes—manage the extracellular mitogenic and anti-mitogenic signals that impinge upon the cell cycle machinery from outside the cell. These signals are processed within individual cells to enable them to converge on the final decisions that determine whether they advance through the active growth-and-division cycle, retreat reversibly into quiescence, or enter irreversibly into a post-mitotic, differentiated state.

In this chapter, we have focused on entirely different cell-physiological processes, most of which are responsible for monitoring the internal well-being of cells. The monitoring apparatus conducts continuous surveillance of vital cell systems, including access to oxygen and nutrients, the physical state of the genome, and the balance of signals flowing through a cell's growth-regulating circuits. If such monitors determine that a vital system is damaged or malfunctioning within a cell, an alarm is sounded and growth is halted or, more drastically, the cell is induced to enter into senescence or activate its previously latent apoptotic program.

These monitors create barriers to tumor formation that incipient cancer cells must override in order to complete the complex, multi-step agenda that leads eventually to the formation of malignant cancers. Thus, as cells evolve from normalcy to a state of high-grade neoplasia, many of their subcellular systems malfunction in one way or another, leading to the risks of cytostasis, senescence, apoptosis, necroptosis, ferroptosis, pyroptosis, or other fates that threaten to derail tumor development.

Any one of these traps can halt further progress down the long road to malignancy. Indeed, attempts by most would-be cancer cells to evade these pitfalls usually fail, as reflected in the high attrition of the cells in premalignant cell populations. The multiple sources of cell attrition also help to explain one of the mysteries of human cancer pathogenesis: even

though each of us experiences ~10^{16} cell divisions in a lifetime, each one of which threatens to create a seed of cancer, most of us will not develop life-threatening malignancies, a testament to the effectiveness of the multiple mechanisms that trigger cell death.

p53 is a central player in many of these responses because elimination of its function is one frequent means of avoiding apoptosis, growth arrest, and senescence, the last representing a permanent exit from the cell cycle (see Section 10.1). The *p53* gene and encoded protein have been the subject of more than 100,000 research reports since the discovery of the p53 protein in 1979. This extraordinary focus on a single gene and protein reflects both the central role that this protein plays in cancer pathogenesis and the frequent presence of mutant *p53* alleles in the genomes of human cancer cells. Still unanswered, however, is the most perplexing puzzle surrounding this protein: Why would cells entrust so many vital alarm functions to a single protein? Once a cell has lost p53 function, it becomes oblivious, in a single stroke, to a range of conditions that would normally call a halt to its proliferation or trigger entrance into the apoptotic program.

As we will see in Chapter 11, the complex, multi-step process that drives tumor development involves changes in multiple cellular control circuits. Because p53 receives signals from so many distinct sensors of damage or cell-physiological distress, the loss of p53 function plays a role in many of these steps. For example, early in the development of bladder, breast, lung, and colon carcinomas, when premalignant growths are present, DNA damage signaling is already active, as indicated by the presence of phosphorylated, functionally active ATM and Chk2 kinases. In addition, the p53 substrate of these kinases is also phosphorylated and apparently active, because the *p53* gene is often still in its wild-type configuration at this stage of tumor progression. This indicates that DNA lesions are widespread in the cells of these growths, even at this early stage of tumorigenesis, and suggests that p53 is striving to constrain the proliferation of the cells in these growths and may even induce with some frequency their elimination by apoptosis. Consequently, these premalignant cells stand to benefit greatly by shedding p53 function, thereby liberating themselves from its cytostatic and pro-apoptotic effects.

At these early stages of tumor development, cells that succeed in eliminating p53 function may also gain special advantage because they have a better chance of avoiding the apoptosis that is triggered by p53 in response to severe hypoxia. Thus, early premalignant growths generally have not yet developed adequate access to the circulation and the oxygen that it brings (via the process of angiogenesis to be described in Chapter 13). In addition, because p53 induces expression of the potently anti-angiogenic molecule thrombospondin (Tsp-1), p53 inactivation can accelerate the development of nearby capillary networks that can cure the hypoxia.

Later in tumor progression, when malignant carcinomas develop, the absence of p53 function will compromise some of the DNA repair systems of the cell and, at the same time, allow cells carrying damaged genomes greater survival advantage; the result is an increased rate of genomic alteration and an associated acceleration in the rate of multi-step tumor development as described in Chapter 11. Additionally, the absence of p53 function may enable these tumor cells to survive the pro-apoptotic side effects of oncogenes such as *Myc*. This short list reveals how truly catastrophic the loss of p53 function can be for a tissue and, ultimately, for the organism as a whole.

The effects of p53 loss may also be manifested even later, in the event that the *p53*-mutant tumor cells become clinically apparent and targeted for chemotherapy and radiation. The success of most existing anti-cancer therapies is predicated on their ability to damage the genomes of tumor cells, thereby provoking the death of these cells by apoptosis. In some cases, the loss of p53 function renders these cancer cells far less responsive to many of these therapeutic strategies (see Figure 9.7B as an example). In other cases, the absence of the p53-dependent cell cycle arrest response allows cells treated with chemotherapeutic agents to progress into the cell cycle with damaged genomes, which can actually *sensitize* them to p53-independent forms of cell death. Hence, the effects of p53 mutation of cancer therapy are highly context dependent.

Our understanding of the p53 protein remains incomplete, in spite of the vast research literature that describes it. One indication of how much more

needs to be learned has come from attempts at systematically cataloging the myriad post-translational modifications of p53. As we have seen, some of these modifications affect p53's stability and thus intracellular concentration. In addition, they also affect the interactions of p53 with other nuclear transcription regulators that control the genes targeted by p53 action. The number of enzymes that modify p53—as evidenced by the variety of modifications shown in Figure 9.15C—is likely to reflect the number of distinct signaling pathways that impinge on p53 and regulate its functioning. Thus, each of the post-translational modifications illustrated in this figure is likely to affect the physical interaction of p53 with another partner protein in the cell, often a signaling protein.

In the case of the apoptotic response, loss of p53 function is only one of many strategies that cancer cells employ to protect themselves against this form of cell death. Alternative strategies include perturbing the expression of death receptors, their ability to activate caspases, and the activities of the caspases themselves. Yet other defensive maneuvers undertaken by cancer cells help to prevent mitochondrial outer membrane permeabilization (MOMP). These diverse strategies (see Figure 9.33) illustrate that the apoptotic machinery, like all well-regulated machines, operates through the balanced actions of mutually antagonistic elements. Cancer cells exploit preexisting anti-apoptotic components of this machinery by increasing their levels or activities, thereby nudging the balance away from apoptosis. These changes in specific components of the apoptotic machinery may compound the effects of p53 loss, further increasing the resistance of cancer cells to a variety of signals that usually succeed in provoking cell death.

Later, in Chapter 17, we will learn about novel forms of therapy that are designed to mobilize components of the pro-apoptotic machinery that remain intact in cancer cells. The hope is that at some time in the not-too-distant future, the circuitry governing apoptosis will be understood with sufficient precision so that we will be able to predict its behavior with accuracy and manipulate it at will within cancer cells.

These discussions of the mechanisms governing apoptotic cell death, which seem to be far removed from the real world, may soon be brought to bear on a major puzzle about human cancer: Why does obesity, as gauged by

body-mass index (BMI), represent a major factor determining cancer incidence? In the United States, obesity represents the second greatest risk factor for developing cancer after tobacco consumption and will soon outpace tobacco as the leading risk factor for developing cancer. An attractive but still-unproven model proposes that obesity increases cancer incidence by protecting incipient cancer cells from death by apoptosis. If this thinking is substantiated, then apoptosis research will soon assume a major role in explaining the onset of cancer as well as the successes that we have in preventing and treating this disease.

OceanofPDF.com

Key concepts

- Organisms attempt to block the development of cancer through the actions of the p53 protein, which can cause cells to enter cell cycle arrest, undergo senescence, or experience apoptosis in the event that the machinery regulating cell proliferation is malfunctioning or the cells are exposed to various types of physiological stress.
- p53 is a nuclear protein that normally exists as a tetramer and functions as a transcription factor.
- The mutant p53 proteins found in many human tumors often carry amino acid substitutions in their DNA-binding domain. When a mutant p53 subunit forms tetrameric complexes with wild-type p53 subunits, it compromises the normal functions of the wild-type subunits and thus with functions of the tetramer as a whole.
- p53 can impose cell cycle arrest through its ability to induce expression of $p21^{Cip1}$ and apoptosis through its ability to promote the expression of a variety of pro-apoptotic proteins.
- p53 normally turns over rapidly. This turnover is blocked when various signals indicate cell-physiological stress, including anoxia, damage to the genome, and signaling imbalances in the intracellular growth-regulating machinery.
- p53 becomes functionally activated when its normally rapid degradation is blocked. In addition, covalent modifications of the resulting accumulated p53 protein modulate its activity as a transcription factor, directing it to activate the expression of the large constituency of genes involved in various cellular responses, notably apoptosis, cytostasis, and senescence.
- p53 levels are controlled by two critical upstream regulators, Mdm2 and $p14^{ARF}$. Mdm2 works to destroy p53, and ARF prevents Mdm2 from driving p53 degradation.
- The apoptotic caspase cascade can be triggered through the induction of mitochondrial outer membrane permeabilization (MOMP), which releases several pro-apoptotic proteins, most importantly cytochrome *c*.

- MOMP is determined by the relative levels of Bcl-2–related anti-apoptotic and pro-apoptotic proteins.
- Apoptosis involves the activation of a cascade of caspases that results in the destruction of a cell, usually within an hour. Apoptosis can be activated by p53 as well as by signals impinging on the cell from the outside, notably those transduced by cell surface death receptors.
- Loss of apoptotic functions allows cancer cells to survive a variety of cell-physiological stresses, including anoxia, signaling imbalances, DNA damage, and loss of anchorage.
- Cancer cells invent numerous ways to inactivate the apoptotic machinery in order to survive and thrive. Included among these are activation of Akt/PKB firing, increase in the levels of anti-apoptotic Bcl-2–related proteins, inactivation of p53 through changes in the *p53* gene or the upstream regulators of p53, methylation of the promoters of a variety of pro-apoptotic genes, interference with cytochrome *c* release from mitochondria, and inhibition of caspases.
- Apoptosis is only one of several forms of regulated cell death that threaten the survival of pre-neoplastic cells. Others include necroptosis, pyroptosis, and ferroptosis.

Thought questions

1. Considering that DNA tumor viruses must suppress the apoptosis of infected cells in order to multiply, what molecular strategies are available for them to do so?
2. What types of factors influence the decision of p53 to act in a cytostatic versus a pro-apoptotic fashion?
3. How can anti-cancer therapeutics be successful in treating cancer cells that have inactivated components of their apoptotic machinery? Given the physiological stresses that are known to activate p53-induced apoptosis, what types of anti-cancer therapeutic drugs might be created to treat cancer cells?
4. What side effects would you predict could result from a general inhibition of apoptosis in all tissues of the body?
5. How might the loss of components of the apoptosis machinery render cancer cells more susceptible than normal cells to certain types of cell death?
6. Enumerate the range of physiological stresses that induce apoptosis that cancer cells must confront and circumvent during the course of tumor development.

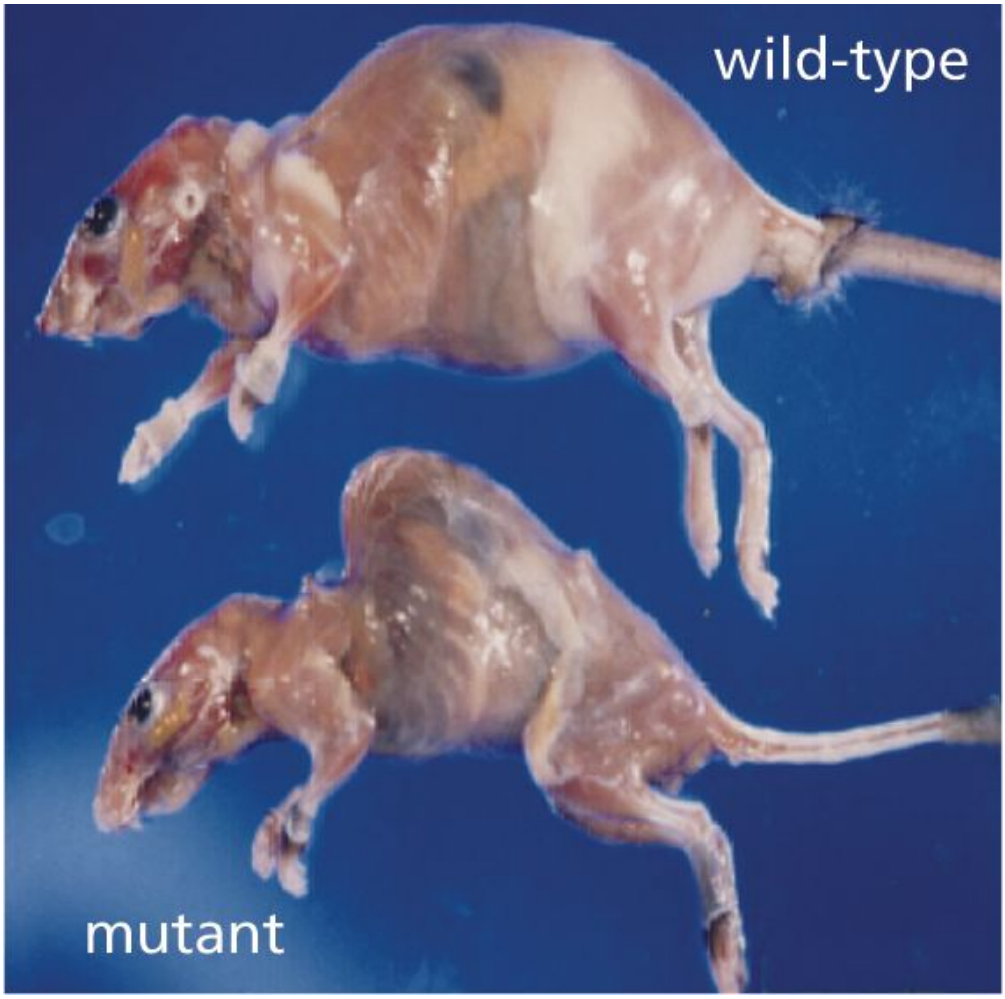
Supplementary Sidebars

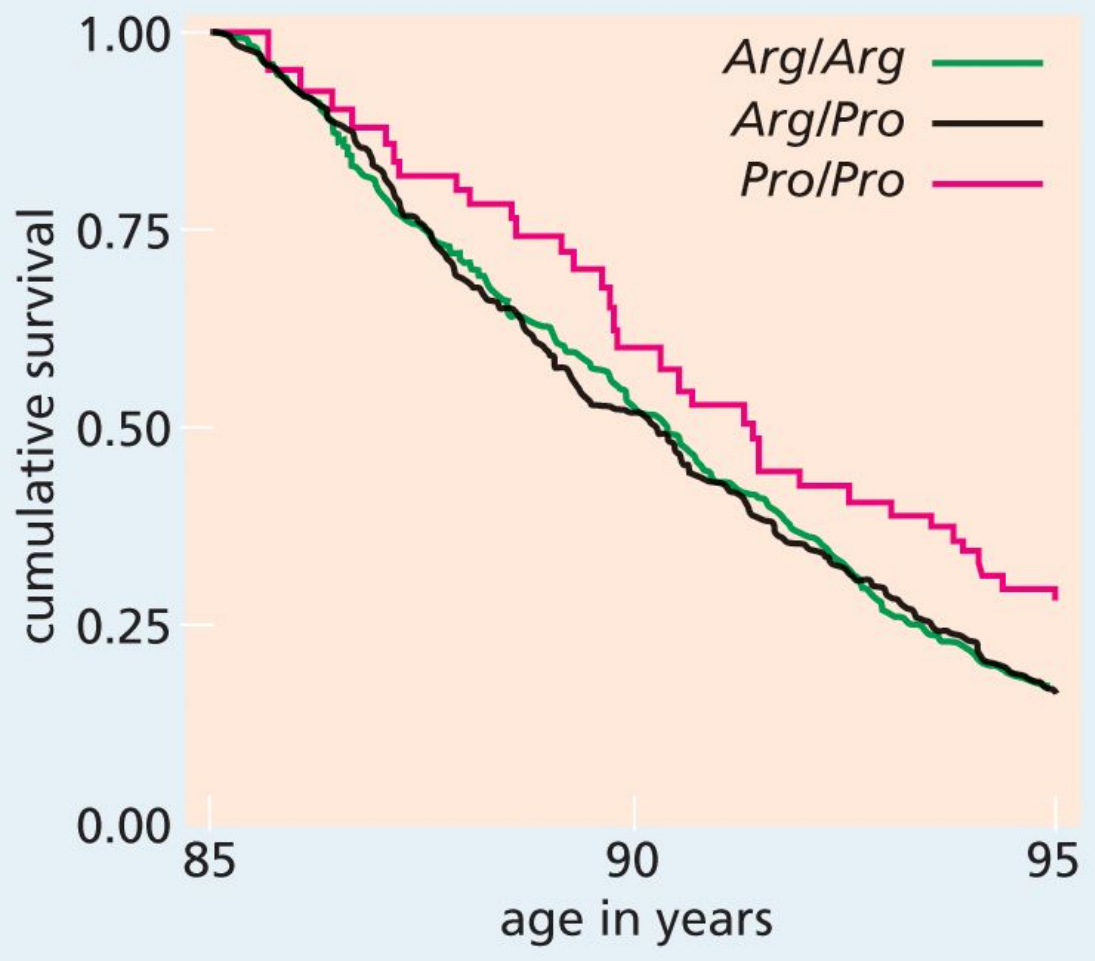
Supplementary Sidebar 9.1 Too much of a good thing: a hyperactive p53 protein causes premature aging

The descriptions of p53 actions in this chapter include ample evidence that the p53 alarm, once activated, provides important protection against the development of cancer. What would happen if a *p53* allele that encodes a constitutively active form of the protein were inserted into the mouse germ line? This has occurred through an experimental accident, in which the first six exons of the *p53* gene were inadvertently deleted during attempts to replace a germ-line wild-type *p53* allele with a point-mutated allele. The p53 protein encoded by this truncated allele behaves as if it were continuously active, even without the alarm signals that are normally required to activate it. Mice heterozygous for this allele are totally protected from the lymphomas, osteosarcomas, and soft-tissue (non-bone) sarcomas that commonly afflict wild-type mice late in life. And fibroblasts from these mice are more resistant than their wild-type counterparts to transformation by a *ras* oncogene introduced *in vitro*. These outcomes, among many others, show that p53 activity does indeed protect tissues from spawning tumors, ostensibly by eliminating cancerous cells before they have had a chance to proliferate into tumors of a significant size.

However, rather than living longer lives, these “cancer-resistant” mice showed a premature aging syndrome, their life span being reduced by some 20%. The accelerated aging included changes frequently observed in aged humans, such as development of a hunched spine, retarded wound healing, reduced replacement of lost white blood cells, plus losses of weight, vigor, muscle mass, bone density, and hair (**Figure S9.1A**). In many tissues, there was a widespread depletion of cells, suggesting a loss of self-renewing stem cells.



(A)



(B)

Figure S9.1 Premature aging induced by an overly active p53 The p53 protein may afford protection against cancer and at the same time accelerate the aging process. (A) A mouse expressing a constitutively active p53 protein (*below*) shows many of the attributes of aging seen in humans, including muscle atrophy and a hunching of the back, when compared with a wild-type mouse of a similar age (*above*); both mice were skinned to reveal the muscle phenotype. These p53 mutant mice also exhibited osteoporosis, atrophy of numerous organs, and diminished tolerance to stress. (B) A prospective study followed the survival of 1226 subjects in the Netherlands beginning at the age of 85. As is apparent from this plot, those with a *Pro*/*Pro* allele (affecting residue 72 of p53) exhibited a markedly improved survival over the course of a decade compared with heterozygotes or those with an *Arg*/*Arg* allele. Although consistent with a key role of *p53* in governing longevity, this striking and statistically significant association does not definitively prove such a role, because it remains formally possible that these alleles are tightly linked with other loci on Chromosome 17 that are the

actual determinants of longevity. (A, from S.D. Tyner et al., *Nature* 415:45–53, 2002. With permission from Nature. B, from D. van Heemst et al., *Exp*. *Gerontol*. 40:11–15, 2005. With permission from Elsevier.)

These phenotypes are consistent with the idea that p53 plays a role in the aging process, but they hardly prove it. An experiment of nature seems to address these issues more directly: a naturally occurring polymorphism in the human gene pool places a proline residue in place of an arginine in residue 72 of p53. *In vitro* experiments show that the Arg^{72} protein is as much as fivefold more effective in triggering apoptosis than the Pro^{72} form of the protein. An epidemiologic study carried out in the Netherlands of a population over 85 years of age demonstrated that those with a $p53^{Pro/Pro}$ genotype had a 2.54-fold increased risk of cancer (compared with those of a $p53^{Arg/Arg}$ genotype). However, those with a $p53^{Pro/Pro}$ genotype showed an overall 41% greater survival during the period studied (Figure S9.1B). Moreover, deaths from general exhaustion and frailty were observed in 21% of the *Arg/Arg* subjects but in only 6% of the *Pro/Pro* individuals. Observations like these add weight to the notion that increased activity of p53 affords greater protection against cancer but at the same time accelerates the age-dependent deterioration of tissues. Hence, too much vigilance by p53 may impose a heavy price on the organism as a whole.

Supplementary Sidebar 9.2 UV-B radiation, HPV, and cutaneous squamous cell carcinomas

Squamous cell carcinomas (SCCs) of the skin occur with a relatively low frequency in the general population, often in light-skinned individuals, and with a greatly increased frequency in organ transplant recipients, who are immunosuppressed in order to prevent organ graft rejection as described in Chapter 15. These tumors are more threatening than the far more common basal cell carcinomas of the skin, which rarely if ever metastasize. Several human papillomavirus (HPV) types have been found in these lesions, although the etiologic role of these has not yet been firmly established.

Recent evidence provides some insights into the mechanisms by which HPV, acting through its E6 protein, might act synergistically with UV-B radiation from the sun to enable the survival of heavily irradiated skin cells, thereby allowing any UV-mutated cells to persist in the skin and serve, over the long term, as the progenitors of SSC skin tumors. In effect, HPV, acting through its encoded E6 oncoprotein, is able to neutralize p53, thereby creating a phenocopy of the state seen in keratinocytes in which the chromosomal *p53* gene has been mutated and rendered inactive.

Normally, in response to DNA damage, HIPK2 (homeodomain-interacting protein kinase 2) phosphorylates p53 on its serine 46 residue, thereby placing p53 in an configuration that promotes apoptosis (**Figure S9.2**). (In fact, this phosphorylation may prove to be a key determinant of whether p53, acting as a transcription factor, induces expression of pro-apoptotic genes rather than, for example, genes that lead to cell senescence.) Such HIPK2-mediated phosphorylation of p53 occurs not only in response to UV-induced DNA damage, but also following genotoxic damage inflicted by a variety of other agents, including cisplatin and doxorubicin, two commonly used chemotherapeutic drugs.

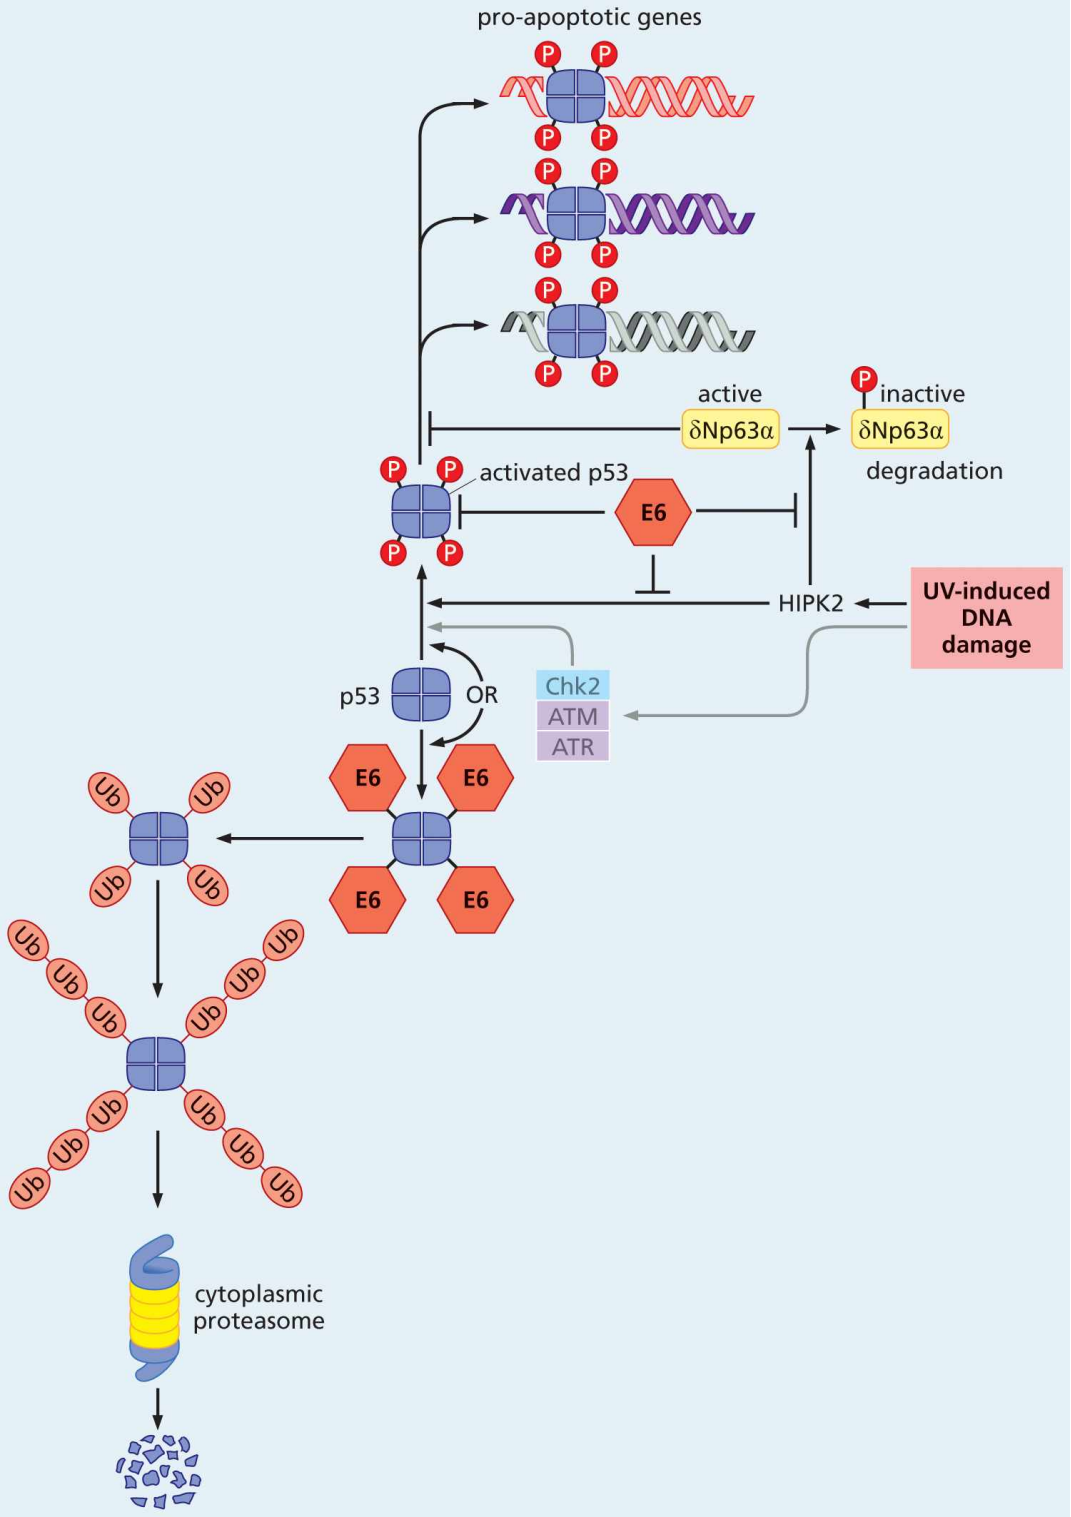


Figure S9.2 HIPK2, HPV E6, and the inactivation of p53 pro-apoptotic functions The HIPK2 kinase is activated in response to severe DNA damage. Once activated, it phosphorylates p53 on its serine 46, thereby converting p53 into a pro-apoptotic transcription factor. [This site of p53 phosphorylation is distinct

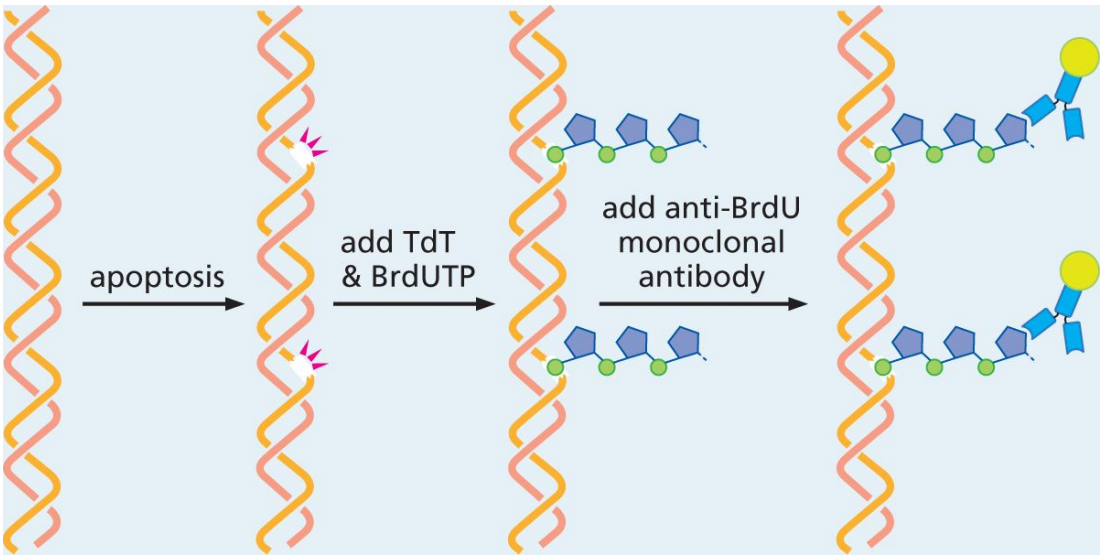
from the sites of ATM phosphorylation (serine 15) and of p53 phosphorylation by Chk2 (serine 20) that are described in Figure 9.15C. Each modification has a distinct effect on p53 function in response to DNA damage.] In addition, the E6 oncoprotein of human papillomavirus (HPV) is deployed by this class of DNA tumor viruses in order to tag p53 for ubiquitylation and destruction in proteasomes (see Table 9.1). Moreover, HPV E6 operates to block the interaction of HIPK2 with p53, thereby preventing p53's conversion, via phosphorylation by HIPK2, into a pro-apoptotic transcription factor. Thus, HPV E6 blocks p53 function via at least two distinct mechanisms, which may provide a mechanistic explanation of how UV radiation and cutaneous HPV types function synergistically to trigger the outgrowth of cutaneous SCCs in humans.

In addition, HIPK2 phosphorylates and inactivates δNp63α, a truncated form of p63, the cousin of p53. δNp63α usually acts as a dominant-negative inhibitor of p53, preventing it from triggering apoptosis. (Its high expression in rapidly proliferating epithelial cells helps to ensure the survival of these cells.)

The E6 oncoprotein made by HPV23—a strain of this virus that is commonly associated with skin cancers—is able to bind HIPK2 and prevent this kinase from phosphorylating p53, thereby blocking the signal released by HIPK2 that activates apoptosis. Moreover, by inactivating HIPK2, HPV E6 protects δNp63α from phosphorylation and resulting degradation; δNp63α can then continue to inhibit the pro-apoptotic functions of p53. In addition, E6 blocks p53 function directly; acting together with E6AP, a ubiquitin ligase of cellular origin, E6 tags p53 with polyubiquitin (see **Supplementary Sidebar 7.5**), thereby marking p53 for rapid destruction in proteasomes. In this way, the inactivation of the *p53* gene resulting from UV-B–induced mutations in keratinocytes can be functionally replaced by an HPV23 infection, which acts via two mechanisms to neutralize p53 protein function. Indeed, because the HPV23 E6 protein is able, in principle, to inactivate all of the HIPK2 in a cell, viral infection may be a far more effective way to prevent p53-induced apoptosis than UV-induced somatic mutations of the *p53* gene. This protection of virus-infected keratinocytes allows these skin cells to survive and accumulate additional UV-induced somatic mutations in other genes; the resulting multiply altered cells (carrying both the viral E6 oncogene and mutated cell genes) may then spawn a squamous cell carcinoma of the skin.

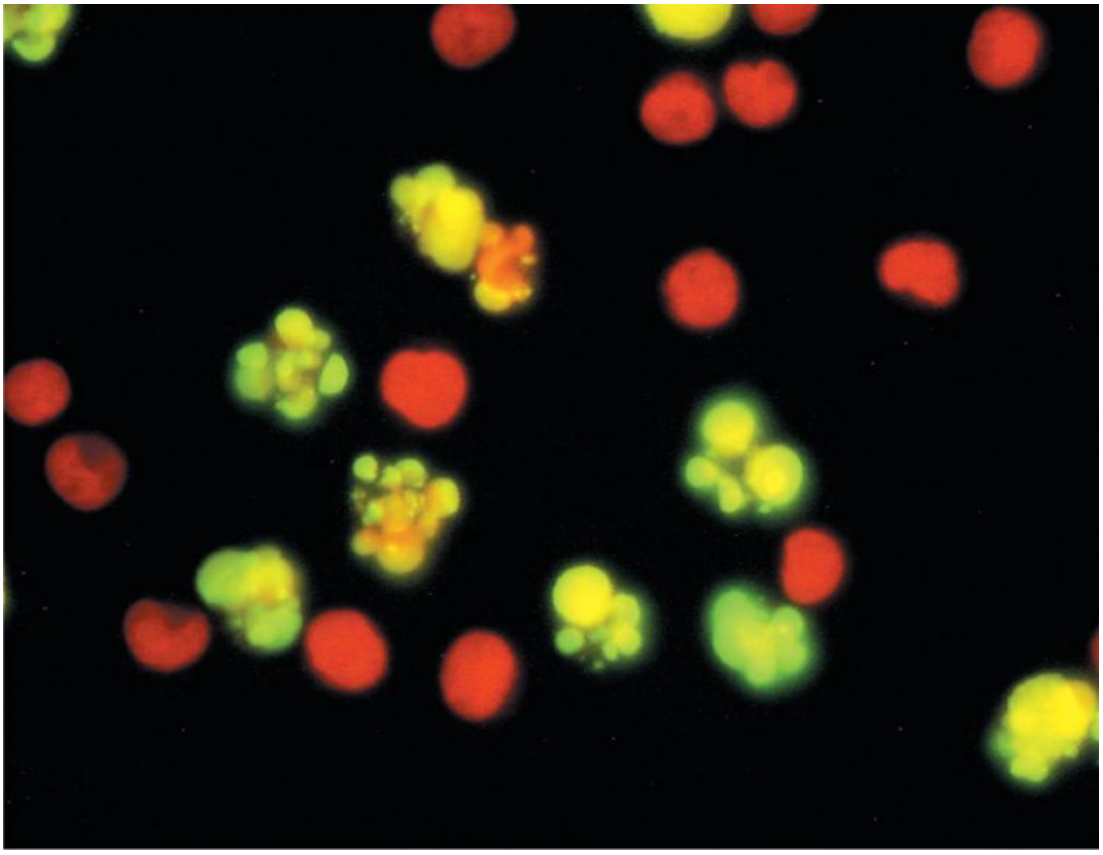
Supplementary Sidebar 9.3 The molecular changes that characterized apoptotic cells can be detected by a variety of assays

Because apoptosis affects a multitude of cellular components (see Figure 9.19), there are multiple alternative ways by which apoptosis can be measured (**Figure S9.3**).

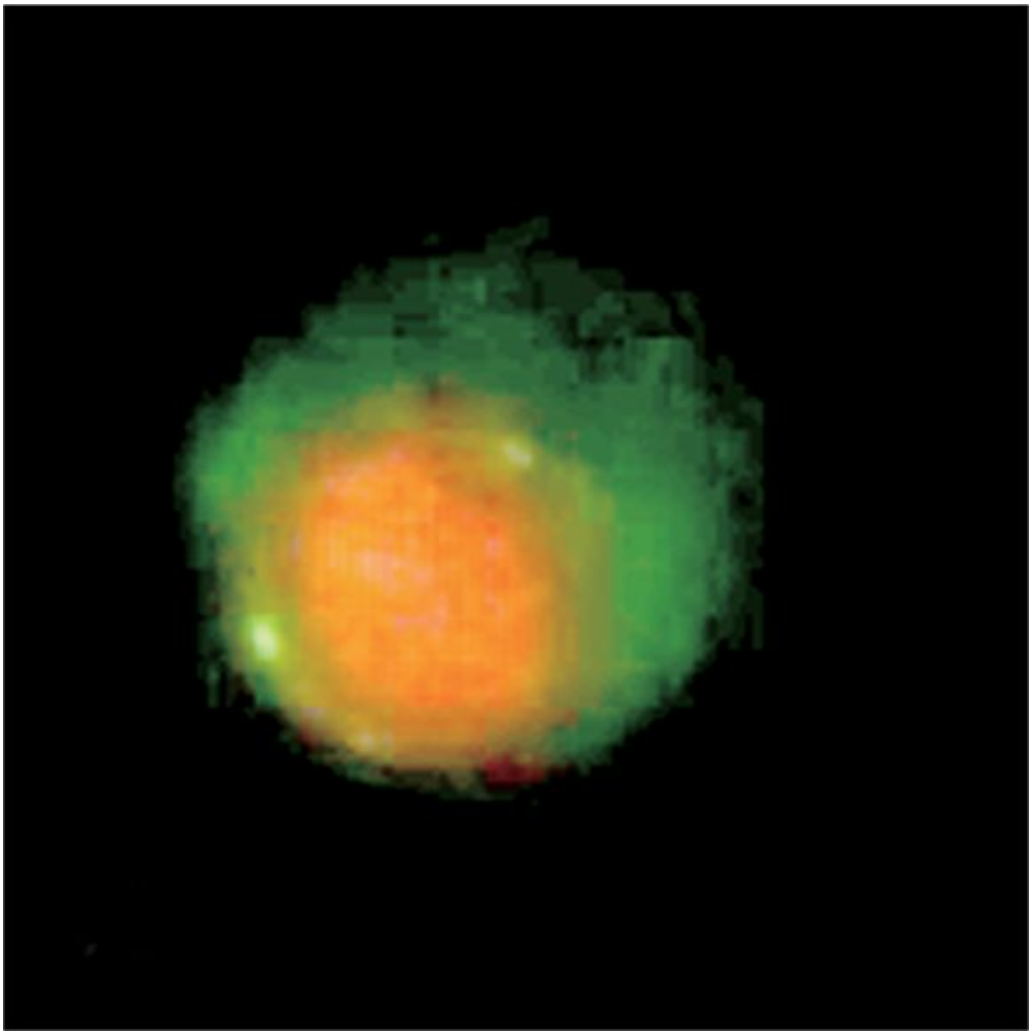


apoptosis
add TdT
& BrdUTP
add anti-BrdU
monoclonal
antibody

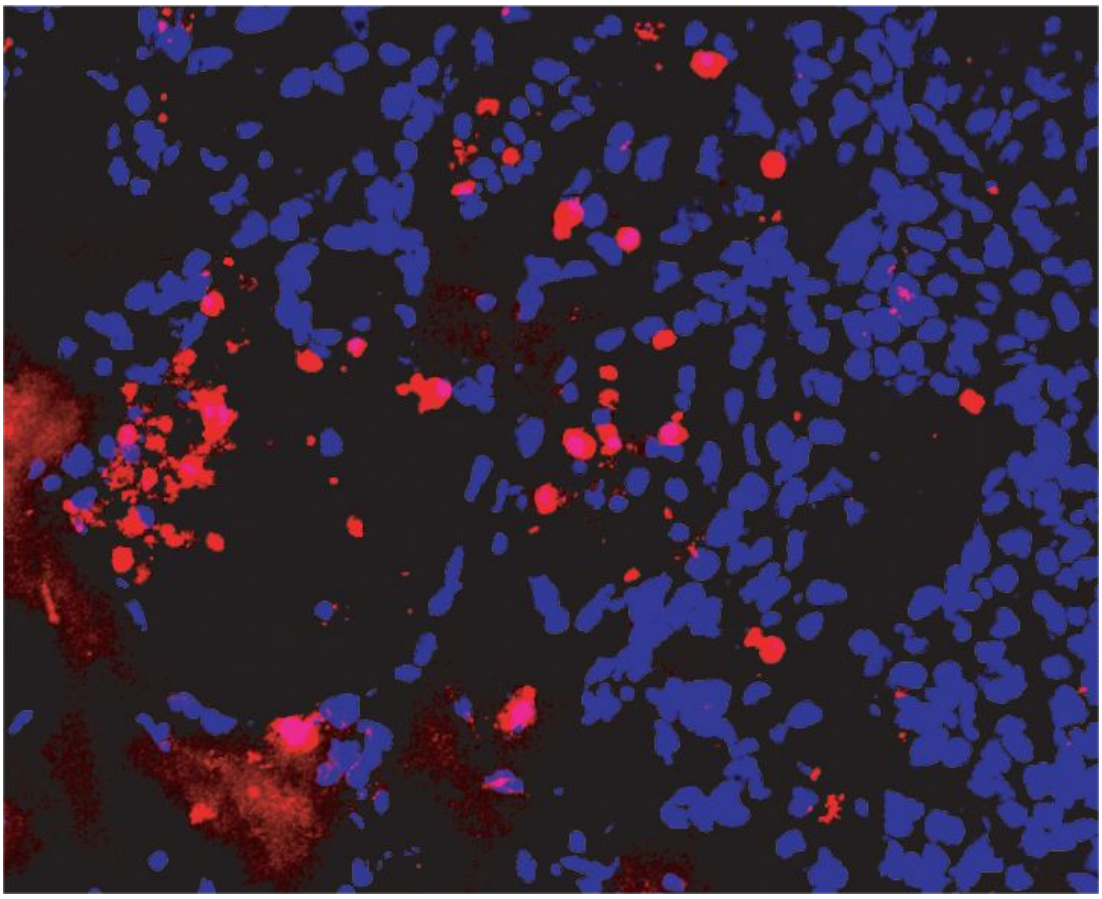
(A)



(B)



(C)



(D)

Figure S9.3 Detecting apoptotic cells (A) Apoptotic cells can be detected because their chromosomal DNA has become fragmented, exposing 3′-OH DNA ends. In the TUNEL assay, these ends are extended by the enzyme terminal deoxyribonucleotide transferase (TdT) using bromodeoxyuridine triphosphate (BrdUTP) as substrate. The resulting BrdU-incorporated oligonucleotide tails can be detected with an anti-BrdU monoclonal antibody that has been coupled to a dye molecule (*yellow-green*). (B) In addition to the apoptotic cells stained by the TUNEL assay (*yellow-green*), cells in this population that have become *necrotic* are revealed through the use of propidium iodide dye (*red*), which is unable to enter cells with an intact plasma membrane but is able to enter freely into such necrotic cells, which lack an intact plasma membrane, and bind nuclear DNA. (C) Early in the apoptotic program, phosphatidylserine (PS) molecules, which are normally exposed on the inner surface of the lipid-bilayer plasma membrane, are flipped and therefore become exposed on its outer surface. PS is bound by the annexin V protein, which here has been coupled to a fluorescent dye and used to detect exposed, cell-surface PS (*green*). Because the cell in this image has advanced to a later stage of apoptosis, its plasma membrane has become

permeable to propidium iodide dye (*yellow-orange*), allowing staining of its nucleus as well. (D) A fluorescent dye–tagged antibody for cleaved (and therefore activated) caspase 3 (*red*), reveals an active apoptotic program (see Section 9.13), and the DAPI stain has been used to stain cell nuclei (*blue*) in cells of an MMTV-Neu transgenic mouse breast adenocarcinoma. (The cancer cells are entering anoikis/apoptosis because they express a dominant-negative integrin β1.) Note that an area of apoptotic carcinoma cells (*left*) contrasts with an area of normal stromal cells (*right*) in which apoptosis is rare. (B, courtesy of Thermo Fisher Scientific. C, from J. Yamamoto et al., *Clin. Cancer Res.* 12:7132–7139, 2006. With permission from American Association for Cancer Research. C, courtesy of W. Guo and F. Giancotti.)

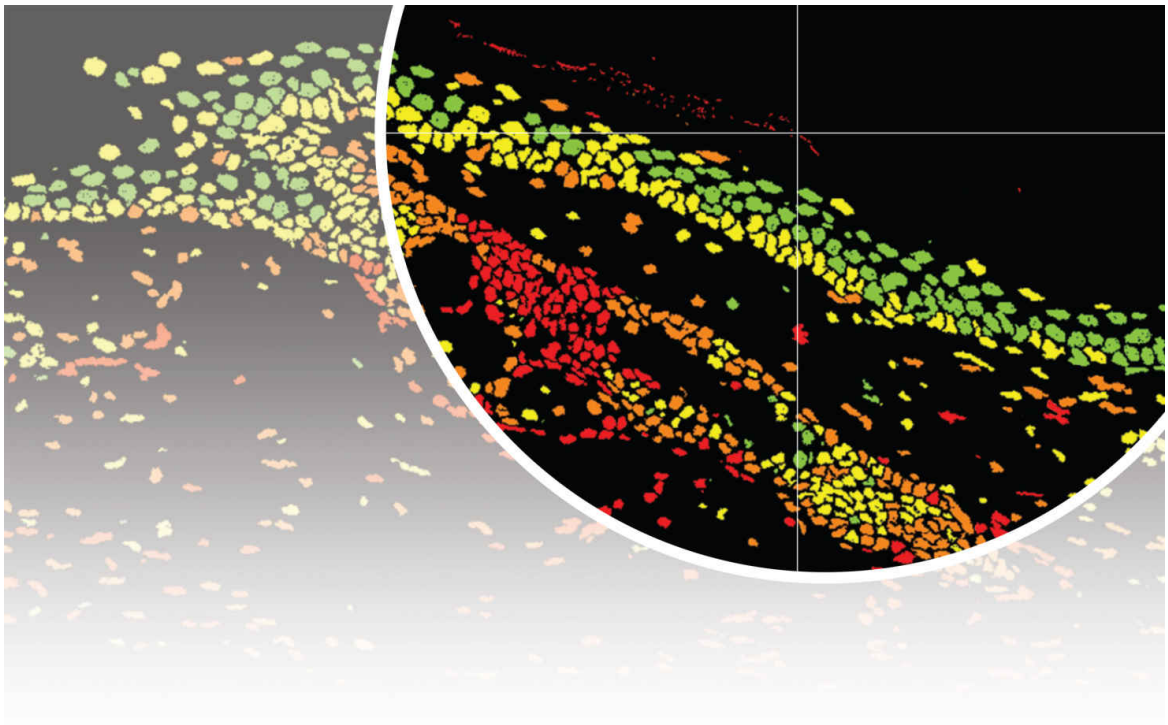
Chapter 10
Eternal Life: Cell Immortalization and Tumorigenesis



A false-color image of a human hair follicle in cross-section, with individual cells appearing red, yellow and green against a black background.

Chapter opener photo: From I. Flores et al., *Genes Dev*. 22:654–667, 2008. With permission from Cold Spring Harbor Laboratory Press.

Death takes place because a worn-out tissue cannot forever renew itself, and because a capacity for increase by means of cell division is not everlasting but finite.

August Weissmann, biologist, 1881

In previous chapters, we read about a number of distinctive traits displayed by cancer cells. In some instances, these traits are acquired through the actions of activated oncogenes; in others, cancer cell–specific traits can be traced back to the loss of tumor suppressor genes. As we will discuss in Chapter 11, the acquisition by human cells of these neoplastic traits (and thus the development of clinically apparent human tumors) usually requires several decades' time.

During this extended period of development, populations of human cells pass through a long succession of growth-and-division cycles as they evolve toward the neoplastic growth state. Such extensive proliferation, however, conflicts with a fundamental property of normal human cells: they are endowed with an ability to replicate only a far smaller number of times. Once normal human cell populations have exhausted their allotment of allowed doublings, the cells in these populations cease proliferating and may even enter senescence or apoptosis.

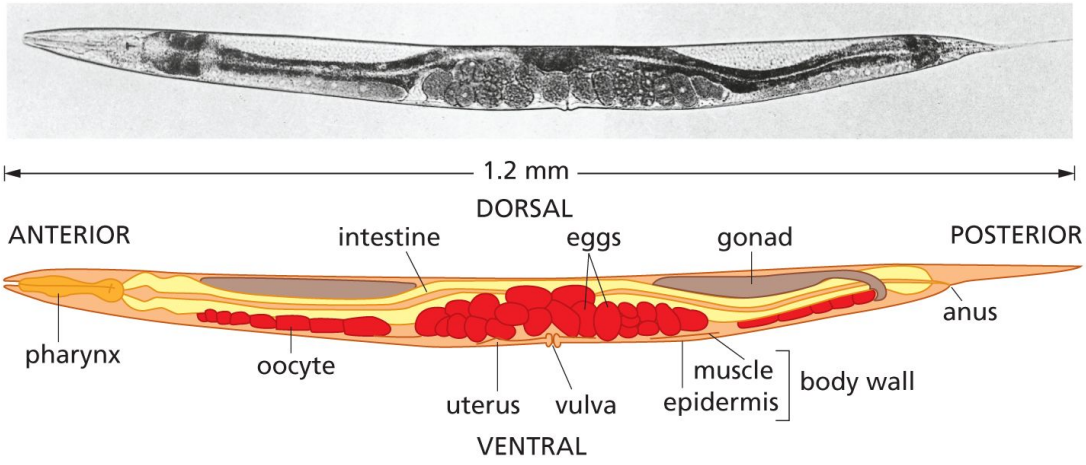
These facts lead us to a simple, inescapable conclusion: in order to form tumors, incipient cancer cells must breach the barrier that normally limits their proliferative potential. Somehow, they must acquire the ability to multiply for an abnormally large number of growth-and-division cycles, so that they can successfully complete the multiple steps of tumor development.

In this chapter, we explore the nature of the regulatory machinery that limits cell proliferation and will see how it must be neutralized in order for cells to become fully neoplastic and form clinically detectable tumors. By neutralizing this machinery, cells gain the ability to proliferate indefinitely—the phenotype of cell immortality. This immortality is a critical component of the neoplastic growth program of many if not all types of tumor cells.

OceanofPDF.com

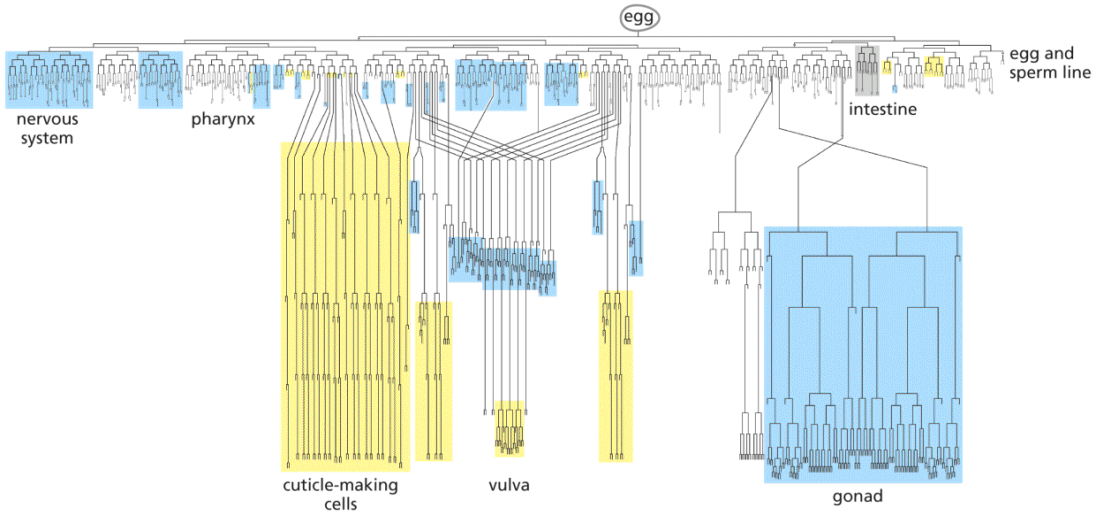
10.1 Normal cell populations appear to register the number of cell generations separating them from their ancestors in the early embryo

In multicellular (metazoan) animals such as ourselves, the origin of each cell can, in principle, be traced through multiple cell generations back to a single ancestor—the fertilized egg. Looking in the other direction, the sequence of cell divisions that stretches from an ancestral cell that existed in the embryo to a descendant cell that exists many cell generations later is often termed a cell lineage. Indeed, in a relatively simple metazoan—the worm *Caenorhabditis elegans*—the lineages of all 959 somatic cells in the adult body have been traced and can be depicted as a pedigree (**Figure 10.1**).



A photo of the transparent worm, which is 1.2 millimeters long. Below the photo is a diagram of the worm's anatomy. It shows, from head to tail, the pharynx, a line of oocytes, intestine, uterus, vulva, eggs, gonad, muscle and epidermis forming the body wall, and the anus.

(A)



A tree diagram showing cell proliferation and differentiation, starting with an egg and producing cells for the nervous system, the pharynx, cuticle-making cells, the vulva, the gonad, the intestine, and egg and sperm line. Many individual branches of the tree terminate early on while others continue.

(B)

Figure 10.1 The pedigree of cells in the body of a worm (A) The adult worm *Caenorhabditis elegans* is composed of 959 somatic cells, and the lines of descent of all cells in this worm have been traced with precision back to the fertilized egg. (B) As is apparent, many of the cell lineages end abruptly because cells stop proliferating or are discarded (usually by apoptosis). The cells in each of the major branches are destined to form a specific tissue. For example, cells in the major, multigenerational branch on the right are destined to form the gonads, whereas those in a small branch at the far left will form the nervous system. (A, from J.E. Sulston and H.R. Horvitz, *Dev. Biol.* 56:110–156, 1977. With permission from Elsevier. B, from A. Chisholm and Y. Jin, eLS, 2003. With permission from John Wiley & Sons.)

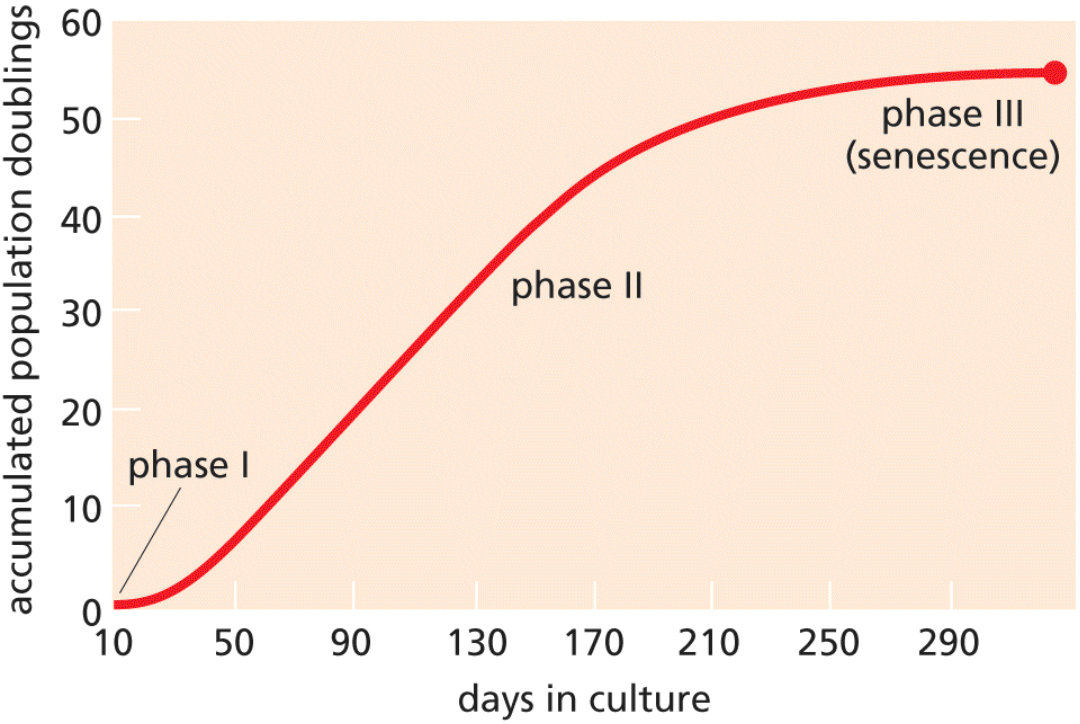
In large, complex mammals, however, the assembling of a comparable pedigree will never happen, because the total number of cell divisions is astronomical: the adult human body, for example, comprises almost 10^{14} cells, and the organism as a whole undergoes as many as 10^{16} cell divisions in a lifetime. Still, we can imagine that for each human body such a cell pedigree must exist, if only as a theoretical construct.

As is the case with *C. elegans*, during the course of human development, early embryonic cells become the founders of specific cell lineages that are committed to assuming various tissue-specific cellular phenotypes, that is, to differentiating (see

Section 8.11). Indeed, the science of developmental biology focuses much of its attention on how individual cells in various cell lineages acquire the information that causes them to enter into one or another program of differentiation. However, developmental biologists do not address a question of great relevance to tumor development: Are there specific controls that determine the number of cell generations through which the cells belonging to a particular cell lineage can pass during the lifetime of an organism? Can each branch and twig of the cell pedigree grow indefinitely, or is the number of replicative generations in each cell lineage predetermined and limited?

To be sure, some cell populations proliferate often in normal tissues, whereas others proliferate hardly at all, further complicating calculations of cell generations (**Supplementary Sidebar 10.1**). Currently available techniques do not allow us to determine with any precision how many times the cells within specific normal cellular lineages within the human or mouse body pass through successive growth-and-division cycles. However, a crude measure of the replicative capacity of a cell lineage can be undertaken by culturing cells of interest *in vitro*. For example, one can prepare fibroblasts from living tissue, introduce them into a Petri dish, and determine how many times these cells will double. (In practice, such experiments require serial passaging, in which a portion of the cells that have filled one dish are removed and introduced into a second dish and allowed to proliferate, after which some of their number are introduced into a third dish, and so forth.)

As first demonstrated in the mid-1960s, primary cells (that is, cells prepared from living tissues and introduced directly into tissue culture) from rodent or human embryos exhibit a limited number of successive replicative cycles in culture. The work of Leonard Hayflick showed that cells would stop growing after a certain, apparently predetermined number of divisions and enter into the state that came to be called replicative senescence (**Figure 10.2**), which closely resembles the senescent state discussed in Section 9.11. As previously described, senescent cells remain metabolically active but seem to have lost irreversibly the ability to re-enter the active cell cycle. Such cells will spread out in monolayer culture, acquire a large cytoplasm, and persist for weeks if not months, as long as they are given adequate nutrients and growth factors; such cells are often described as taking on the appearance of a fried egg (see Figure 9.17). The supplied growth factors help to sustain the viability of the senescent cells, but they are unable to elicit the usual proliferative response observed when the same factors are applied to healthy, nonsenescent cells. Correlated with the unusual appearance of senescent cells are a number of biochemical alterations within these cells.



A line graph showing accumulated population doublings as a function of time. In phase 1, the curve begins at 0 doublings after 10 days in culture. During phase 2, the curve rises to 25 percent after 10 days; this is the steepest point. In phase 3, called senescence, the curve levels out at 55 percent after about 325 days.

Figure 10.2 The proliferative capacity of cells passaged extensively in culture The ability of human fibroblasts to proliferate in culture was gauged in Leonard Hayflick's work by counting the number of times that the population of cells had doubled (*ordinate*). As is apparent, these cells, beginning soon after explantation from living tissue into culture (phase I), were able to proliferate robustly for about 60 doublings (phase II) before entering into senescence (phase III), in which state they could remain viable but nonproliferating; such senescent cells could remain viable for as long as a year. (From J.W. Shay and W.E. Wright, *Nat. Rev. Mol. Cell Biol.* 1:72–76, 2000. With permission from Nature.)

The precise number of replicative doublings exhibited by cultured cells before they reach senescence depends on the species from which the cells were prepared, on the tissue of origin, and on the age of the donor organism. Some experiments with human cells indicate that cells prepared from newborns are able to double in culture a greater number of times than comparable cells taken from middle-aged or elderly adults (**Supplementary Sidebar 10.2**). Such behavior suggests that cells from older

individuals have already used up part of their allotment of replicative doublings prior to being introduced into tissue culture.

Although this is the simplest explanation, other explanations are equally plausible. For example, lineages of nondividing cells within a living tissue may sustain damage from, say, long-term exposure to reactive oxygen species (ROS) leaking from their mitochondria. In this case, the subsequently observed loss of proliferative capacity *in vitro* may be proportional to the *elapsed time* since these cells were first formed and may be unconnected directly with the *number of successive cell generations* their lineage has passed through. In fact, certain experiments have raised the question of whether replicative senescence, as defined by Hayflick, is a physiological process operating in living tissues or a reflection of the shortcomings of *in vitro* tissue culture techniques (**Supplementary Sidebar 10.3**).

OceanofPDF.com

Glossary

serial passaging
: Practice of transferring a cell population or viral population from one culture vessel or host cell to another, taking the products of this initial passage, and transferring a portion of them to yet another host cell or culture vessel to allow a new cycle of proliferation, doing so serially and repeatedly. *See* **passaging**.

primary cells
: (1) Literally, cells that have been recently explanted from living tissue into culture vessels and have not been propagated thereafter in culture. (2) More commonly, cells that have been explanted from living tissue into culture dishes and have been subjected to a relatively small number of successive *in vitro* passages thereafter.

replicative senescence
: The cell state entered when chromosomal telomeres have undergone erosion or, more commonly, when cells have experienced cumulative physiological stress over multiple cell generations in culture due to suboptimal conditions of propagation. *See* **senescence**.

OceanofPDF.com

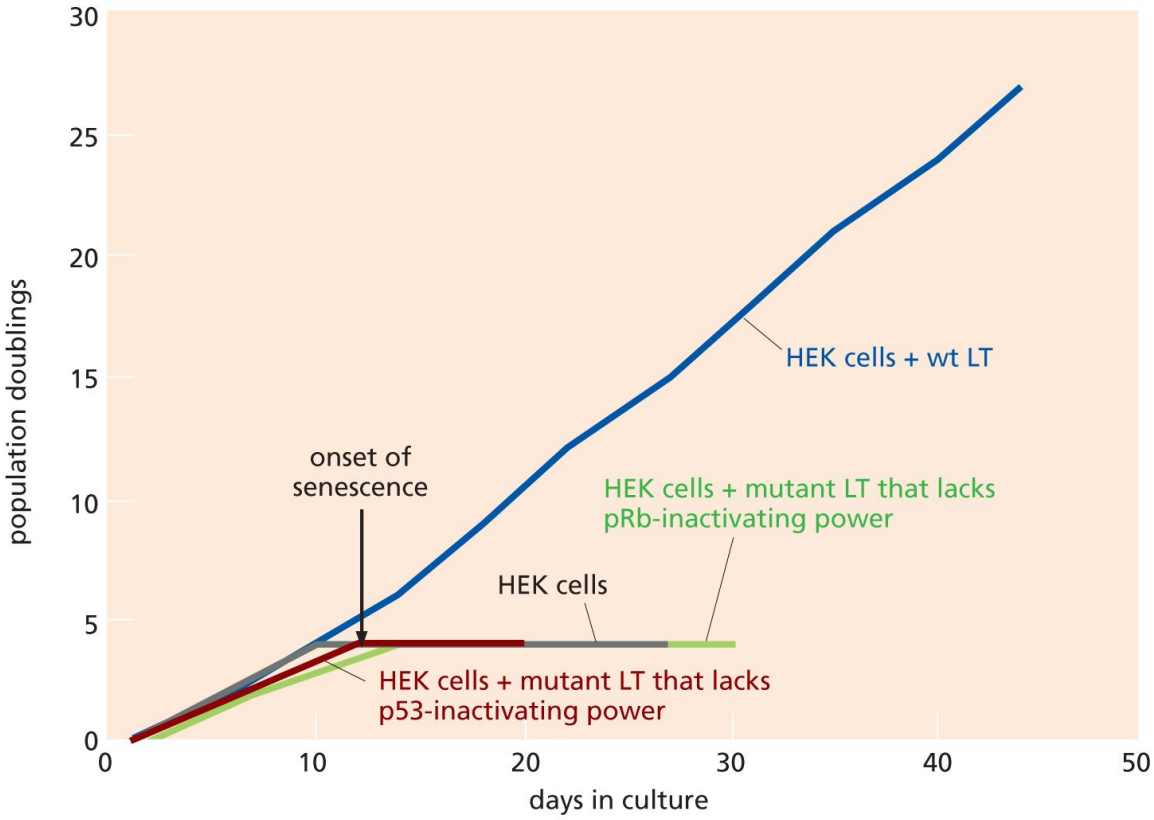
10.2 Cells need to become immortalized in order to form a cell line

Whether or not replicative senescence is a tissue culture artifact, it stands in the way of propagating cell populations over long periods of time using standard tissue culture techniques. Thus, following their extraction from living tissues and introduction into tissue culture, cells almost invariably enter senescence and halt proliferation after an almost-predictable number of cell doublings. This represents a major obstacle for those investigators who would like to propagate cell populations indefinitely *in vitro*, which requires that the cells in these populations have undergone the process of immortalization.

The onset of replicative senescence is accompanied by increasing expression of the two key CDK inhibitors, $p16^{INK4A}$ and $p21^{Cip1}$. As discussed earlier (see Section 8.4), these CDK inhibitors are capable of halting cell cycle advance and driving a cell into a nongrowing state. Taken together, such evidence suggests that these two proteins may actually be responsible for imposing the senescent state on cultured cells. This notion is supported by forcing expression of $p16^{INK4A}$ in cells, which on its own suffices to create a cell-biological state that is similar if not identical to senescence. To complete this logic, various types of cell-physiological stress (including stresses experienced in tissue culture) activate expression of $p16^{INK4A}$ and $p21^{Cip1}$, which proceed to shut down cell proliferation and induce the cell phenotypes associated with senescence.

The prominent role of $p16^{INK4A}$ in triggering senescence is supported by other kinds of experiments: variants of human keratinocytes that succeed in escaping the fate of early senescence *in vitro* are often found to carry inactivated copies of the gene encoding the $p16^{INK4A}$ tumor suppressor protein; by shutting down $p16^{INK4A}$ expression, these cells can ostensibly avoid entrance into a post-mitotic senescent state. Moreover, the early senescence of cultured human keratinocytes can be circumvented by experimentally forced over-expression in these cells of high levels of CDK4; recall that this cyclin-dependent kinase can bind and thus sequester $p16^{INK4A}$ (see Figure 8.11), thereby preventing it from halting cell proliferation.

Imagine that the environment experienced by pre-neoplastic and neoplastic cells within living tissues forces them to cope with a variety of physiological stresses similar to those experienced by cells in culture. One suggestion of this comes from experiments showing that the senescence of cultured normal primary human cells can be avoided by ectopic expression of the SV40 large T antigen (**Figure 10.3**). Large T is able to bind and sequester both pRb and p53 (see Table 9.1) and its ability to do so is critical for circumventing entrance into this state (see Figure 10.3). Recall that (1) the pathways controlled by these two tumor suppressor proteins are also found to be inactivated in the great majority of human tumors, as we read in Chapters 8 and 9, and (2) pRb and p53 serve as the key downstream effectors of the two proteins—$p16^{INK4A}$ and $p21^{Cip1}$—that are induced as cells enter replicative senescence. Accordingly, when cancer cells are extracted from human tumors and placed into tissue culture, the previous inactivation of their pRb and p53 pathways that occurred *in vivo* (mimicking the actions of the SV40 large T antigen introduced experimentally *in vitro*) is likely to help these cells resist many of the stresses imposed by *in vitro* culture conditions and thereby to avoid senescence.



A line graph showing population doublings as a function of time for four different cell types. On the y axis is days in culture from 0 to 50. All cell

types start along the same trajectory. H E K cells, H E K cells plus mutant LT that lacks p R b-inactivating power, and H E K cells plus mutant LT that lacks p53-inactivating power reach onset of senescence after 10 to 12 doublings and the line plateaus. H E K cells plus w t L T continue past 25 doublings along a positive almost linear slope.

Figure 10.3 Role of large T antigen in circumventing senescence
Experiments with a variety of human cell types indicate that both pRb and p53 must be functionally inactivated to ensure that these cells do not senesce in culture. This can be achieved through the expression of the SV40 large T antigen (LT) in these cells. As seen here, human embryonic kidney (HEK) cells senesce after 10 to 12 population doublings in culture (*gray line*). However, if they express the wild-type LT protein (*blue line*), they circumvent senescence and continue to proliferate for an extended period of time. Mutants of LT that have lost the ability to sequester either p53 (*brown line*) or pRb (*light green line*) fail to prevent senescence. Importantly, such cells that have bypassed senescence will eventually enter into crisis, which the expression of LT does not prevent. (Adapted from W.C. Hahn et al., *Mol. Cell. Biol*. 22:2111–2123, 2002.)

This reasoning suggests that avoidance of senescence is critical to the progression and survival of neoplastic cells *in vivo* and that, as a consequence, senescence is indeed a physiological process (rather than being simply an artifact of *in vitro* cell culture). Indeed, diverse observations indicate that a variety of other cell-physiological stresses besides extended *in vitro* propagation can also induce a cellular state that is indistinguishable from replicative senescence. Included among these are hyperoxia (that is, supranormal oxygen tensions leading to intracellular oxidative stress), DNA damage created by endogenously generated reactive oxygen species, X-rays, chemotherapeutic drugs, dysfunctional telomeres (see below), and aberrant signaling by certain oncoproteins, as discussed in Section 9.11. Nonetheless, even when tissue culture conditions are optimized and the SV40 large T oncoprotein is deployed to circumvent replicative senescence, as seen in Figure 10.3, cells will still not possess unlimited proliferative ability and instead will eventually be forced to halt proliferation by a process that is discussed in some detail below and is termed crisis. Hence, a second obstacle to unlimited proliferation (that is, entrance into an immortalized growth state) operates even after the initial obstacle of senescence has been surmounted. Unlike senescence, the obstacle erected by crisis does indeed seem to count the number of successive replicative doublings through which lineages of cells have passed since their origins in the early embryo.

There are, in fact, naturally occurring cells with unlimited proliferative potential *in vitro*: embryonic stem (ES) cells, which are prepared from the inner cell mass of very early mammalian embryos, retain the ability, under the proper conditions, to seed all the differentiated lineages in the body. When provided with the proper culture media, the ES cells show unlimited replicative potential in culture and are thus said to be immortal. (The term is a bit misleading, because it is really a *lineage* of ES cells in culture that is immortal rather than individual ES cells.)

These various observations convey the notion that very early in embryogenesis, cells have an unlimited replicative capacity. However, as specific lineages of differentiated cells in the developing organism (for example, dermal fibroblasts, neurons, mammary epithelial cells) are formed, each seems to be allocated a predetermined number of subsequent postembryonic doublings. This limited proliferative power of the normal differentiated cell lineages contrasts with the replicative behavior of a variety of cancer cells, which resembles, at least superficially, that of ES cells.

This immortalized behavior of cancer cells is illustrated dramatically by HeLa cells. Over the past half century, these cultured cells have been the human cell type most frequently used to study the molecular biology of human cells. They were derived in 1951 from an unusual, particularly aggressive cervical adenocarcinoma discovered in Henrietta Lacks, a young woman from Baltimore, Maryland, who soon died from the complications of this tumor. Ever since that time, these cells have proliferated in culture in hundreds of laboratories across the world, dividing approximately once a day. HeLa cells constitute a cell line, in that they have become established in culture and can be passaged indefinitely, in contrast to many cell populations that have a limited replicative ability after being removed from living tissue. Even more impressive is the history of the cells forming the canine transmissible venereal tumor, one of several cancers that is spread during sexual intercourse from a tumor-bearing host to other members of its species via transmission of neoplastic cells. Sequencing of the genomes of these tumors, borne by dogs throughout the world, trace the origins of these tumors to a single progenitor cell and tumor that first arose more than 6000 years ago, whose direct descendants have been transmitted via mating ever since. (These tumors thrive even though they are not syngeneic with the hosts that carry them.)

OceanofPDF.com

Glossary

immortalization
: Process whereby a cell population normally having limited replicative potential acquires the ability to multiply indefinitely.

crisis
: (1) Cellular state arising when cells lose telomeres of a length that is required to protect the ends of chromosomal DNA, resulting in the end-to-end fusion of chromosomes, karyotypic chaos, and widespread cell death by apoptosis. (2) Clinical state when patients whose tumors have been under therapeutic control relapse into a highly aggressive phase of disease.

immortal
: Process whereby a cell population normally having limited replicative potential acquires the ability to multiply indefinitely.

cell line
: Strain of cells that has been adapted for indefinite propagation in culture.

supranormal
: Higher than normal physiological levels.

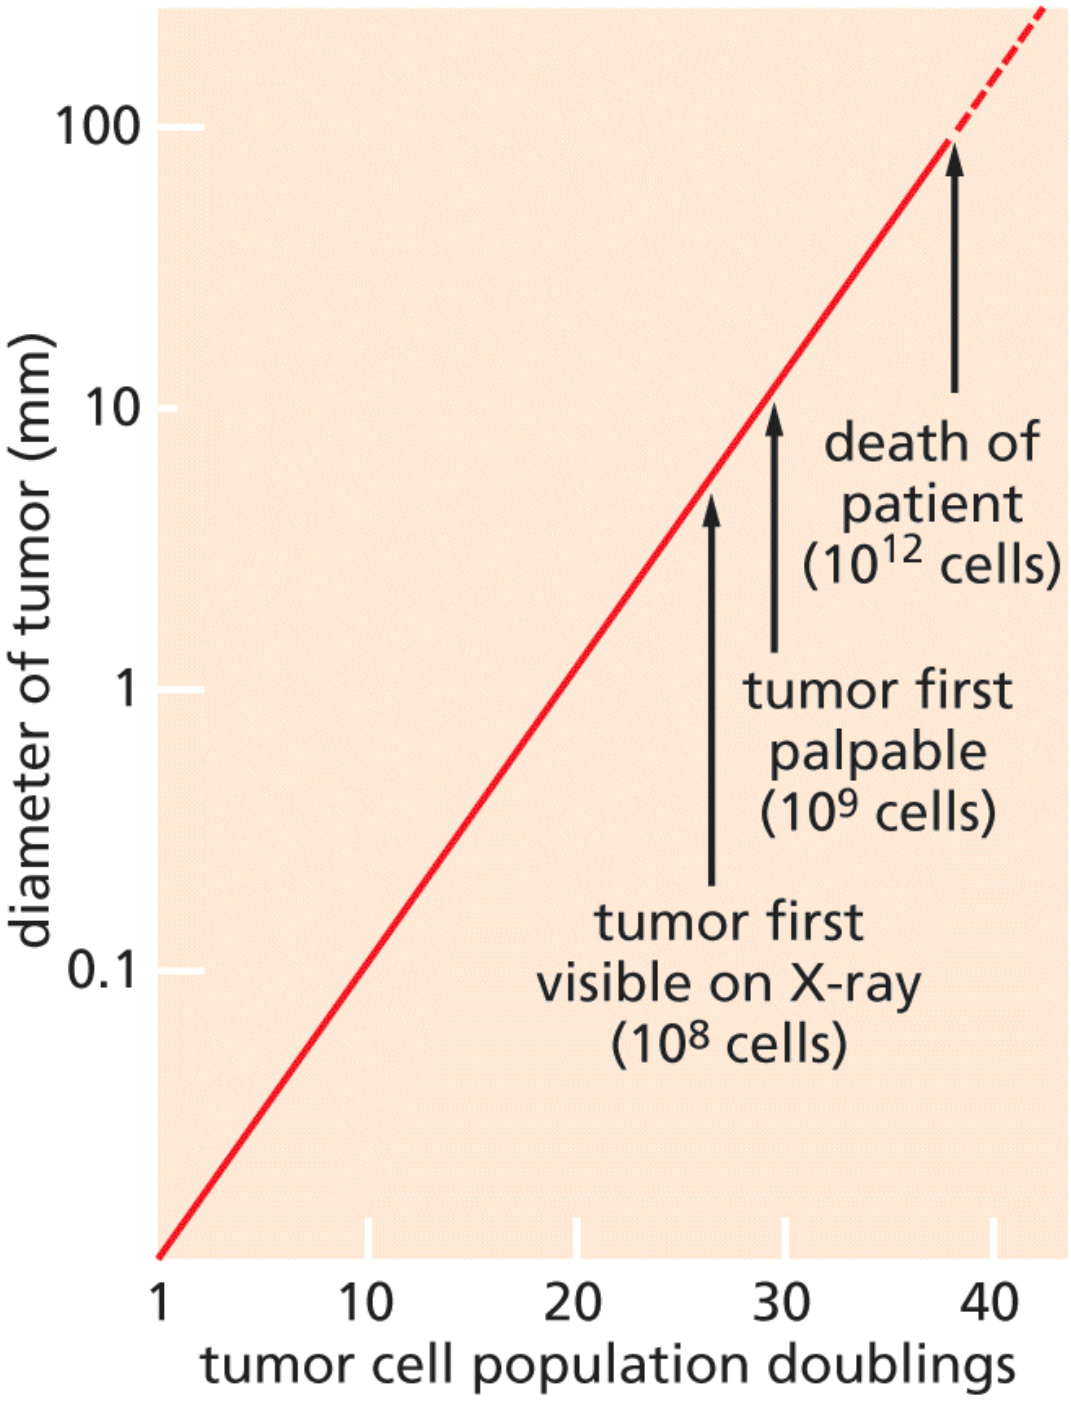
10.3 Cancer cells need to become immortal in order to form tumors

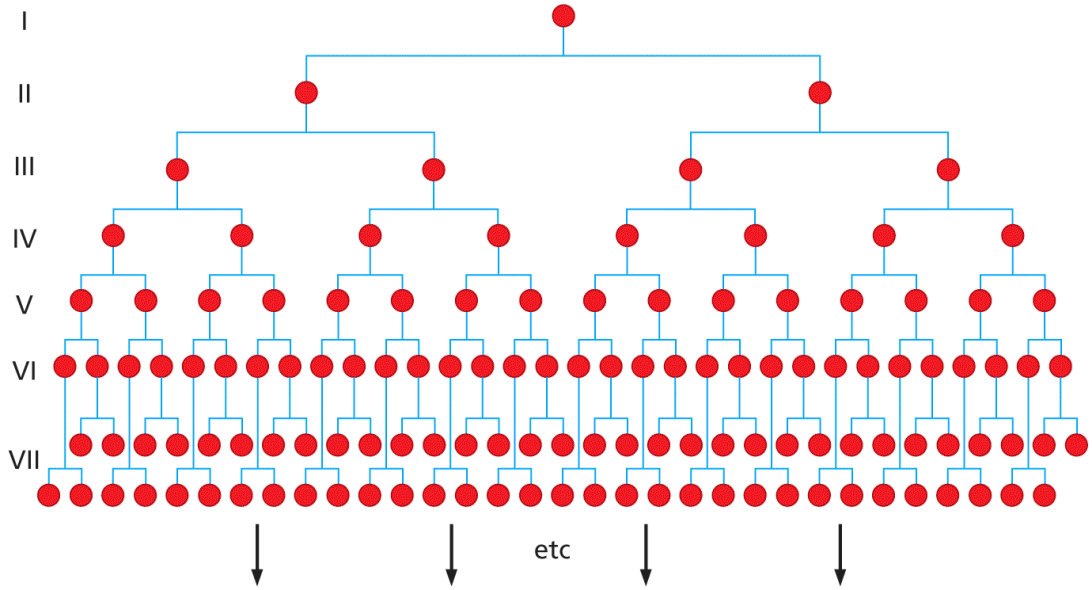
The observation that cancer cells, once adapted to growth in tissue culture, are often found to be immortal strongly suggests that immortalization is an integral component of the cancer cells' transformation to a neoplastic growth state. That is, cancer cells are immortal because they need to be in order to form a tumor. Why, conversely, are lineages of normal cells deprived of immortalized growth properties? Perhaps the body endows its normal cells with only a limited number of replicative generations as an anti-cancer defense mechanism. For example, if one or another cell in the body were to accidentally acquire certain oncogenes and shed critical tumor suppressor genes, its descendants would begin to proliferate uncontrollably, and the population of these tumor cells might well increase exponentially. However, if endowed with only a limited replicative potential, these cells might exhaust their allotment of cell doublings long before they succeeded in forming a life-threatening tumor mass; as a consequence, tumor development would grind to a halt.

The credibility of this model depends on some critical numbers. Specifically, we need to know how many successive cell generations are required to make a clinically detectable human tumor (**Figure 10.4A**) and how many generations are granted to normal cell lineages throughout the body. We know that human tumors are clonal, in the sense that all the neoplastic cells in the tumor mass descend from a common ancestral cell that underwent transformation at one point in time (see Section 2.5). With this fact in mind, we can ask how many cell generations separate the neoplastic cells forming a large human tumor from their common progenitor.



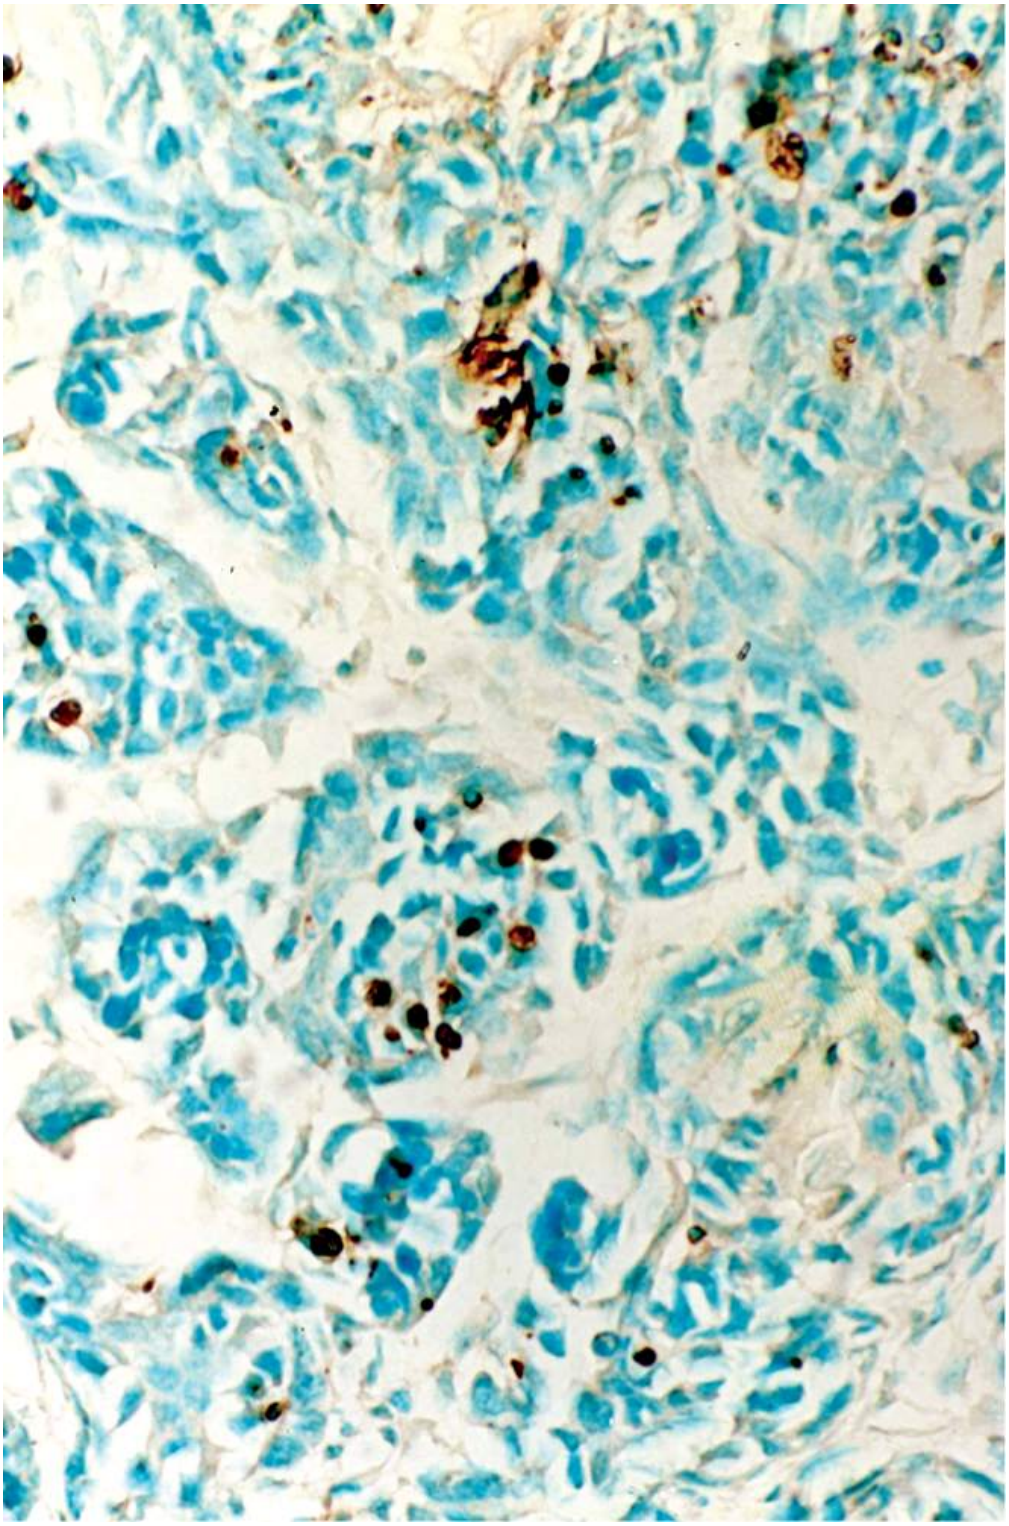
A line graph with tumor cell population doublings on the horizontal axis and tumor diameter in millimeters, logarithmically scaled, on the vertical axis. A straight line runs from 0.01 millimeters after 1 doubling up through 100 millimeters after 40 doublings. Labeled points along the line include tumor first visible on X-ray (10 to the eighth power cells) after 27 doublings, tumor

first palpable (10 to the ninth cells) after 30 doublings, and death of patient (10 to the twelfth cells).
(A)



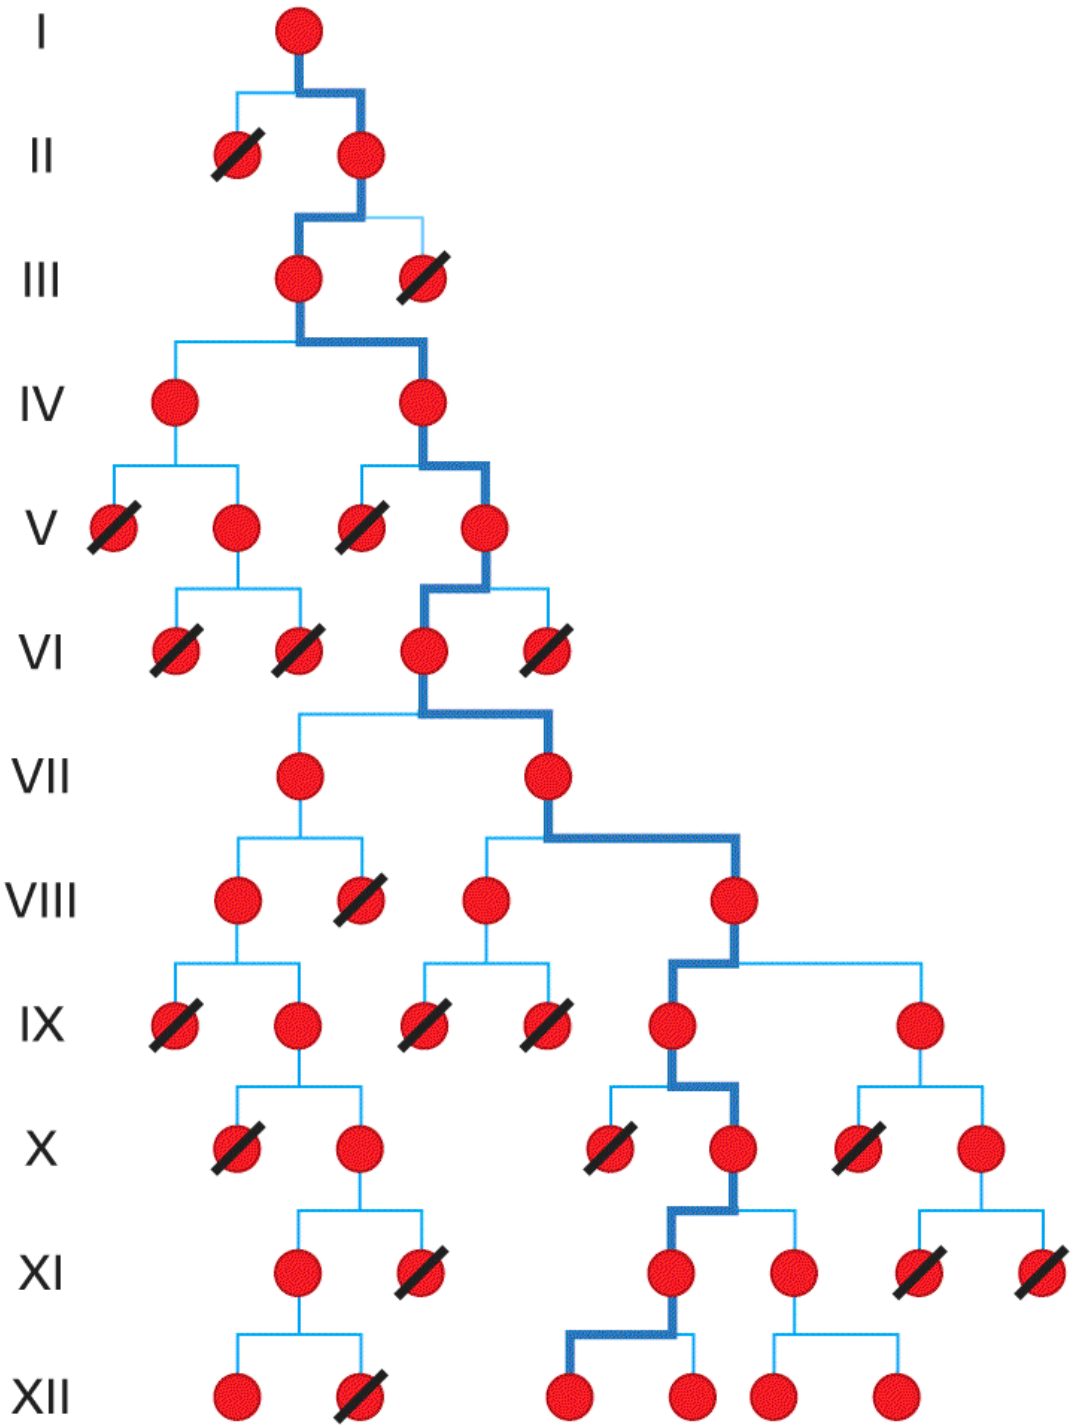
An idealized tree diagram showing successive generations produced by perfect doubling: one cell in generation 1, two cells in generation 2, four cells in generation 3, and so on.

(B)



A histology image in which most of the cells are turquoise blue but a few are coffee brown.

(C)



A realistic tree diagram showing successive generations in which many lines go extinct, so that in generation 12 there are only 5 cells instead of 2 to the eleventh power.

(D)

Figure 10.4 Generations of cells forming a tumor mass (A) The growth of a human tumor—from detectable to palpable to life-threatening size—can be related to the minimum number of cell population doublings of the tumor-associated cancer cells. (B) The plot in panel A assumes that each time the cancer cells in a tumor divide, this cell population as a whole will double in size. (Only six doublings are shown here.) Consequently, the number of successive population doublings theoretically required to generate a lethal tumor from a single founding ancestral cell can be calculated from the graph in panel A to be about 40. (C) In reality, cell populations that are evolving toward the neoplastic state or are already neoplastic experience substantial attrition during each cell generation. This attrition is evident from the apoptotic cells—detected here by the *dark brown* staining of the TUNEL assay (see Figure 9.12)—in a mammary tumor that arose in a mouse carrying an oncogenic *Wnt-1* transgene in its germ line. In fact, this assay greatly underestimates the rate of apoptosis in each cell generation, because apoptotic cells persist only for an hour before they are consumed by neighboring cells and by macrophages. Moreover, cancer cells within a tumor may become senescent and thereby enter irreversibly into a post-mitotic state. (D) The high rate of attrition leads to loss of many cells in each cell generation (*diagonal slashes*). Accordingly, an ancestral founder cell that should have generated 2^{11} descendants leaves instead only five descendants in the 12th generation. The number of successive cell generations required to generate a tumor of life-threatening size is therefore far larger and, in the absence of precise knowledge of attrition rates, incalculable. Also shown is the *lineage* of a cell in the 12th generation (*thick blue line*). (A, from B. Alberts et al., Molecular Biology of the Cell, 6th ed. New York: W.W. Norton, 2015. C, courtesy of L.D. Attardi and T. Jacks.)

The arithmetic works out like this. The volume of a cubic centimeter (cm^3) within a tumor cell mass contains about 10^9 cells, and a life-threatening human tumor has a size, say, of 10^3 cm^3. We can calculate that these 10^{12} cells seem to have arisen following 40 cycles of exponential growth and division (Figure 10.4B)—that is, 40 cell generations separate the founding cell from its descendants in the end-stage, highly aggressive tumor ($10^3 \approx 2^{10}$; hence $10^{12} \approx 2^{40}$).

In fact, some types of normal human cells are known to pass through 50 or 60 cycles of growth and division in culture before they stop growing. According to the arithmetic above, and assuming that these numbers shed light on the proliferative potential of normal cells *in vivo*, these 50 or 60 cell generations of exponential growth are far more than are required in order for a founding cell to spawn enough descendants to constitute a life-threatening tumor mass. Indeed, 60 cell doublings suffice to create a tumor mass of 10^{15} to 10^{18} cells $\approx 10^9$ $cm^3 \approx 10^6$ kilograms. Something is drastically wrong with these numbers!

The error in our calculations lies in a flawed premise: they assume an exponential expansion of populations of cancer cells (see Figure 10.4B). The biological reality of tumor growth is much different. Thus, a number of defense mechanisms built into the body's cells and tissues (for example, see Chapters 7 and 8) make life very difficult for incipient cancer cells, indeed, so difficult that in each cell generation, a significant number of these cells die off (Figure 10.4C). Early in tumor development, the defense mechanisms deployed by the tissues around them include depriving tumor cells of growth factors, of adequate oxygen, and of the ability to eliminate metabolic wastes via the vasculature. Moreover, a number of the anti-tumor cell defense mechanisms operating in the hard-wired regulatory circuitry of cells operate to weed out aberrantly behaving, premalignant cells (as described in Chapter 9). As a consequence of the resulting attrition in each cell generation, the pedigree of cells in a tumor mass actually looks quite different (Figure 10.4D). Many branches of the tree are continually being pruned by the high death rate of tumor cells in each generation.

This ongoing attrition (**Sidebar 10.1**) means that the number of cell generations required to form a tumor mass of a given size is vastly greater than would be predicted by simple exponential growth kinetics. For example, a clonal population of 10^3 tumor cells might be thought, on the basis of its size, to have gone through 10 successive cycles of exponential growth and division since its founding by an ancestral cell; in reality, 20 or 30 or more cell generations may have been required to accumulate this many cells. (Figure 10.4D illustrates as well the *lineage* of a cell in a population of descendant cells.) Yet other calculations provide strong indication of extensive attrition of cells during neoplastic progression (**Sidebar 10.2**).

Sidebar 10.1 A key cause of attrition: a poisonous dose of Ras

A *ras* oncogene has been found to induce cell senescence when introduced into cultured cells by a viral vector, suggesting paradoxically that this potent transforming gene acts more to halt cell proliferation than to foster it. This result on its own created a puzzle, in that it suggested that virtually all cells that acquire a *ras* oncogene by somatic mutation were shunted immediately into the post-mitotic senescent state rather than becoming precursors of vigorously growing tumors.

Some years later, researchers explored these effects by using a different experimental strategy to establish a *ras* oncogene in cells: this strategy relied on activating an endogenous, chromosomal *ras* proto-oncogene in a genetically modified strain of mice (see Sidebar 7.5). This activation could be targeted to a specific tissue and induced by an experimental stimulus. Under these conditions, *ras* activation in the lungs and in the gastrointestinal tract resulted in hyperplasias (rather than senescence). Similar results could be observed in the pancreas and in the myeloid compartment of the bone marrow.

The critical difference here could be traced to how the *ras* oncogene was being expressed: in the earlier *in vitro* experiments, its expression was driven by a highly active transcriptional promoter present within a recombinant viral vector (see **Supplementary Sidebar 3.9**), whereas in the later mouse experiments, the oncogene was present in single copy number per cell and was being driven by its own native transcriptional promoter. This later experimental strategy recapitulated the state of cells that have acquired a *ras* oncogene through the process of point mutation. Hence, the critical difference came from the *level* of expression, which suggested that *ras* oncogenes created by somatic mutations can "fly under the radar" of the surveillance system that is designed to immediately weed out mutant, potentially neoplastic cells through the induction of senescence.

Interestingly, as tumor progression proceeded in the lung cancer model, the *ras* oncogene, initially present in single copy number in premalignant lung adenomas, underwent amplification. Prior to this time, the presence or absence of a functional *p53* gene had little if any effect on these early-stage lung adenomas; however, once the *ras* oncogene underwent amplification, elimination of p53 function became critical to permit the survival and continued expansion of the cells in the resulting, more aggressive adenocarcinomas. (Such p53 inactivation ostensibly allowed the evolving tumor cells to avoid the senescence that would otherwise be provoked by higher levels of Ras signaling; the elevated levels of Ras oncoprotein, for its part, appeared to provide these cells with increased mitogenic stimulation and thus enhanced proliferation.) Of note, this mouse model of lung cancer development reflects the behavior of many human tumors, in which mutant *ras* oncogenes undergo amplification as tumor progression proceeds. As the sixteenth-century alchemist Paracelsus put it, "the dose makes the poison."

Sidebar 10.2 Ongoing attrition makes the numbers add up

The profound effects of continual cell attrition are highlighted by observations of the genomes of the carcinoma cells forming human colorectal primary carcinomas and metastases. By measuring the frequency of randomly acquired point mutations present throughout these genomes, which accumulate at a predictable rate per cell generation together with other metrics of cumulative successive cell generations, investigators have estimated that in some of these tumors, many hundreds of cell generations intervene between the founding neoplastic cell and those cells present in a surgically resected tumor. In the absence of frequent, ongoing attrition, the founding cell would have spawned, as an example, $\sim 2^{500} = \sim 10^{150}$ cells, and such cells would weigh, in aggregate, ~1012 kilograms =~10 billion times the weight of a (large) human body.

These revised calculations provide credible support for the notion that the human body endows its cell lineages with only a limited number of growth-and-division cycles in order to protect itself against the development of tumors. For example, if cell populations must pass through a succession of 100 replicative generations in order to form a clinically detectable human tumor, it is plausible that most incipient tumor cell populations will exhaust their normal allotment of 50 or 60 cell divisions long before they succeed in creating such a mass.

Having accepted, at least for the moment, this argument and its conclusions, we are now left with some major puzzles: How can normal cells throughout the body possibly remember their replicative history? And how can aspiring cancer cells erase the memory of this history and acquire the ability to proliferate indefinitely, or at least as long as is required to form a macroscopic, clinically detectable tumor?

A solution to the problem of replicative history must, sooner or later, be spelled out in terms of the actions of specific molecules within cells. Whatever its nature, the solution is hardly an obvious one. Organisms as complex as humans possess no innate biological clock for counting the number of (organismic) generations that separate each of us from ancestors who lived 100 or 1000 years ago. When we humans wish to learn the number of these generations over extended periods of time, we usually hire genealogists to chart them for us. No biological counting device inside our bodies can provide us with such answers. How, then, can far simpler biological entities—individual human cells—keep track of their generations?

In addition, this generational counting mechanism is likely to be, in the language of developmental biologists, cell-autonomous; that is, it must be intrinsic to a cell and not influenced by the ongoing interactions of the cell with its neighbors and with the body as a whole. Recall the contrasting situation of oncogenes and tumor suppressor genes. The products of most of these genes perturb the pathways responsible for processing the signals received by cells from their surroundings—*non-cell-autonomous* processes. Finally, the hypothesized generation-counting device must be relatively stable biochemically, because it needs to store a record of the past history of a cell lineage in a form that survives over extended periods of time, often many decades.

In principle, the counting processes of this “generational clock” (which measures elapsed cell generations rather than elapsed time) might depend on the concentrations of some intracellular molecule that (1) is synthesized early in development and not thereafter, (2) is present in high concentrations in the embryonic cells that are the ancestors to various lineages, and (3) undergoes progressive dilution by a factor of 2 each time a cell in the lineage divides. Senescence might then be triggered after the levels of this compound fall below some threshold level. Though plausible to mathematicians, this arrangement cannot work in the real world of biology.

Biochemistry dictates that no molecule can be present in a cell over a concentration range of 2^{50} or 2^{60}.

This realization forced researchers to look elsewhere for the molecular embodiments of the generational clock. They came upon two regulatory mechanisms that govern the replicative capacity of cells growing *in vitro* and possibly *in vivo*. The first of these appears to measure the cumulative physiological stress that lineages of cells experience over extended periods of time and halts further proliferation once that damage exceeds a certain threshold; this yields the senescence discussed above (see Section 10.1).

The second regulator measures how many replicative generations a cell lineage has passed through and sounds an even more drastic alarm once the allowed quota has been used up; this alarm leads to the state termed crisis, which results in the apoptotic death of almost all cells in a population in culture. Crisis, as discussed below, represents a process and mechanism that can operate to constrain cell proliferation and abort the formation of tumors and, in other settings, paradoxically fosters tumor progression.

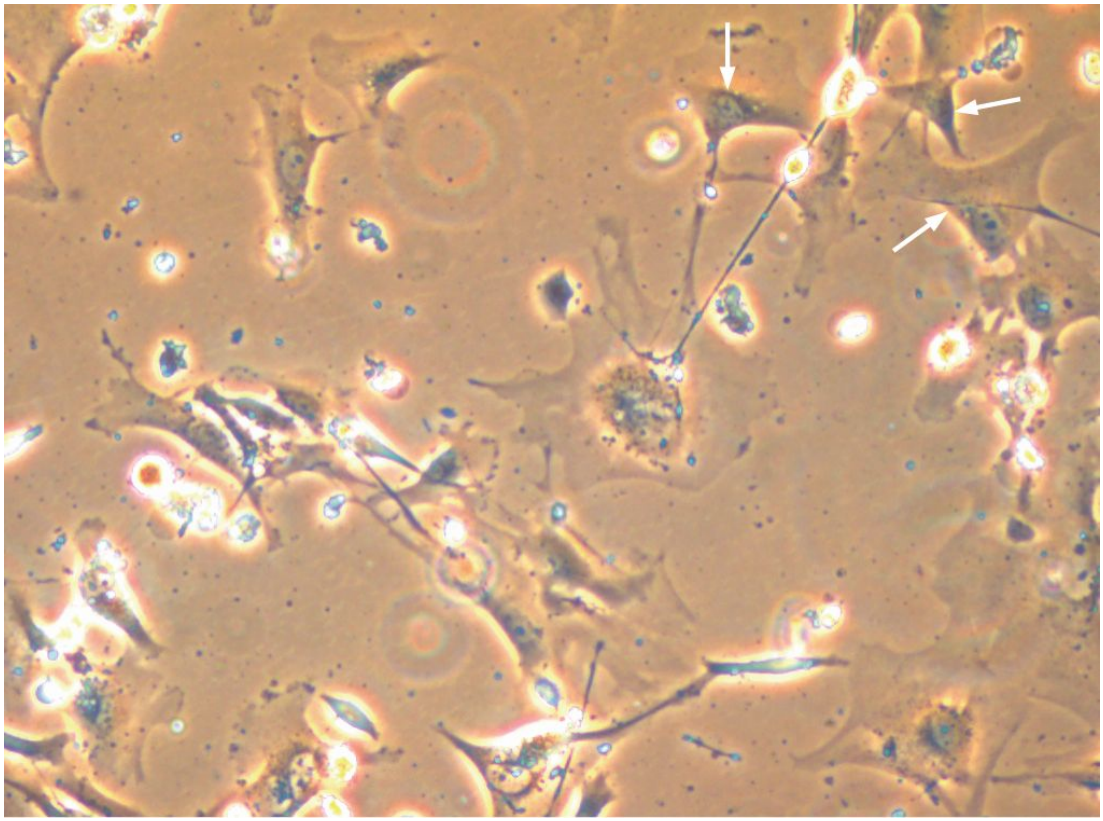
Glossary

cell-autonomous
: Referring to a trait or behavior of a cell that is governed by its own genome and internal physiology and not by its ongoing interactions with other cells and its tissue microenvironment.

OceanofPDF.com

10.4 The proliferation of cultured cells is also limited by the telomeres of their chromosomes

Primary cells, as mentioned above, confront two obstacles to their continued long-term proliferation in culture. The first of these is entrance into a state of replicative senescence and the second, subsequent one involves crisis. To contrast the two, senescence represents a halt in cell proliferation with retention of cell viability over extended periods of time, whereas crisis involves death by apoptosis (see Section 9.13; **Figure 10.5**). Senescent cells seem to have a reasonably (but not totally) stable karyotype, whereas cells in crisis show widespread karyotypic disarray. Moreover, experimental evidence indicates clearly that senescence is more than a tissue culture artifact, but instead operates in a variety of biological states *in vivo* to limit or circumscribe further cell proliferation (see Section 9.). In the case of human embryonic kidney (HEK) cells propagated *in vitro*, expression of the SV40 large T oncoprotein enables bypass of the first hurdle—senescence (see Figure 10.3)—but it will fail, on its own, to immortalize these cells. Thus, after an additional number of cell generations—sometimes 10 to 20—beyond the time when they would usually senesce, cell populations enter into crisis and exhibit widespread apoptosis. The SV40 large T antigen, even with its potent p53-inactivating ability, clearly does not protect against the apoptotic death associated with crisis.



A microscope photo with dark, irregular patches, identified by arrows as normal cells, and bright round flecks, which represent fragments of disintegrated cells.

Figure 10.5 Apoptosis associated with cell populations in crisis Cell populations in crisis show widespread apoptosis, with a high percentage of cells in the midst of disintegrating and numerous cell fragments (*white refractile spots*). Because populations of cells enter into crisis asynchronously, some of the cells in such populations still appear relatively normal (*arrows, top right*). (Courtesy of S.A. Stewart.)

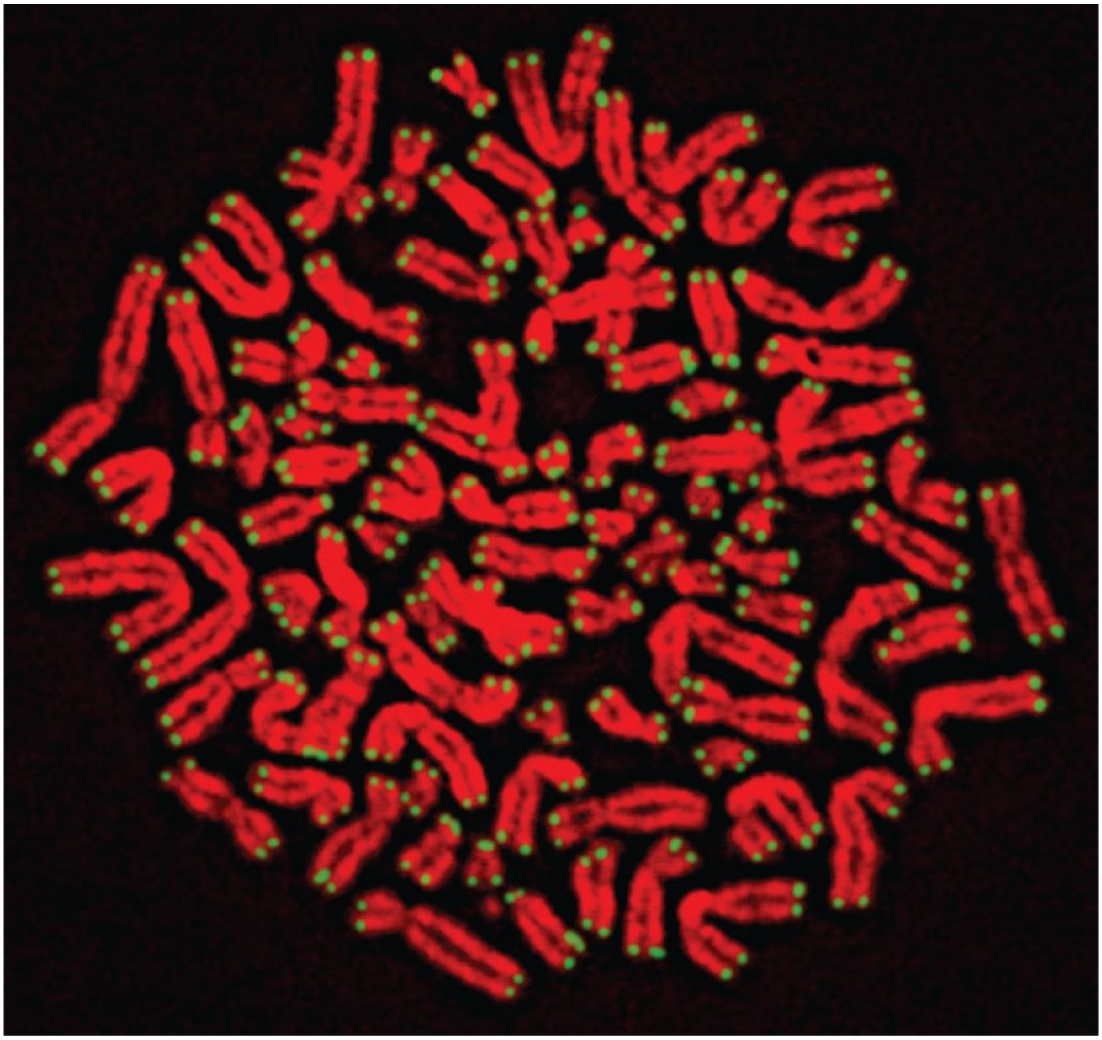
The timing of crisis and the appearance of cells in crisis suggest the involvement of a second mechanism, one operating independently of the mechanisms triggering senescence described above. The workings of this second mechanism have been traced back to the chromosomal DNA of cells. Unlike the mechanisms leading to senescence, the molecular apparatus that initiates crisis is truly a functional counting device that tallies how many successive growth-and-division cycles cell lineages have passed through since their founding in the early embryo.

At first glance, the chromosomal DNA would seem to be an unlikely site for mammalian cells to construct such a “generational clock.” We know that the structure

of chromosomal DNA is highly stable and therefore should be unchanged from one cell generation to the next. A generational clock, in contrast, must depend on some progressive molecular change that is noted and recorded during each cell generation. How can chromosomal DNA molecules, which seem to be so immutable, register an additional cell generation each time a cell passes through a growth-and-division cycle?

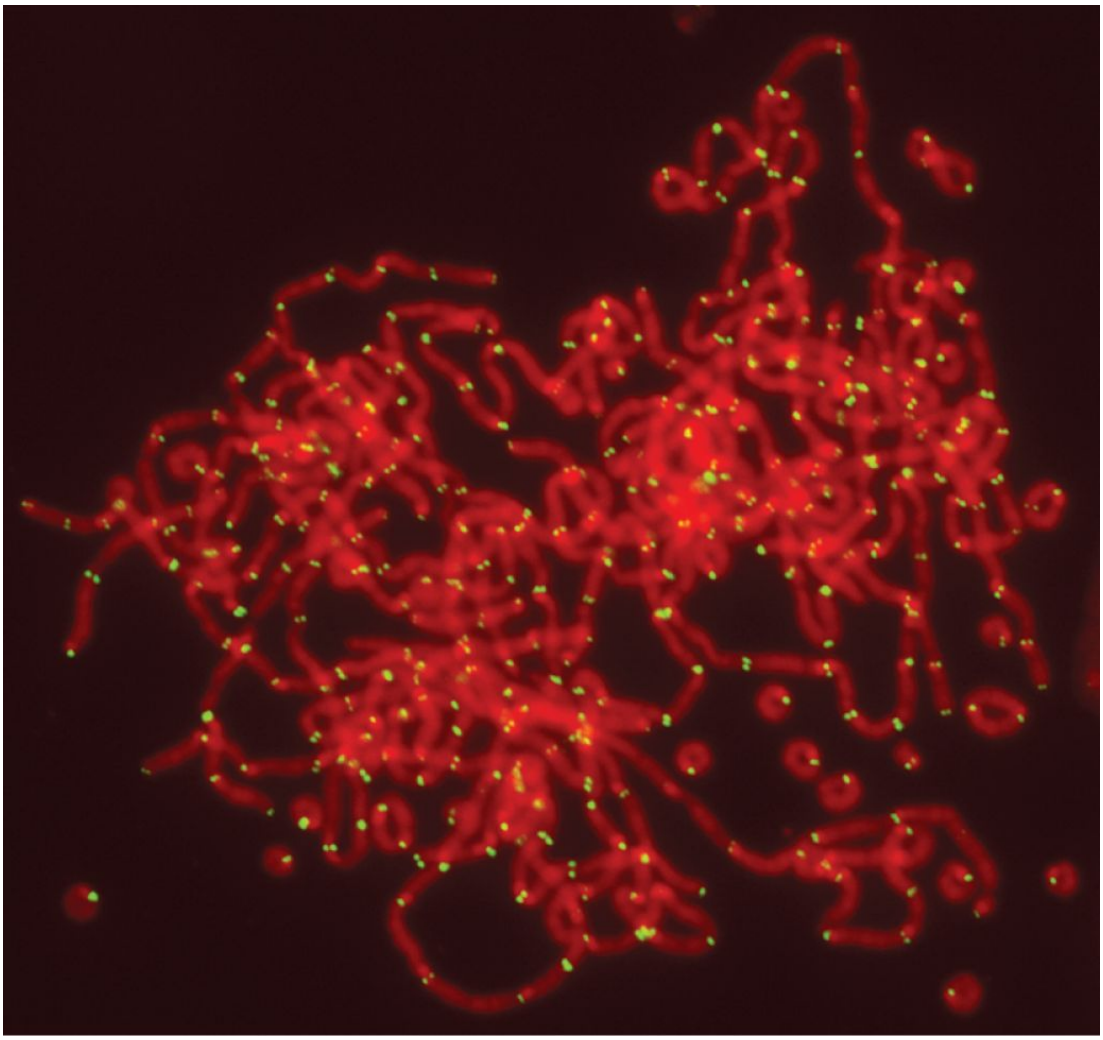
The key lies in the structure of chromosomal DNA: each mammalian chromosome carries a single, extremely long DNA molecule (ranging from ~247 mb for Chromosome 1 to ~47 mb for Chromosome 21). As it turns out, the two ends of this linear DNA molecule create a serious problem for the cell—a problem dramatically revealed by the experimental technique of DNA transfection (see Section 4.1). After entering cells, transfected linear DNA molecules are rapidly fused end-to-end through the actions of a variety of nucleases and DNA ligases that are active in most if not all mammalian cell types. Hence, linear DNA molecules are intrinsically unstable in our cells, yet the linear DNA molecules forming the backbones of chromosomes clearly persist.

The telomeres located at the ends of the chromosomes (**Figure 10.6**) explain how these linear DNA molecules can stably coexist with the cell's various DNA-modifying enzymes. Telomeres act to prevent the end-to-end fusion of chromosomal DNA molecules and, hence, the fusion of chromosomes with one another. In effect, telomeres serve as protective shields for the chromosomal ends, much like the aglets safeguarding the tips of shoelaces. As we will see, the catastrophic events of crisis are triggered when cells lose functional telomeres from their chromosomes.



A fluorescence microscopy image in which a large number of condensed human chromosomes appear in red, each with four green ends.

(A)



A fluorescence microscopy image with a single, massive strand of chromosomal D N A appearing in red. Pairs of green dots appear at many points along its length.

(B)

Figure 10.6 Telomeres detected by fluorescence *in situ* hybridization
Telomeres can be detected by the technique of fluorescence *in situ* hybridization (FISH), in which a DNA probe that recognizes the repeated sequence present in telomeric DNA is coupled with a fluorescent label. (A) In this micrograph, human cells have been trapped in metaphase using a microtubule antagonist. The telomeres of the resulting condensed chromosomes (*red*) are then visualized through a probe that labels the telomeric DNA (*yellow green dots*). Each chromatid carries telomeres at both its ends. Because these cells are in metaphase, the paired, recently replicated chromatids have not yet separated. (B) The karyotype seen in panel A can be compared with that of cells that have been

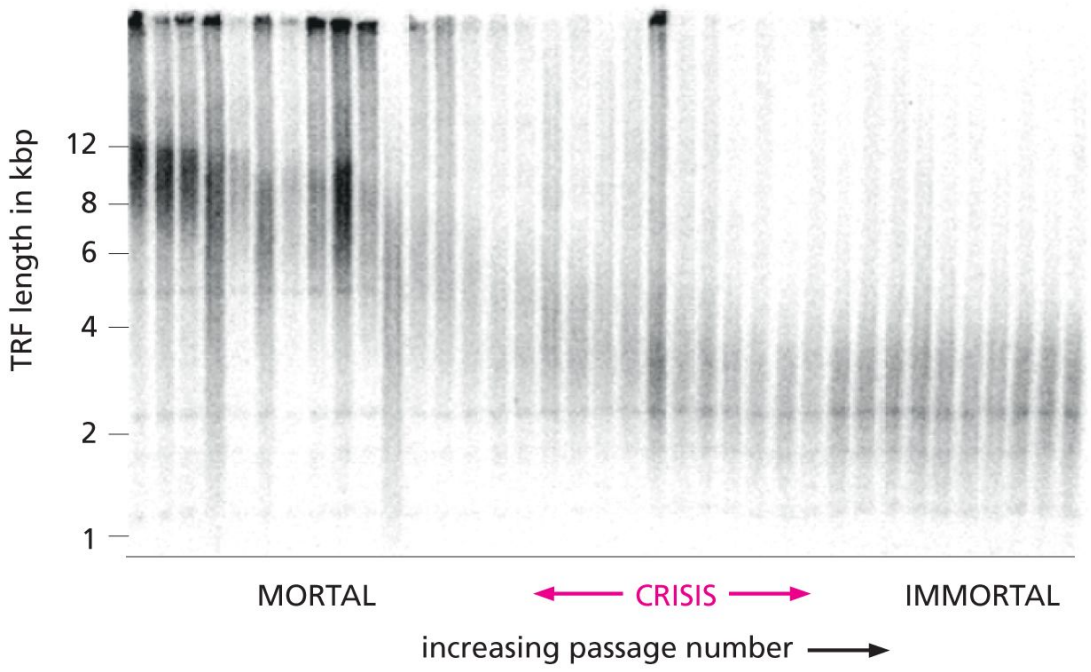
deprived of TRF2, a key protein in maintaining normal telomere structure (see Sidebar 10.4). In these cells, the telomeres lose their protective function (although telomeric DNA remains), resulting in dozens of end-to-end fusions involving all of the chromosomes in a cell and yielding one huge chromosome. (A, courtesy of J. Karlseder and T. de Lange. B, from G.B. Celli and T. de Lange, *Nat. Cell Biol.* 7:712–718, 2005. With permission from Nature.)

Discoveries reported in 1941 by Barbara McClintock (**Figure 10.7**) concerning her studies of the chromosomes of corn first revealed that chromosomes that have lost functional telomeres at their ends soon fuse, end-to-end, with one another. The resulting megachromosomes possess two or more centromeres, the specialized chromosomal structures that become attached during mitosis to the fibers of the mitotic spindle. An extreme form of this fusion is shown in Figure 10.6B, in which virtually all the chromosomes of a cell have fused into one giant chromosome after they all have been deprived of functional telomeres.

A black and white photo of Barbara McClintock, examining a lab sample. A large microscope sits to her left.

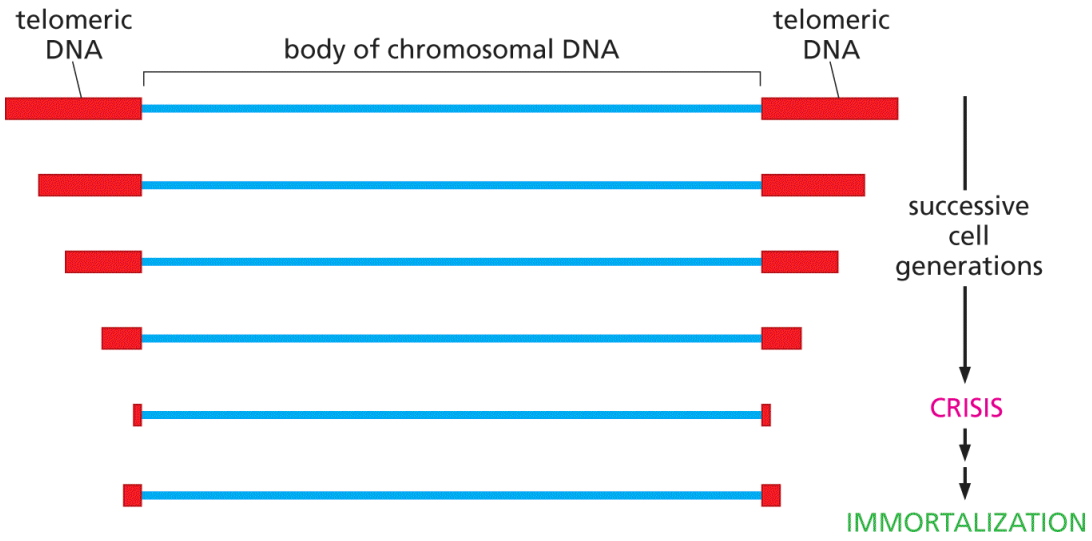
Figure 10.7 Barbara McClintock Barbara McClintock's detailed studies of the chromosomes of corn (maize) revealed specialized structures at the ends of chromosomes—the telomeres—that protected them from end-to-end fusions. This work, and her demonstration of movable genetic elements in the corn genome, later called transposons, earned her the Nobel Prize in Physiology or Medicine in 1983. (Courtesy of American Philosophical Society.)

As discussed in greater detail below, the DNA component of each telomere in our cells is composed of the 5′-TTAGGG-3′ hexanucleotide sequence, which is tandemly repeated thousands of times; these repeated sequences, together with associated proteins, form the functional telomere. The telomeric DNA (and thus the telomeres) of normal human cells proliferating in culture shorten progressively during each growth-and-division cycle, doing so until they become so short that they can no longer effectively protect the ends of chromosomes (**Figure 10.8**). At this point, crisis occurs, chromosomal DNA ends fuse with one another, and widespread apoptotic death is observable. Hence, in such cells, it is *telomere shortening* that functions to register the number of cell generations through which cell populations have passed since their origin in the early embryo.



An image shows the results of passaging a culture of human lymphocytes. Increasing passage number is on the horizontal axis, transitioning from mortal on the left, through crisis, to immortal on the right. T R F length in kilobase pairs is on the vertical axis. The predominant T R K length is initially 8 to 12

kilobase pairs but during crisis shortens to 3 kilobase pairs, after which it stabilizes at about 2 and a half kilobase pairs.
(A)



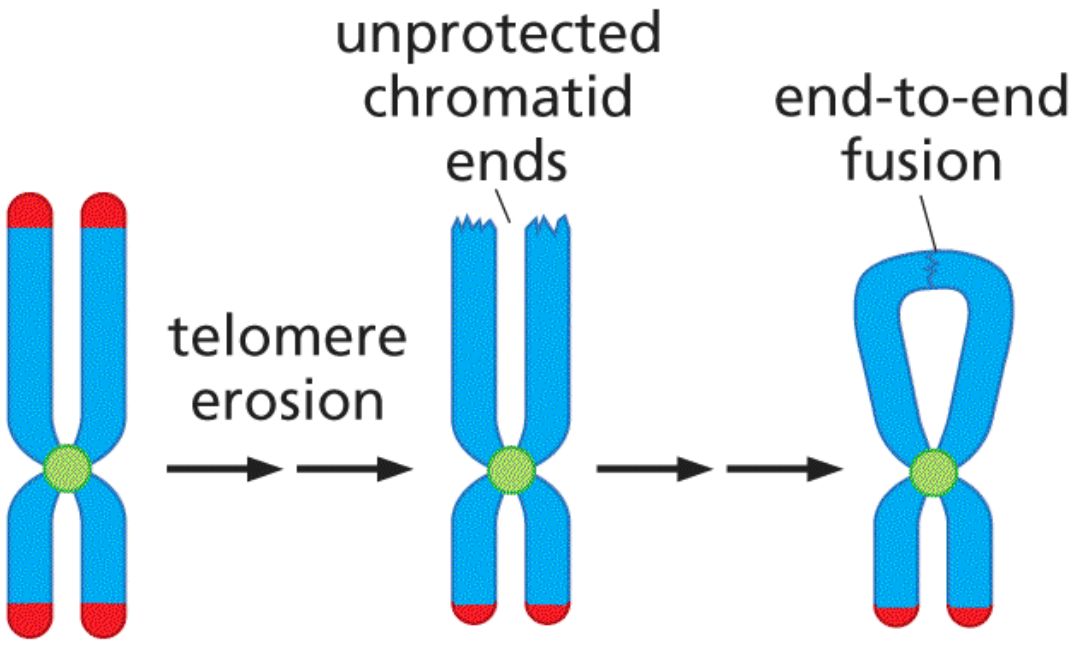
A schematic depiction of what happens to telomeres over successive generations. A chromosome has a long body of chromosomal D N A in the middle and a segment of telomeric D N A at each end. Over successive cell generations, the telomeric segmentss shorten, until during crisis they have nearly disappeared. But then in immortalization they become slightly longer.

(B)

Figure 10.8 Shortening of telomeric DNA in concert with cell proliferation (A) Here, a culture of human lymphocytes that had circumvented culture-induced senescence following infection by Epstein–Barr virus was passaged, and a portion of each culture was set aside for analysis of the cells' telomeric DNA. Each passage represented three to six population doublings. The length of telomeres was measured by treating genomic DNA with several restriction enzymes that do not cleave within the repeating TTAGGG sequence that constitutes telomeric DNA but do cleave frequently throughout the rest of the chromosomal DNA. The only high–molecular-weight genomic fragments such treatment leaves behind are the telomeric restriction fragments (TRFs). Their lengths can then be determined by gel electrophoresis followed by Southern blotting analysis using a probe that recognizes the TTAGGG sequence. Because the telomeres within a given cell vary in length and the extent of telomeric DNA shortening differs from one cell to another, the size distribution of telomeric DNA in each sample is heterogeneous. In the analysis shown, the TRFs of mortal (i.e., non-immortalized) human lymphocytes grew shorter with every successive passaging by 50 to 100 bp per

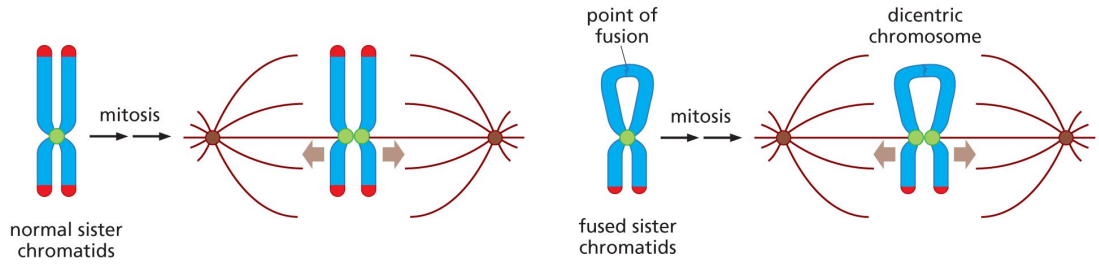
cell generation. When the TRFs became less than about 3 kbp long, cells entered crisis. Later, when cells emerged spontaneously from crisis (and became immortalized), they maintained their telomeric DNA at slightly longer sizes than those seen in crisis. (B) Such observations have led to the model shown, in which telomeric DNA (*red*) shortens progressively each time a cell passes through a growth-and-division cycle until the telomeres are so eroded that they can no longer protect the ends of chromosomal DNA. This telomere collapse provokes a cell to enter into crisis. [In fact, the TRFs of panel A include both pure TTAGGG repeats at the terminus of each telomere and long stretches of TTAGGG-like sequences located at the internal (centromeric) end of each telomere; the latter may not be functional in protecting the chromosomal ends. Telomeres may lose their protective function when their regions of pure TTAGGG repeats have eroded down to a length of ~12 repeats.] In most tumors, crisis is ended when cells acquire the expression of hTERT, resulting in slightly longer telomeres that succeed in protecting the ends of the telomeres and thus of the chromosomal DNA. Note that this drawing is not to scale: telomeric DNA is usually 5 to 10 kbp long, whereas the body of chromosomal DNA (*blue*) is tens to hundreds of megabase pairs (Mbp) long. (A, from C.M. Counter et al., *J. Virol*. 68:3410–3414, 1994. With permission of American Society for Microbiology.)

In human cells entering crisis, the initial end-to-end fusion events often occur between the eroded telomeric ends of the two sister chromatids that form the two halves of the same chromosome (**Figure 10.9A**). Recall that paired chromatids exist during the G_2 phase of the cell cycle—a period after S phase has created two chromatids from a parental chromosome and before M phase, when these two sister chromatids are destined to be separated from one another (see Figure 8.3). Such fusions between the ends of sister chromatids (rather than between the ends of two unrelated chromosomes) are favored for at least two reasons. First, the two chromatids, and thus their ends, are held in close proximity through their joined centromeres. Second, for unknown reasons, telomeres shorten at different rates on different chromosomal arms. Consequently, the two homologous telomeric DNAs (for example, the pair of telomeres at the ends of the long arms of the chromatids of human Chromosome 9), having just been generated anew by DNA replication, possess virtually identical molecular structures. Therefore, if the telomeric end of one chromatid has become shortened, frayed, and vulnerable to fusion, its counterpart on the other paired chromatid is likely to be in the same state.



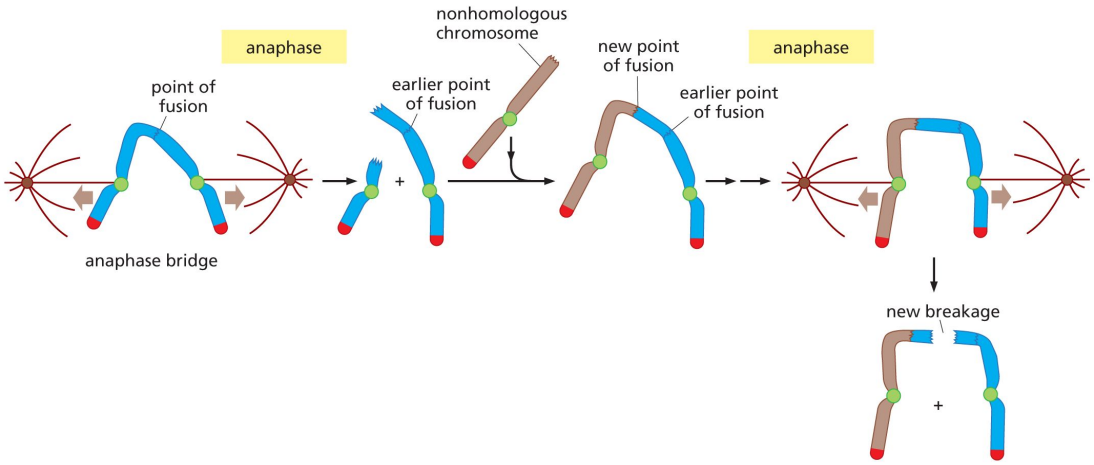
An X-shaped chromosome with two long ends and two short ends. Telomere erosion shortens the telomeres on the short ends and completely removes the telomeres on the long ends, which then fuse to each other, joining the sister chromatids end-to-end.

(A)



A normal chromosome and a fused one each undergoing mitosis and the mitotic spindle attaching.

(B)



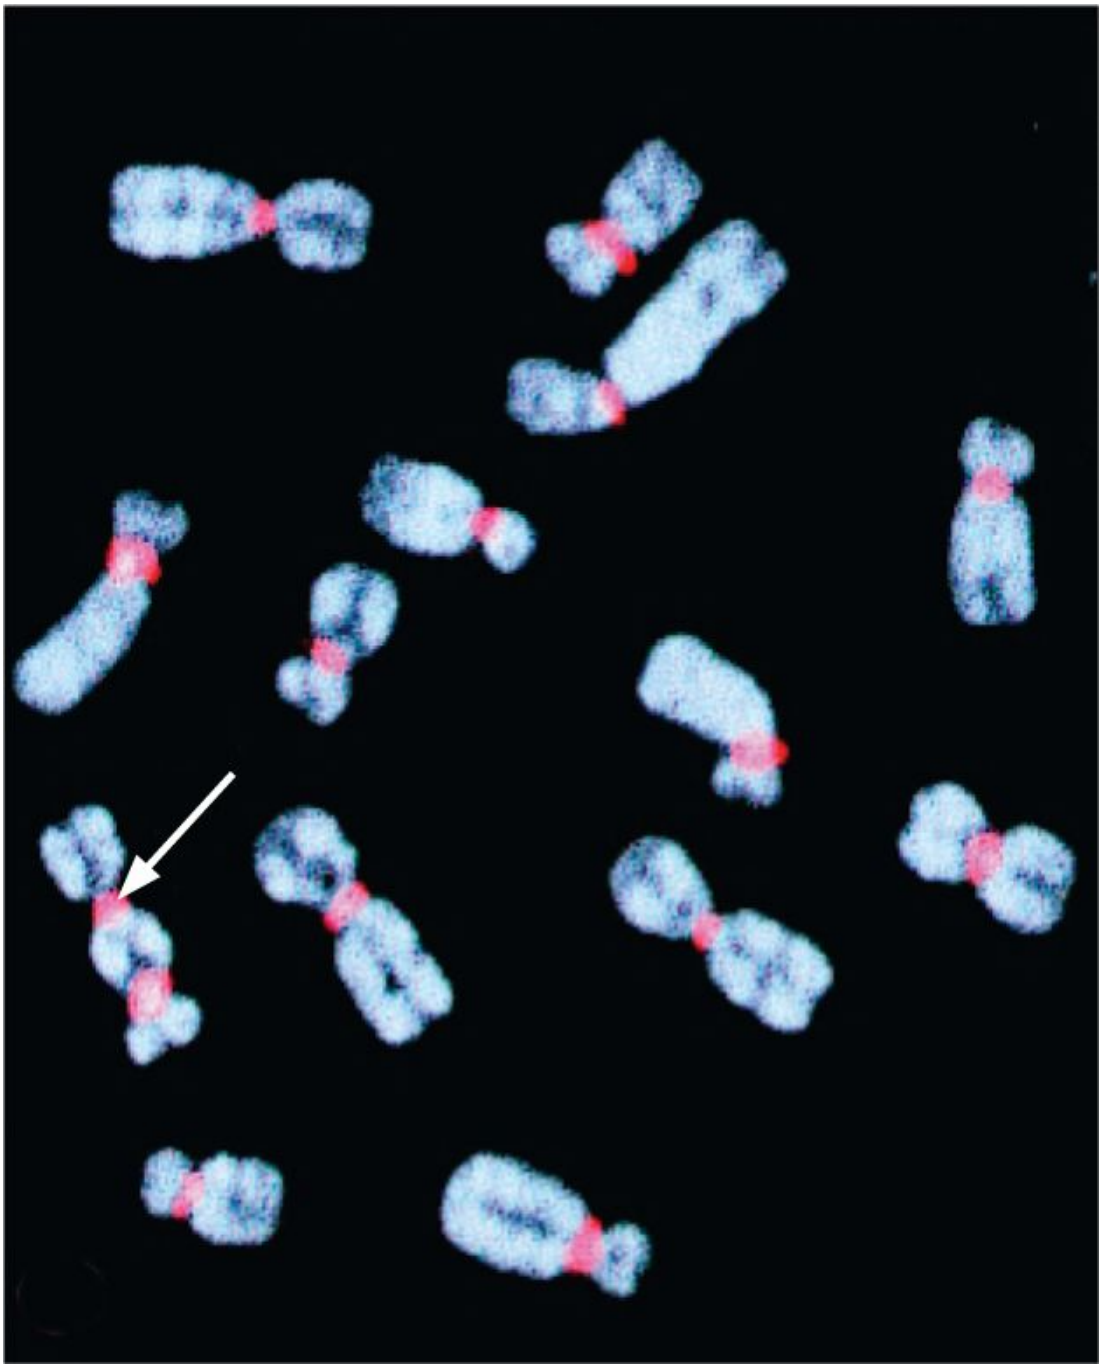
A diagram shows what happens to the fused, dicentric chromosome during anaphase. When the centromere is pulled apart, the chromosome forms an anaphase bridge. When this bridge then tears in two at a point different from the original fusion point, the opportunity arises for another, nonhomologous chromosome with a broken end of its own to fuse to one of the original fragments, forming a new bridge. Eventually there will be yet another breakage at a new point, distinct from the first two fusion points.

(C)

Figure 10.9 Mechanisms of breakage–fusion–bridge cycles (A) Chromosomal breakage, fusion, and bridge formation occur when telomeres (*red*) have become too short to protect the ends of chromosomal DNA. Pictured here is the configuration of a chromosome in the G_2 phase of the cell cycle. During this phase of the cell cycle, its two chromatids remain attached to one another by their shared centromere (*green*). (In fact, it is the multi-subunit centromere-associated protein complex known as the kinetochore, *not shown*, that associates with the centromeric DNA and is responsible during the G_2 phase for holding the two chromatids together and during mitosis for binding the chromosome to microtubules of the mitotic spindle.) As shown, the telomeres on the long arms of this *blue* chromosome have eroded before those of the short arms. Both ends of the long arms are equally eroded since they have recently been duplicated during the previous S phase. The ends of these two arms, held in close proximity by the shared centromere, now fuse with one another, leading to a *dicentric* chromatid, which contains two telomeres and two half-centromeres. (B) During a normal mitosis (*left*), the two sister chromatids will be pulled apart to opposite centrosomes located at the two polar ends of the mitotic spindle (*left*). Likewise, the mitotic spindle will pull the centromeres (*green*) of a dicentric chromosome in opposite directions, unaware that these two chromatids are joined via their long arms. (C) Unlike normally configured chromatid pairs, which will separate cleanly

and segregate in groups near the two centrosomes, the dicentric chromosome described in (B) will be unable to do so and will instead create a temporary bridge between the two poles of the mitotic spindle during the anaphase of mitosis, explaining the term anaphase bridge. Eventually, the dicentric chromosome will be ripped apart at some weak point. During the next cell cycle, the larger fragment lacking a telomere at one end (*blue*) may fuse with another atelomeric chromosome (*beige*), creating a new dicentric chromosome, which itself will be pulled apart during a subsequent mitosis, resulting once again in a breakage–fusion–bridge cycle. (The fate of the shorter chromatid fragment generated by the first cycle of breakage is not shown.)

When these fused chromatids participate in the mitosis that follows, their two centromeres will be pulled in opposite directions by the mitotic spindle (Figure 10.9B), creating the dramatic *anaphase bridges* that are often seen following extensive telomere erosion (**Figure 10.10**). Sooner or later, the mitotic apparatus that is pulling on such a dicentric chromatid (that is, one with two centromeres) will succeed in ripping it apart at some random site between the two centromeres (Figure 10.9C). This yields two new chromosomal ends, neither of which possesses a telomere. Such unprotected ends may fuse with one another or with the unprotected ends of other, nonhomologous chromosomal DNA molecules. (In the event that a dicentric chromosome is not actually ripped apart during anaphase, the nuclei formed during the ensuing telophase will be joined by the anaphase bridges seen in Figure 10.10.)

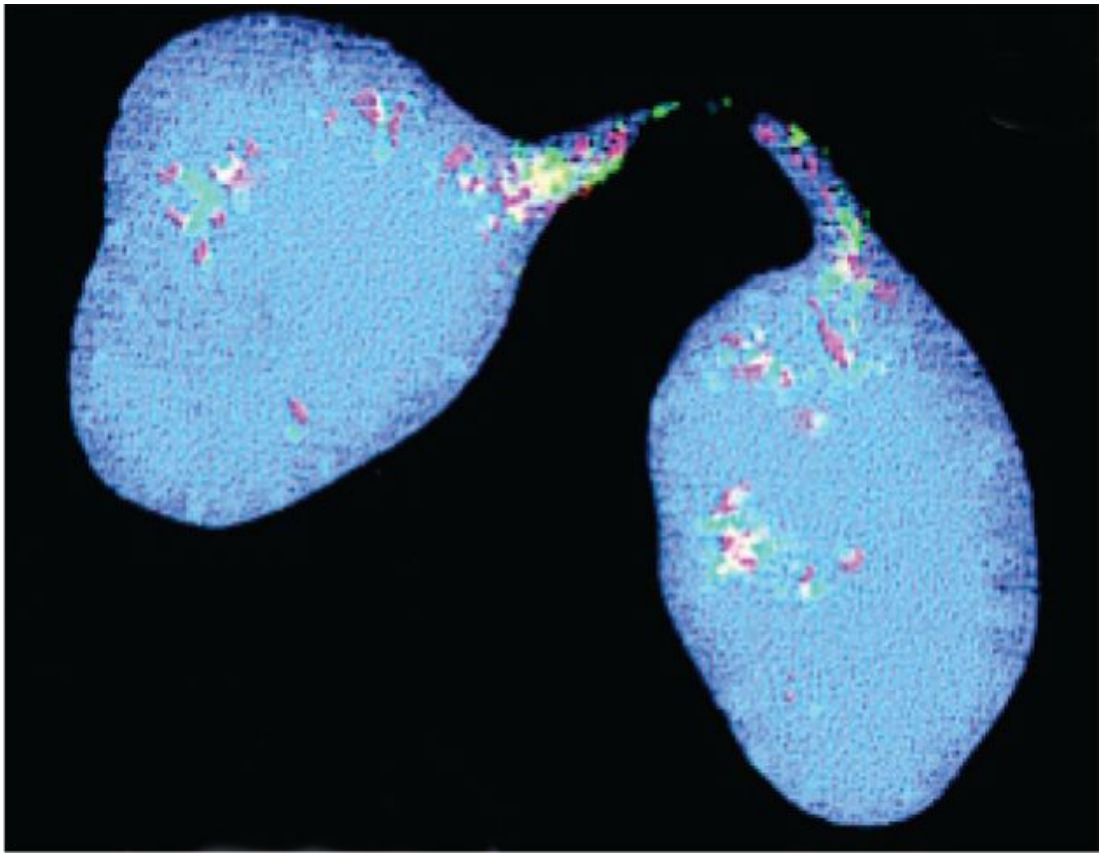


14 chromosomes in metaphase, with the centromeres stained pink. One chromosome has two centromeres, which join the chromatids at two different points.

(A)

Two masses of chromosomes shown as dark bundles, one above and one below, connected by several chromosome bridges.

(B)



Two nuclei connected by a thin bridge.

(C)

Figure 10.10 Dicentric chromosomes, anaphase bridges, and internuclear bridges (A) A dicentric chromosome is seen (*white arrow*) in a metaphase spread of cells from a human pancreatic carcinoma cell line. Centromeric regions have been stained *pink*. (B) Such dicentric chromosomes often result in the formation of anaphase bridges, several of which are seen in a cell of a human malignant fibrous histiocytoma. The two opposing groups of chromosomes are unable to separate properly from one another because they are still connected by multiple anaphase bridges. Observation of such anaphase bridges provides strong evidence that chromosomes within such cells are participating in breakage–fusion–bridge cycles because they no longer possess adequate telomeres. (C) Although most anaphase bridges are broken during telophase or cytokinesis, some may persist in the resulting interphase cells, causing, for example, the nuclei of two daughter cells *(light blue)* of a human lipomatous tumor cell to be linked by a chromatin bridge. (From D. Gisselsson et al., *Proc. Natl. Acad. Sci. USA* 97:5357–5362, 2000. With permission of National Academy of Sciences, U.S.A.)

In the event that the resulting defective, nontelomeric end of a chromosome fuses with the end of an unrelated (nonhomologous) chromosome, the fate of the resulting new, dicentric chromatid during the next mitosis is more ambiguous (see Figure 10.9C). Half of the time, on average, the two centromeres will be pulled in the same direction toward the centrosome that nucleates one of the two soon-to-be-born daughter cells, and no breakage will occur. The other half of the time, the two centromeres of a dicentric chromatid will become attached to the two opposing spindle bodies, as shown, and thus to the two centrosomes located at opposite sides of the mitotic cell (see Figure 10.9C). When chromatids are separated during the anaphase of mitosis, this second configuration (like the earlier one between sister chromatids) will once again prove to be disastrous because it will involve the tearing apart of a chromatid and the generation of ends that are, as before, unprotected by telomeres.

These newly created chromosomal ends will once again attempt to fuse with yet other chromosomes, yielding more dicentric chromosomes and a new cycle of chromosome breakage. This sequence of events is termed the *breakage–fusion–bridge* (BFB) *cycle* because it involves the initial *breakage* of dicentric chromatids in anaphase, the subsequent *fusion* of the resulting atelomeric DNA ends with yet other chromatids, and the formation once again of anaphase bridges by the new dicentric chromosomes resulting from these fusions (see Figure 10.10). While they are occurring, these BFB cycles create karyotypic chaos that has the potential to affect many chromosomes within a cell, as proposed in 1941 by McClintock.

Cells that have entered crisis provide a clear indication that the molecular machinery triggering crisis resides in the telomeres because those cells show precisely the type of karyotypic disarray that is observed when chromosomes lose their telomeres. Moreover, the chromosomes that are fusing within these cells possess especially short telomeres, or none at all. Note that the karyotypic instability occurring during crisis, which has been termed “genetic catastrophe,” is so severe that apoptosis often occurs even in the absence of p53 function.

Glossary

ligase
: An enzyme that covalently joins two molecules together; in the context of DNA, ligases join the 3′ end of one ssDNA to the 5′ end of another other via a phosphodiester linkage.

telomere
: Nucleoprotein structure at the end of a eukaryotic chromosome that protects this end from degradation and from fusion with the ends of other chromosomes.

centromere
: Region of a chromosome that holds the two chromatids together and that binds, via a kinetochore, with mitotic or meiotic spindle fibers.

dicentric
: Referring to a chromosome or chromatid that bears two distinct centromeres.

atelomeric
: Lacking a telomere.

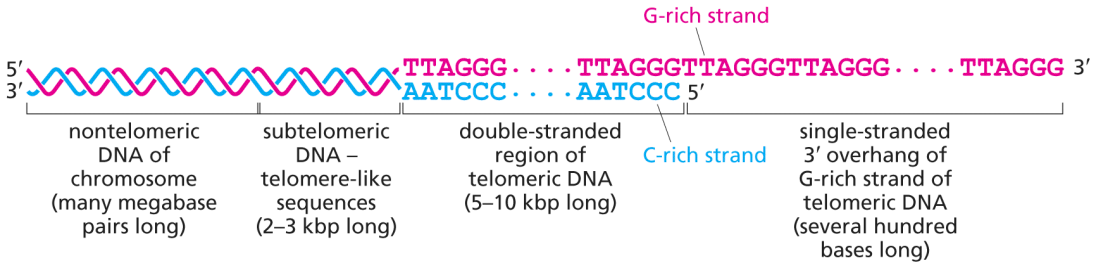
10.5 Telomeres are complex molecular structures that are not easily replicated

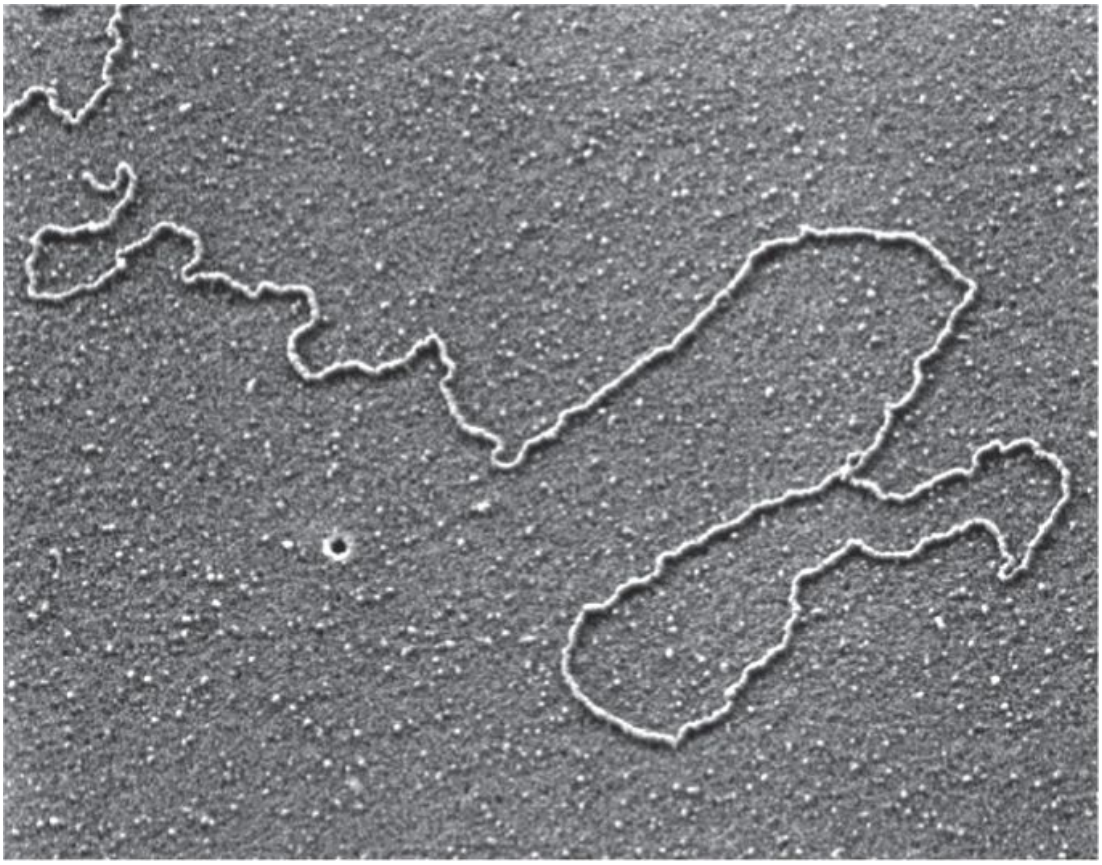
Research conducted since the mid-1980s has revealed the molecular structure of telomeres and their DNA. To begin, and as cited earlier, the telomeric DNA of mammalian cells (as well as the cells of many other metazoa) is formed from the repeating hexanucleotide sequence 5′-TTAGGG-3′ in one strand (the “G-rich” strand) and the complementary 5′-CCCTAA-3′ in the other (the “C-rich” strand). In normal human cells, telomeric DNA is formed from several thousand of these hexanucleotide sequences, resulting in 5- to 15-kbp-long stretches of such repeating sequences at the ends of all human chromosomes.

The telomeric DNA of mammalian cells, and possibly the cells of all higher eukaryotes (metazoa and metaphyta), possesses an additional, distinctive feature: its G-rich strand is longer than its C-rich strand by one hundred to several hundred nucleotides, resulting in a long 3′ single-strand overhang (**Figure 10.11A**). This overhanging strand is often found in a most unusual molecular configuration termed the t-loop. It was discovered in the late 1990s, when electron microscopy showed the ends of telomeric DNA to be configured in a loop, in effect a lariat (Figure 10.11B). This structure has been interpreted to depend on the formation of a three-stranded complex of DNA (Figure 10.11C). The t-loop may be present at the ends of all telomeres, although it has been observed in only a subset of those viewed, probably because of the technical difficulties associated with preserving and visualizing this structure in the electron microscope. The t-loop clearly helps to protect the ends of linear DNA molecules, because the end of the single-stranded overhanging region is tucked into a double-stranded region, out of harm’s way.



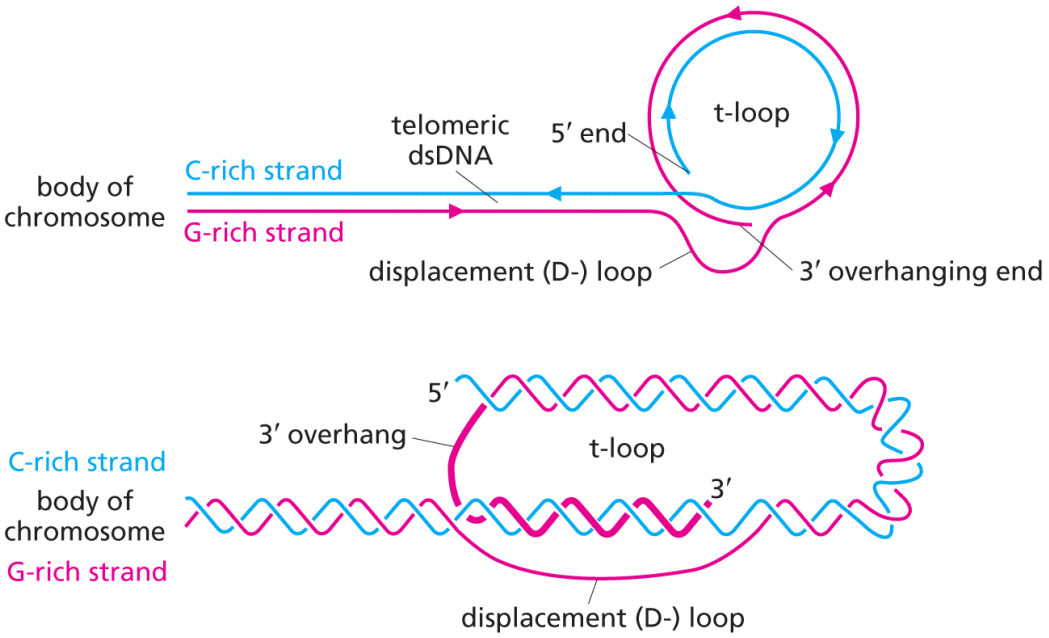
A D N A molecule, with one strand in red and the other in blue. At the left end, the red 5 prime and blue 3 prime ends align. This is the start of a region

of nontelomeric D N A of chromosome that is many megabase pairs long. Then comes a region of subtelomeric D N A–telomere-like sequences that is 2 to 3 kilobase pairs long. The double strand ends with a region of telomeric DNA that is 5 to 10 kilobase pairs long. The blue 5 prime side of this region is C rich. The red 3 prime region is G rich and continues past the 5 prime end as single-stranded overhang of G-rich telomeric D N A for another several hundred base pairs.
(A)



An electron micrograph of a piece of D N A in the form of a lasso, with a large loop at one end.

(B)



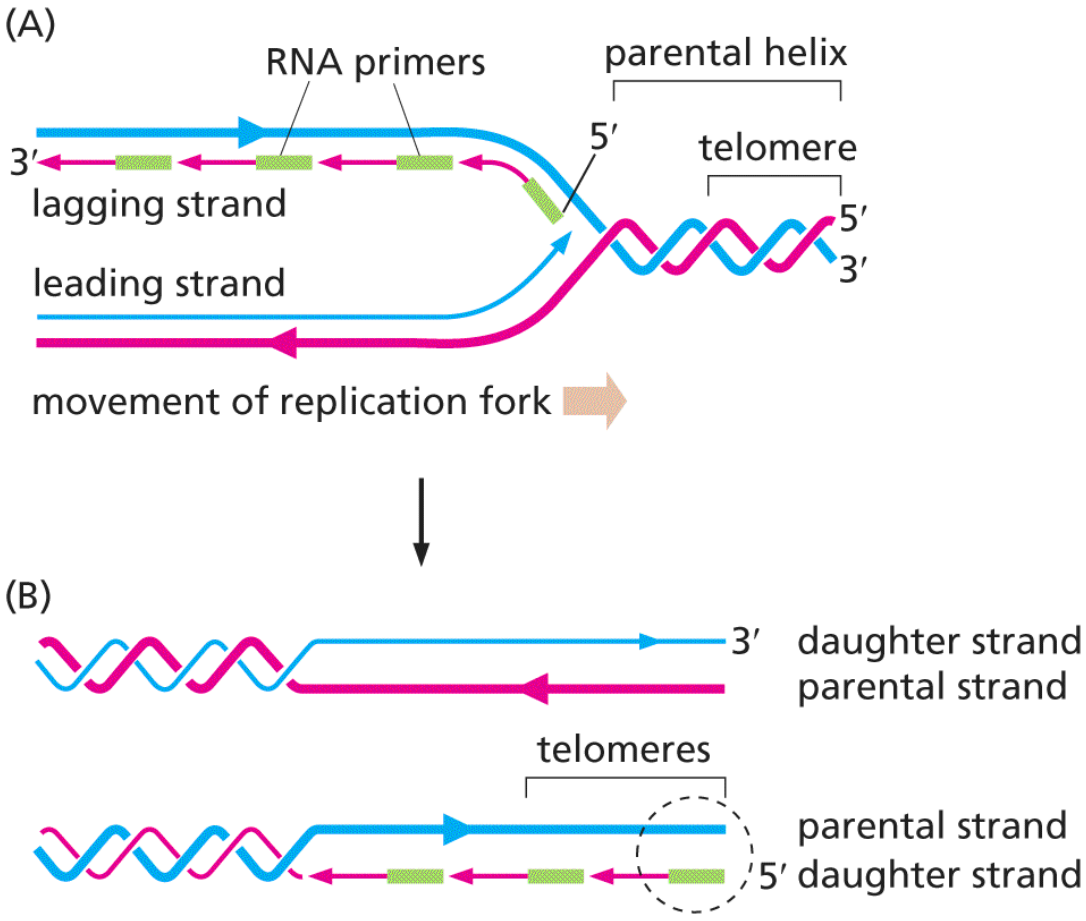
Two diagrams show, first very schematically and then in more detail, how the lasso-like t loop is formed when the 3 prime overhanging end displaces an earlier section of the same G rich strand in attaching the C rich strand. The displaced section of G rich strand is called the D-loop.

(C)

Figure 10.11 The 3′ overhang of telomeric DNA and the t-loop (A) The G-rich strand of telomeric DNA (*pink*) extends beyond the C-rich strand (*blue*). This creates a 3′ overhang (*right*) that is often several hundred nucleotides long. This overhang is far shorter than the double-stranded portion of telomeric DNA (*middle*), which is often 5 to 10 kbp long and is not drawn to scale. In addition, a subtelomeric region of DNA lies between the functional telomeric DNA (*middle*) and the nontelomeric chromosomal DNA (*far left*). This subtelomeric DNA contains imperfect copies of the TTAGGG sequence and does not function to protect the end of the chromosome. However, it is usually included in the telomere restriction fragments (TRFs; see Figure 10.8A) because of its telomere-like sequence content. (B) Purification of telomeric DNA from mouse cells (following stabilization of double-stranded structures through chemical cross-linking) reveals, upon electron microscopy, lariats, called *t-loops*, at the ends of chromosomal DNA. (C) The t-loop is illustrated with the double helices drawn and the 3′ overhanging end emphasized in a *heavier pink line*. Although this figure depicts the t-loop as being formed by the overhanging end of one of the two strands, there is evidence that the other strand can also occasionally form t-loops. (B, from J.D. Griffith et al., *Cell* 97:503–514, 1999. With permission from Elsevier.)

Both the relatively long double-stranded telomeric DNA and the short overhanging end are bound by specific proteins. As might be expected, some of the proteins possess domains that specifically recognize and bind to the hexanucleotide sequence present in the double- and the single-stranded regions of telomeric DNA (**Supplementary Sidebar 10.4**). Together, these telomere-binding proteins, yet other associated proteins that remain to be identified, and the telomeric DNA form the nucleoprotein complexes that function as telomeres.

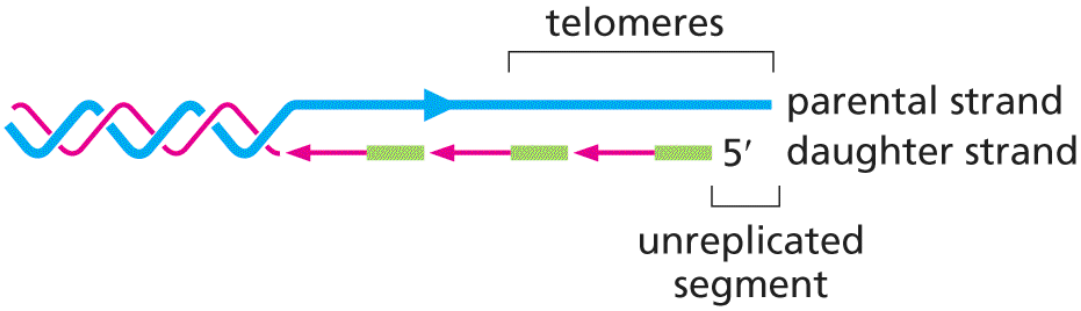
Although the replication machinery that operates during the S phase of the cell cycle is highly effective at copying the sequences in the middle of linear DNA molecules, such as those in the body of each of our chromosomes, this machinery has great difficulty faithfully copying sequences at the very ends of these molecules. The difficulty can be traced to the requirement that the synthesis of all DNA strands during DNA replication must be initiated at the 3′-hydroxyl end of an existing DNA or RNA strand, which serves as a primer to nucleate DNA strand elongation; alternatively, in the absence of an available DNA primer, the 3′ end of a short RNA molecule, can serve as a primer for DNA synthesis (**Figure 10.12**).



A double-stranded D N A is unwound on the left end and wound on the right end, where the last end segment is labeled telomere. The two strands of the parental helix are a red strand with its 5 prime end on the right and a blue strand with its 3 prime end on the right. On the left, replication is proceeding by the creation of two daughter strands. A blue daughter strand, labeled the leading strand, is being replicated directly and continuously off the red parent strand. At the time same time, a red daughter strand, labeled lagging strand, is being replicated of the blue parent strand, but this is being done in short segments, each with an R N A primer at the right end, the 5 prime end of the daughter segment.

The replication process is nearing completion. The parental helix is completely unwound, on the left the two parent-daughter pairs have wound together, and on the right the replication of the daughter strands has arrived at the telomere.

(C)



The effects of underreplication in the lagging daughter strand, the one where R N A primers were involved. A short, final segment of the parental strand has no corresponding segment on the daughter strand.

Figure 10.12 Primers and the initiation of DNA synthesis (A) During normal DNA replication, the parental DNA double-helix (*right*) is unwound by a helicase enzyme (*not shown*), creating two template strands (*left*) and allowing the replication process as a whole to progress in a rightward direction (*light brown arrow*). Elongation of the *leading* daughter strand (*thin blue line*) can occur continuously, because its 5′-to-3′ synthesis proceeds in the same direction as the replication fork. In contrast, synthesis of the new *lagging* daughter strand (*thin pink line*) proceeds in a direction opposite to that of the progress of the replication fork, because DNA strand synthesis must occur in a 5′-to-3′ direction. This necessitates the involvement of short RNA primer segments (*green segments*) that are laid down at intervals of several hundred nucleotides by the *primase* enzyme. The 3′-hydroxyl ends of these short RNA primers serve as sites of initiation of

newly made daughter-strand segments, which are termed Okazaki fragments prior to the removal of the RNA primers, the filling in by DNA polymerases of the resulting gaps, and the joining of these fragments by a DNA ligase (*not shown*). (B) For these reasons, the leading-strand synthesis (*thin blue line, above)* will proceed all the way to the end of the telomere (*right*) and thereby generate a faithful copy of the telomeric DNA sequences in one of the two new daughter helices. However, the lagging-strand synthesis (*thin red line, below*) will require an RNA primer near the end of the telomeric DNA (*circled*). (C) Because this RNA primer will subsequently be removed and because it may not be deposited precisely at the end of the parental template strand *(thick blue line)*, sequences complementary to the 3′ end of the parental strand will not be present in the ultimately synthesized DNA molecule. Consequently, there is under-replication of the parental strand of DNA and loss of a limited stretch of telomeric DNA sequences from the chromosome of a daughter cell. (In addition, certain exonucleases degrade this specific stretch of DNA, compounding the effects of the under-replication.) The 5′-to-3′ orientation of each strand is indicated by the arrowheads. The parental DNA strands are drawn more thickly than the newly synthesized daughter strands.

If the primase enzyme, which is responsible for laying down short RNA primers, happens to deposit a primer at some distance from the 3′ terminus of a template strand on which “lagging-strand synthesis” is occurring (see Figure 10.12), a DNA polymerase will initiate synthesis of a new DNA strand that lacks a substantial number of the bases complementary to the very 3′ end of this template strand. (Even if the primase sits down and constructs an RNA primer at the very end of the template strand, the sequences corresponding to the approximately 10 nucleotides of the RNA primer will not be present in the newly synthesized daughter strand, because the RNA primer will be degraded after it has served its purpose of initiating DNA strand elongation.) The end result is that the nucleotide sequences at the very tip of one of the two template strands of DNA will not be properly replicated.

This end-replication problem provides a molecular explanation for the observed shortening of telomeric DNA each time a normal human cell passes through a cell cycle. In addition to the under-replication of telomeric DNA ends, there are exonucleases within cells that chew on the ends of telomeric DNA in order to maintain the t-loops described above and are likely to contribute significantly to telomere erosion. For whatever reason, in many types of normal human cells, telomeres lose 50 to 100 bp of DNA during each cell generation (see Figure 10.8). This progressive erosion of telomeric DNA represents a simple molecular device that limits how many generations of descendant progeny a cell can spawn and solves the problems, enumerated in Section 10.3, of how to construct a stable, long-lived generation-counting device.

We can imagine, for example, that in human embryonic cells, the telomeric DNA begins rather long, perhaps 8 to 10 kb in length. As various lineages of descendant cells throughout the developing body proceed through their repeated cycles of growth and division, the telomeres in these cells grow progressively shorter. Ultimately, in some cells, the telomeric DNA erodes down to a size that is so short that it can no longer perform its intended function of protecting the ends of the chromosomal DNA, the result being the breakage–fusion–bridge cycles and chromosomal translocations that are illustrated in Figure 10.9. Indeed, it is plausible that the aging of certain tissues derives from the loss by individual cells of replicative potential, and that this loss is attributable, in turn, to telomere erosion.

Although the supporting evidence is still indirect, it is highly likely that telomere shortening, by limiting the replicative potential of cell lineages, creates an obstacle to the accumulation of large populations of cancer cells. Thus, as argued earlier, should a clone of cells acquire oncogenic mutations (involving oncogene activation and tumor suppressor gene inactivation), the ability of this clone to expand to a large, clinically detectable size is likely to be constrained by its eroded telomeres.

OceanofPDF.com

Glossary

t-loop
: Lasso-like structure at the end of a telomere that serves to protect the termini of a chromosomal DNA molecule from end-to-end fusions and degradation by exonucleases.

primer
: A DNA or RNA molecule whose 3′ end serves as the initiation point of DNA synthesis by a DNA polymerase.

primase
: An enzyme that initiates DNA synthesis by laying down a short RNA segment on the template strand; the 3′-hydroxyl end of this RNA primer then serves as the site for attachment of the initial deoxyribonucleotide by a DNA polymerase. *See also* **primer**.

end-replication problem
: Inability of the main DNA replication machinery to completely copy the end of one of two DNA strands being replicated, specifically the strand bearing a 3’ nucleotide at its end.

10.6 Incipient cancer cells can escape crisis by expressing telomerase

The detailed behavior of pre-neoplastic cell clones *in vivo* is difficult to study, and so we are largely forced to extrapolate from observations of cultured cells, such as human fibroblasts. As mentioned earlier, if these cells are allowed to circumvent senescence through the expression of the SV40 large T oncoprotein, they will continue to replicate another 10 to 20 cell generations and then enter crisis. On rare occasion, a small group of cells will emerge spontaneously from the vast throng of cells in the midst of crisis. These variant cell clones—arising perhaps from a single cell among 10 million cells in crisis—proceed to proliferate and continue to do so indefinitely (for example, see Figure 10.8A). They have become immortalized, seemingly as the consequence of some random event.

This transition, observed with cultured cells *in vitro*, seems to recapitulate the behavior of premalignant cell populations *in vivo*. Thus, both cell populations enter crisis sooner or later, having passed through large numbers of replicative generations and suffered extensive erosion of their telomeres. Both are capable of spawning rare immortalized variants that have apparently solved the problem of telomere collapse, but how?

At first glance, telomere collapse and crisis would appear to be irreversible processes from which cells can never escape. As it turns out, the route to immortality is simple and, in retrospect, obvious: cells can emerge from crisis by regenerating their telomeres, thereby erasing the molecular record (their shortened telomeres) that previously blocked their proliferation and drove them into crisis.

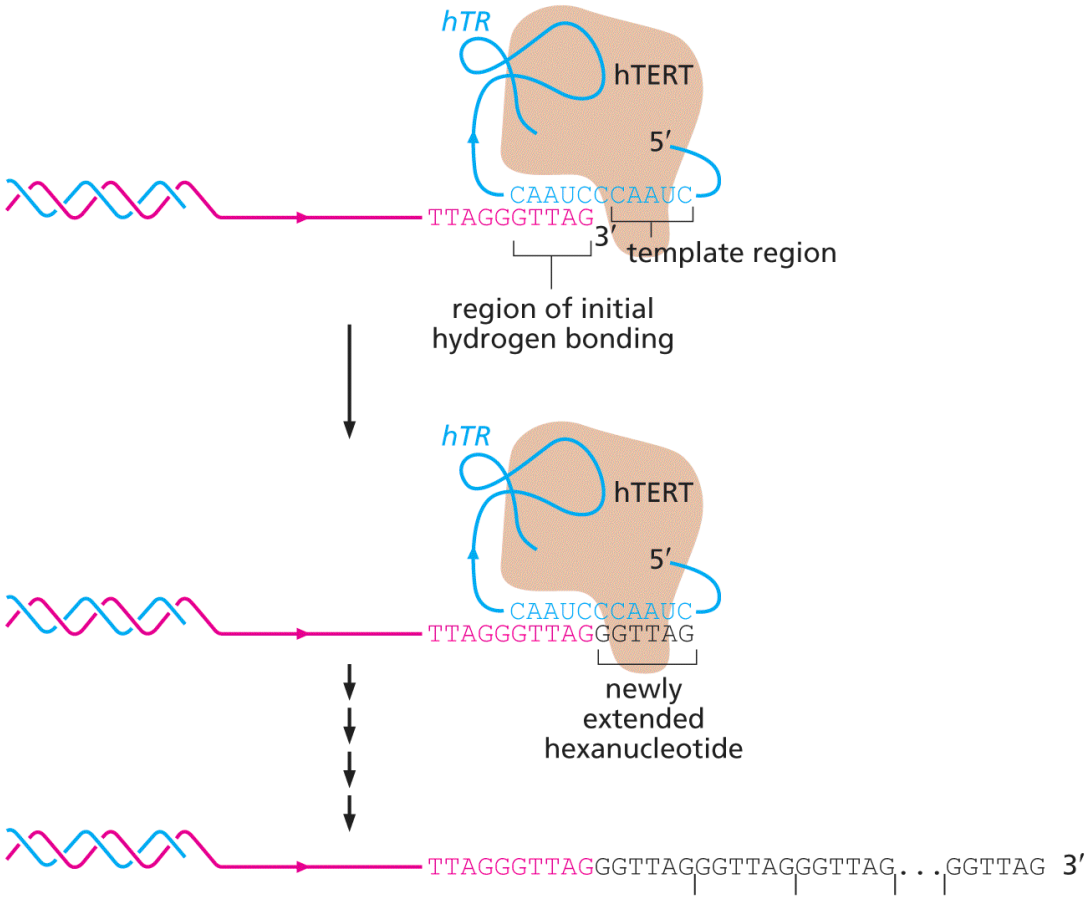
Telomere regeneration can be accomplished through the actions of the telomerase enzyme, which functions specifically to elongate telomeric DNA. A striking finding is that telomerase activity is clearly detectable in 85 to 90% of human tumor cell samples, and is present at very low levels in the lysates of most types of normal human cells, as measured by the TRAP assay (**Supplementary Sidebar 10.5**). Although these low levels of telomerase activity may enable some type of minimal maintenance of the ends of telomeric DNA (such as repair or regeneration of the t-loop), they are clearly unable to prevent the progressive erosion of the double-stranded region of telomeres that accompanies passage of normal human cells through each cell cycle.

In adult humans, there are actually several known exceptions to the generally observed low levels of telomerase activity in normal cells. For example, substantial enzyme activity is present in the germ cells of the testes, and lymphocytes express a burst of telomerase activity when they become functionally activated.

The available evidence indicates that strong expression of the telomerase enzyme is present early in embryogenesis and is largely lost during the cellular differentiation that produces most of the body's tissues. Thus, during the course of early mouse and cow embryogenesis, telomerase is strongly expressed in embryonic cells in the time between the morula and blastocyst stages and seems to disappear thereafter; a similar control of telomerase expression is likely to operate during human embryonic development. Accordingly, most normal human somatic cells, which carry the full complement of genes specifying the multi-subunit telomerase holoenzyme, are denied the services of this enzyme because they do not *express* all of the encoding genes at significant levels.

Among the large populations of cultured cells in crisis, however, rare variants find a way to de-repress the gene or genes encoding telomerase and thereby acquire high levels of constitutively expressed enzyme. This enables them to extend their telomeric DNA to a length that permits further proliferation. Indeed, as long as their descendants continue to express this enzyme, such cells will continue to proliferate and thus will be considered to be immortalized. A similar sequence of events is presumed to occur *in vivo* when populations of pre-neoplastic cells enter into crisis and, on rare occasion, generate immortalized variants that become the progenitors of large neoplastic cell populations.

The telomerase enzyme was developed early in eukaryotic cell evolution and is present in the cells of almost all descendant organisms, both protozoan and metazoan. Its presence in single-cell eukaryotes afforded its initial detection and characterization, first in baker's yeast using genetic analyses and in a ciliate through biochemical purification. It is a complex enzyme composed of a number of distinct subunits, not all of which have been characterized. At the core of the mammalian telomerase holoenzyme are two subunits. One subunit is a DNA polymerase, more specifically a reverse transcriptase, which functions, like the related enzymes made by retroviruses (see Section 3.7) and a variety of other viruses and transposable elements, to synthesize DNA from an RNA template. (**Figure 10.13**). However, unlike these other reverse transcriptases (**Supplementary Sidebar 10.6**), the telomerase holoenzyme cleverly packs its own RNA template—the second essential subunit. A short segment of this 451-nucleotide-long RNA molecule serves as the template that instructs the reverse transcriptase activity of the holoenzyme.



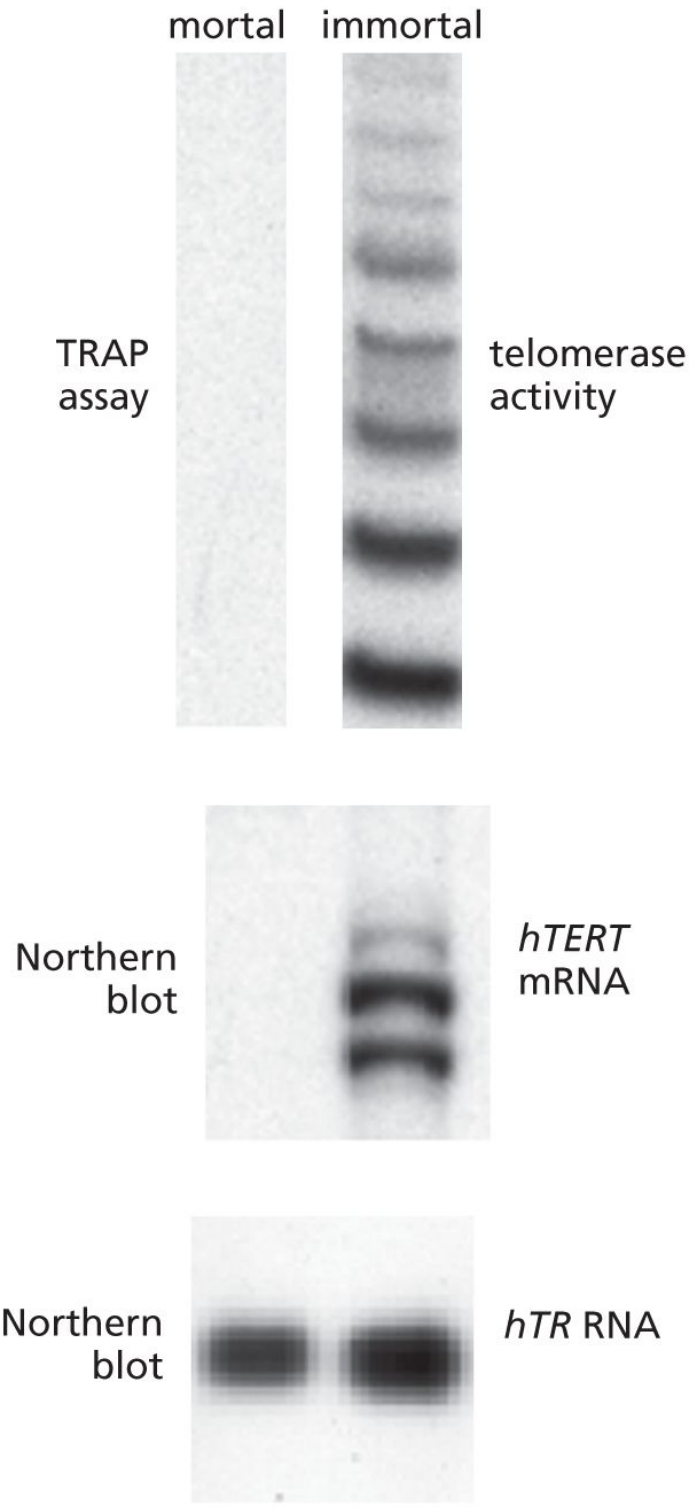
Telomere extension by human telomerase holoenzyme. The holoenyme has a large h TERT subunit that acts as a catalyst and an h R T R N A strand in which the base sequence C C A A U C, in the 3 prime to 5 prime direction, is the six-base template region. h TERT copies this region onto the telomere end of a single D N A strand in the 5 prime to 3 prime direction as the sequence G G T T A G. The newly extended hexanucleotide lengthens the telomere six bases at a time.

Figure 10.13 Core subunits of the human telomerase holoenzyme The human telomerase holoenzyme is composed of two core subunits, the hTERT catalytic subunit (*light brown*) and the associated *hTR* RNA subunit (*blue*); its mouse counterparts are termed mTERT and *mTR*. (Five other proteins, some present in two copies, are required to form a functional holoenzyme.) The holoenzyme attaches to the 3′ end of the G-rich strand overhang (*pink*), doing so in part through the hydrogen bonding of *hTR* to the last five nucleotides of the G-rich strand. Subsequently, by reverse transcription of sequences in the *hTR* subunit, hTERT is able to extend the G-rich strand by six nucleotides (*black*). By repeating this process in hexanucleotide increments (*ticks*), the enzyme can extend the G-rich strand by hundreds, even thousands of nucleotides, doing so in a *processive* fashion. Arrowheads indicate the 5′-to-3′ orientation of the nucleic acids. Upon

completion of this elongation, a conventional DNA polymerase can fill in the complementary (*blue*) strand after RNA primer molecules have been laid down by a primase enzyme (*not shown*).

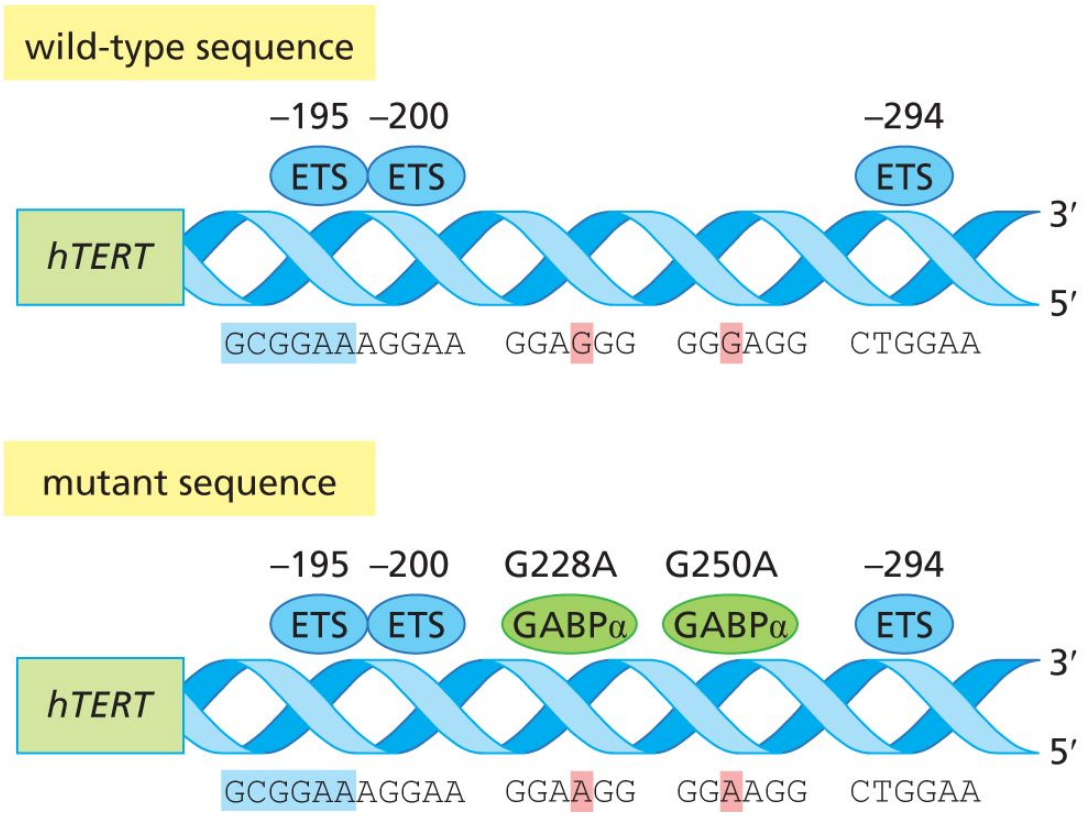
Isolation of substantial quantities of telomerase protein from the ciliate *Euplotes aediculatus* (see **Supplementary Sidebar 10.6**) allowed determination of the amino acid sequence of its catalytic subunit and, in turn, cloning of the gene encoding the ciliate enzyme as well as the homologous human gene. In human cells, this catalytic subunit, termed hTERT (for **h**uman **te**lomerase **r**everse **t**ranscriptase), synthesizes a DNA molecule that is complementary to six nucleotides present in the telomerase-associated RNA molecule (*hTR*; its encoding gene is sometimes called *TERC*), attaching these nucleotides to the G-rich 3′ overhanging end of the preexisting telomeric DNA (see Figure 10.13). The complementary strand of the telomeric DNA is then presumably synthesized by conventional DNA polymerases.

As would be predicted from the scenario described earlier, before entering crisis, human cells are essentially telomerase-negative and do not express appreciable levels of the *hTERT* mRNA. However, should a rare immortalized variant emerge from a population of cells in crisis, its descendants usually express significant levels of *hTERT* mRNA and exhibit substantial levels of telomerase enzyme activity (**Figure 10.14A**). This observation demonstrates directly that de-repression of *hTERT* gene expression accompanies the escape of these cells from crisis.



A TRAP assay for telomerase activity records none in mortal cells but significant activity in immortal ones. Similarly, a Northern blot for h TERT m R N A records none in mortal cells but a great deal of it in immortal ones. By

contrast, a Northern blot for h T R R N A records a significant amount in mortal cells and only a little more in immortal ones.
(A)



Two diagrams of double stranded D N A with an h TERT unit attached on the left. The upper D N A is a normal wild-type sequence, with E T esses attaching at bases minus 195, minus 200, and minus 294. Between the latter two, there are two hexanucleotide sequences each with a G highlighted. The lower D N A is a mutant sequence in which the aze have been replaced by jeeze. At each of those two sites, a G A B P alpha has attached. The left one is labeled G228A, the right G250A.

(B)

Figure 10.14 Spontaneous activation of telomerase (A) Individual B lymphocytes can escape at low frequency from a cell population in crisis and begin to grow robustly, thereby becoming immortalized (see Figure 10.8A). The pre-crisis “mortal” cells lack telomerase activity, as measured by the TRAP assay (see Sidebar 10.5), whereas the spontaneously immortalized (“immortal”) cells show abundant activity (*top*). The *hTERT* mRNA, which encodes the catalytic subunit of the telomerase holoenzyme, is essentially absent in the pre-crisis cells

but clearly present in the immortalized cells (*middle*). However, levels of the *hTR* RNA, which functions as a template for hTERT during telomeric DNA elongation (see Figure 10.13), are increased only slightly (*bottom*), suggesting that levels of hTERT expression determine the levels of enzyme activity in the cell. (B) Point mutations in the *hTERT* promoter have been documented in the genomes of numerous human tumors. The strong localization of the recurring point mutations indicates the significant survival advantage that evolving pre-neoplastic cells acquire by significantly elevating hTERT expression levels. Each of the two mutually exclusively occurring point mutations (at bases −228 and −250 from the start site of transcription) adds a binding site for the GABPα ETS-type transcription factor, substantially increasing *hTERT* transcription. These two mutations have been observed in the genomes of 83% of primary glioblastomas, 66% of bladder carcinomas, and 71% of human melanomas. [Indeed, the presence of these recurring mutations at a small number of sites in the *hTERT* promoter echoes the highly localized, recurring mutations affecting the reading frame of the promoters of the *ras* oncogenes in human tumors (see Figure 4.6).] (A, from M. Meyerson et al., *Cell* 90:785–795, 1997. With permission from Elsevier. B, adapted from G.M. Sizemore et al. *Nature Rev. Cancer* 17:337–351, 2017. With permission from Nature.)

Unanswered by this work are the mechanisms that enable the induction of hTERT expression in cells that previously failed to express it at significant levels. For many years, the prevailing view was that one or more transcription factors capable of driving transcription of the *hTERT* gene become expressed or overexpressed spontaneously in cells in crisis, driving in turn its sudden expression. The Myc oncoprotein, which is overexpressed in many types of human cancer cells, figures importantly here through its ability to directly drive expression of this gene (**Sidebar 10.3**). More recently, a number of reports have documented point mutations in the promoter of the *hTERT* gene that create binding sites for Ets transcription factors, resulting in elevated *hTERT* transcription (Figure 10.14B). [Indeed, the strong localization of sites within the *hTERT* promoter of these recurring point mutations is reminiscent of the behavior of the point mutations responsible for activation of *Ras* oncogenes, the latter affecting the reading frames of the *Ras* proto-oncogenes (see Figure 4.6)!]

Sidebar 10.3 Oncoproteins and tumor suppressor proteins play critical roles in governing *hTERT* expression

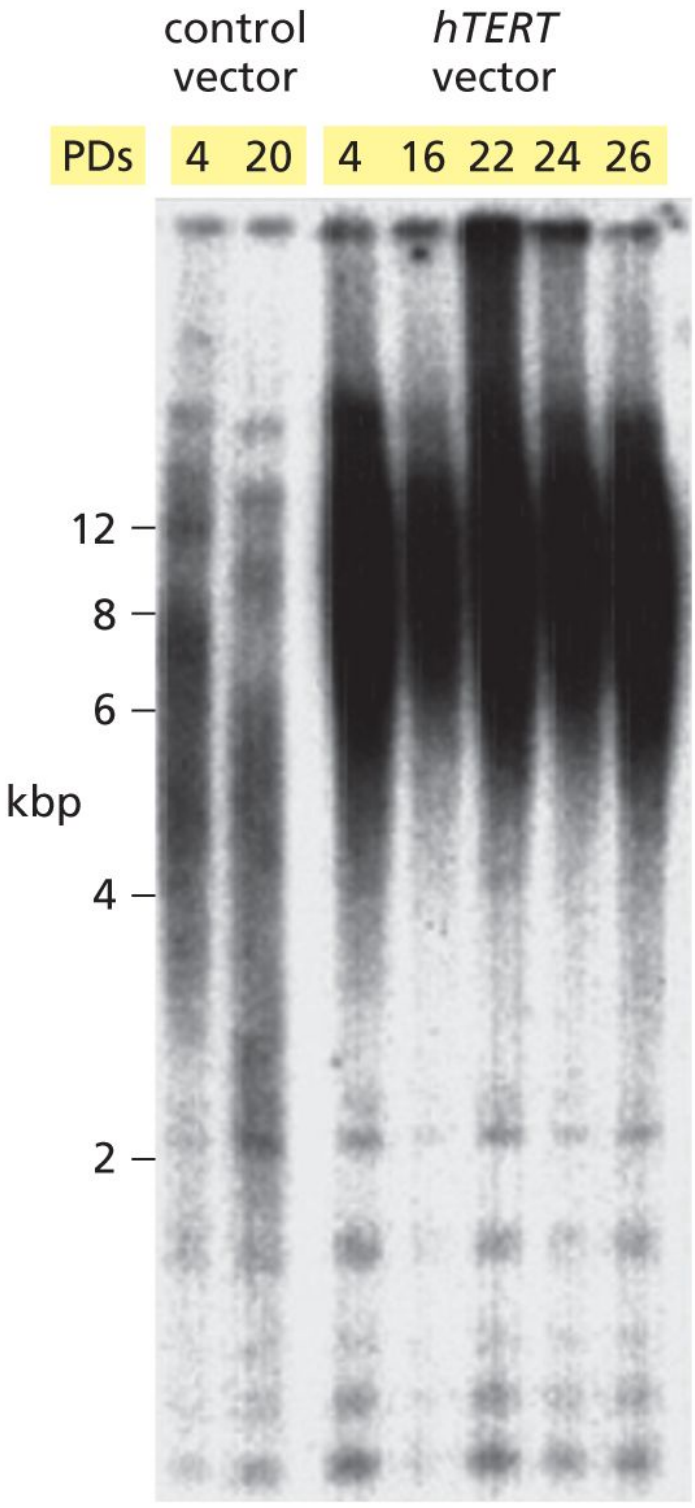
The mechanisms that lead to the de-repression of *hTERT* transcription during tumor progression in humans are complex and still quite obscure. Multiple transcription factors appear to collaborate to activate the *hTERT* promoter. Once expressed, the resulting *hTERT* transcripts allow the synthesis of substantial amounts of hTERT

protein; the latter, by complexing with other subunits of the telomerase holoenzyme, suffices to generate high levels of telomerase activity. The Myc protein, which acts as a transcription factor that controls the cell cycle clock and thousands of genes involved in other aspects of cell physiology (see Section 8.9), also contributes to *hTERT* transcription. There are at least two recognition sequences for bHLH transcription factors like Myc in the promoters of the mouse and human *TERT* genes.

The connection between Myc and *hTERT* expression can also be demonstrated by biological experiments. For example, cells from a human melanoma cell line have been isolated that express high levels of Myc and are tumorigenic. Three clonal variant subpopulations of this cell line have been isolated that exhibit as much as an eightfold reduction in Myc expression and have lost tumorigenicity. Their tumorigenic growth could be restored if they were supplied with an hTERT->expressing gene construct. Hence, in these cells, the loss of tumorigenicity following reduction of Myc expression levels could be attributed largely, if not exclusively, to an associated loss of *hTERT* gene expression.

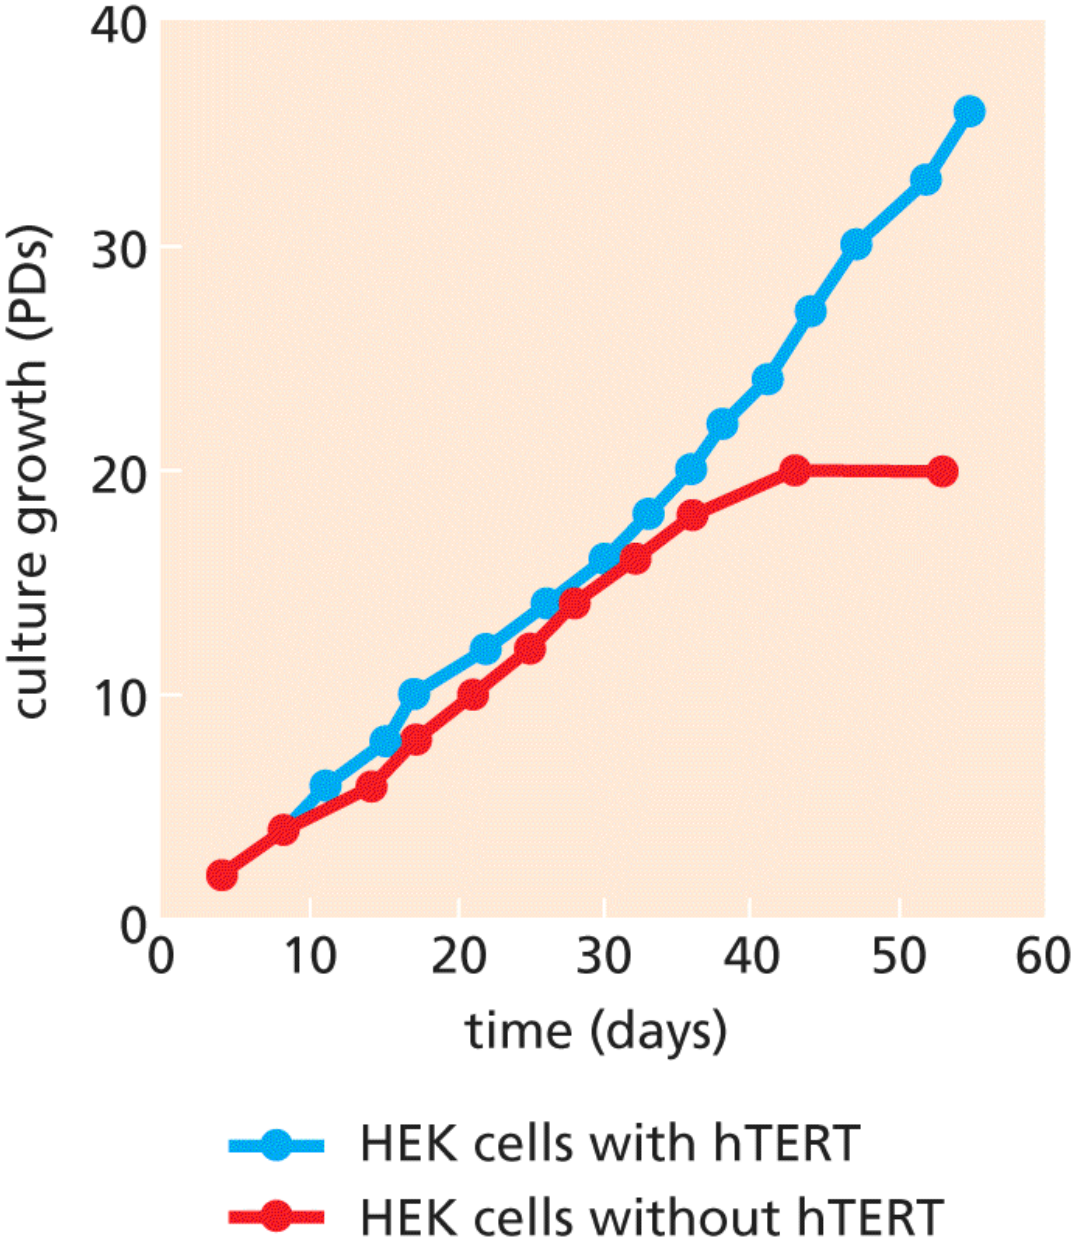
In addition to Myc, the E6 oncoprotein of HPV (see Side-bar 9.6) and the ER81 transcription factor, which is activated by the Ras–MAPK pathway, stimulate *hTERT* transcription. Working in the opposite direction, Menin—the product of the *MEN1* tumor suppressor gene (see Table 7.1)—associates with the *hTERT* promoter and represses *hTERT* transcription. A similar repressive role has been attributed to p53, Mxd (see Figure 8.21A), the WT1 tumor suppressor protein, and the Sp1 transcription factor, whose expression is induced by TGF-β.

Cancer cells use other molecular strategies to de-repress *hTERT* expression to acquire high levels of telomerase activity (see Sidebar 10.3). The sudden acquisition of telomerase activity might be only a *correlate* of escape from crisis rather than a *cause*. This ambiguity can be resolved by a simple experiment: a cDNA version of the *hTERT* gene can be introduced into cells just before they are destined to enter crisis. The introduced *hTERT* cDNA confers telomerase activity on these cells, causes elongation of their greatly shortened telomeres, prevents entrance into crisis, and enables such cells to grow indefinitely (**Figure 10.15**).



A Southern blot with seven channels. The first two are for a control vector. They show that telomere length decreased, from mostly in the 4 to 12 kilobase pair range after 4 population doublings to mostly in the 2 to 8 range after 20 doublings. The other five channels show that for the h TERT vector, telomere

length remained in the 6 to 15 kilobase pair range from 4 population doublings all the way up to 26 doublings.
(A)



A line graph with time on the horizontal axis and culture growth in population doublings on the vertical axis. For H E K cells with h TERT, the line rises steadily to about 37 doublings after 55 days. For H E K cells without h TERT, the line levels off at 20 doublings after 42 days.

(B)

Figure 10.15 Prevention of crisis by expression of telomerase (A) This Southern blot reveals the lengths of telomeric DNAs that were generated by cleaving genomic DNA with a restriction enzyme that does not cut within the repeating hexanucleotide sequence of telomeres, followed by hybridization to a DNA probe that recognizes this same sequence. As is seen, telomerase-negative human embryonic kidney (HEK) cells infected with a control retroviral vector that specifies no protein carry telomeres that decrease in size between the 4th and 20th population doublings (PDs; *left two channels*). However, infection of such cells with a retroviral vector specifying hTERT causes the telomeres to substantially increase in length, maintaining their sizes through the 26th population doubling (*right channels*). (Because these telomeres are much longer, they generate a stronger signal upon Southern blotting.) The size markers are given in kilobase pairs. (B) This population of human embryonic kidney (HEK) cells was destined to enter crisis by 40 days, which is the equivalent of roughly 20 population doublings (PDs; *red line*). However, when hTERT was ectopically expressed in these cells (*blue line*), they gained the ability to proliferate indefinitely. (From C.M. Counter, W.C. Hahn, W. Wei et al., *Proc. Natl. Acad. Sci. USA* 95:14723-14728, 1998. With permission from National Academy of Sciences, U.S.A.)

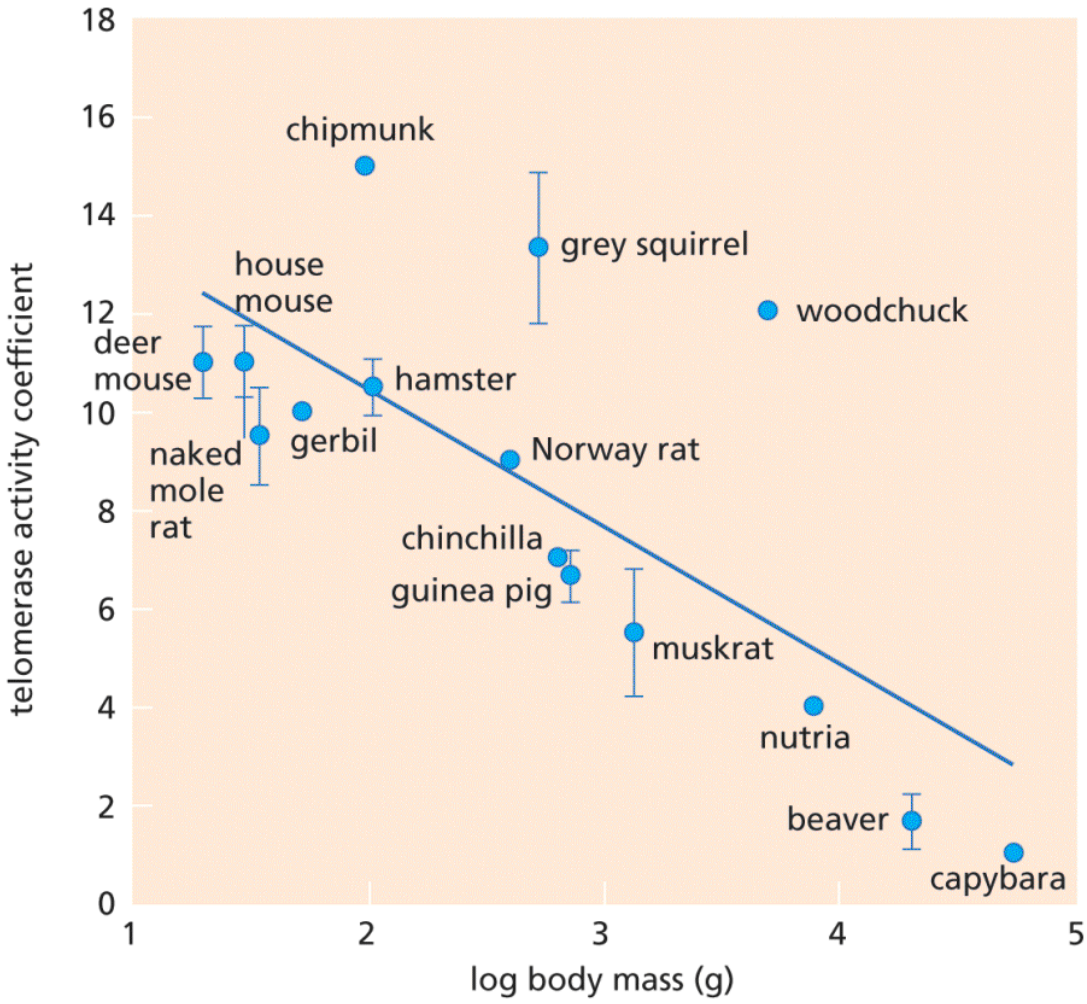
The outcomes of this experiment and similar experiments actually prove three related points. First, although the telomerase holoenzyme may be composed of multiple, distinct subunits, the only subunit missing from normal, pre-crisis human cells is the catalytic subunit encoded by the *hTERT* gene; the remaining subunits of the telomerase holoenzyme, including the *hTR* telomerase-associated RNA molecule, seem to be present in adequate amounts in pre-crisis cells. Second, because expression of telomerase (rather than another enzyme) allows cells to avoid crisis, and because telomerase acts specifically on telomeric DNA, these observations demonstrate that one cause of crisis must indeed be critically shortened telomeres. Third, this experiment shows that the acquisition of telomerase activity, which can be achieved spontaneously by rare variant cells scattered amid a population of cells in crisis, is sufficient to enable cells to escape crisis and generate descendants that can grow in an immortalized fashion.

We can conclude further that telomerase succeeds in allowing cells to circumvent crisis because it subverts the operations of the generational clock. When telomerase is expressed at significant levels, telomeres are maintained at lengths that are compatible with unlimited further replication. In effect, the generational clock that depends on progressive telomere shortening is rendered inoperative.

With these insights in mind, the normal biological roles of telomerase now become clearer. In single-cell eukaryotic species, such as ciliates and yeast, the exponential growth of cells requires the continuous presence of high levels of telomerase activity

to ensure that telomeres are maintained indefinitely at a length that is compatible with chromosomal stability. By elongating telomeric DNA, the telomerase in these protozoan cells is able to compensate for the continued erosion of telomeric DNA due to the under-replication of DNA termini by the bulk DNA replication machinery as well as degradation by certain exonucleases (see Figure 10.12). Being single-celled, these eukaryotes have no need to fear cancer.

Expression of telomerase activity is programmed differently in complex metazoans, notably humans. Because telomerase expression is largely repressed in postembryonic cell lineages, these lineages are granted only limited postembryonic replicative potential before they enter crisis. This limitation seems to represent one component of the human body's anti-cancer defenses. Thus, the repression of TERT activity has been found to be regulated as a function of the number of cell divisions experienced in an organism's lifetime, supporting the notions that (1) the risk of developing tumors is correlated with the number of cell divisions that an organism experiences in an average life span and (2) one mechanism for reducing cancer risk is to limit the access of normal somatic cells to TERT activity (**Figure 10.16**).



A scatter plot with telomerase activity coefficient from 0 to 18 on the vertical axis and log body mass in grams from 1 to 5 on the horizontal axis. The 15 mammals represented include, from smallest to largest, deer mouse, house mouse, naked mole rat, gerbil, chipmunk, hamster, Norway rat, gray squirrel, chinchilla, guinea pig, muskrat, woodchuck, nutria, beaver, and capybara. The trend line for the plot runs from 13 on the vertical axis down to extrapolated 6 on the horizontal axis. Most of the mammals lie fairly close to the line, but chipmunk, gray squirrel, and woodchuck are outliers, having much higher telomerase activity coefficients than their body masses would predict.

Figure 10.16 Repression of TERT expression as a function of body mass The notion that repression of TERT activity in mammals represents a tumor-suppressing mechanism has been tested by examining the activity of the enzyme in the tissues of a diverse array of rodents whose body sizes vary over almost three orders of magnitude. Given that the sizes of individual proliferating cells appear to be equivalent among these species, body mass measurements are likely to serve as

one metric of the cumulative number of cell divisions that an organism experiences in its lifetime. Thus, more cell divisions are required to generate and maintain various tissues in larger organisms, an effect that is compounded because larger mammals generally have longer lifespans. Also, as described in Chapter 12, cell divisions represent a significant source of the somatic mutations that contribute to tumor pathogenesis. Consequently, during the course of their evolution, large, long-lived mammals must have developed increased anti-neoplastic mechanisms to compensate for their intrinsically increased risk of developing cancers. One such mechanism might be to limit TERT activity in somatic tissues, a notion that is supported by this study of TERT activity and body mass among a group of 15 species, all of which are members of a single mammalian order—Rodentia. Rodent body mass varies from 20 g to 55 kg. In this case, the TRAP enzyme assay (see Sidebar 10.5) was used to gauge TERT activity in various differentiated cells of rodents. (From A. Seluanov et al., *Aging Cell* 6:45–52, 2007 and V. Gorbunova et al., *Nat. Rev. Genet.* 15:531–540, 2014. With permission from John Wiley & Sons.)

Another perspective on this problem comes from attempting to compare the relative numbers of cell divisions in the lives of laboratory mice relative to humans: mice may experience ~10^{11} cell divisions in a lifetime, whereas humans are thought to undergo about 10^{16}, suggesting that there is a roughly 100,000-fold difference in the risk of acquiring cancer-causing somatic mutations deriving from errors in DNA replication occurring during cell division. Indeed, studies of telomerase activity in a variety of rodents indicates an inverse relationship between body mass and basal telomerase activity (see Figure 10.16). This finding provides further support for the notion that limiting telomerase activity represents one mechanism evolved to compensate for the large number of cell divisions and associated risk of somatic mutations in a variety of mammals.

This mechanistic model also provides a compelling explanation of how human cells can escape from crisis and become immortalized. It fails, however, to address another long-standing mystery: How does experimentally induced expression of telomerase enable certain types of cultured cells to avoid senescence (**Sidebar 10.4**, **Figure 10.17**)?

Sidebar 10.4 The puzzle of senescence and telomeres

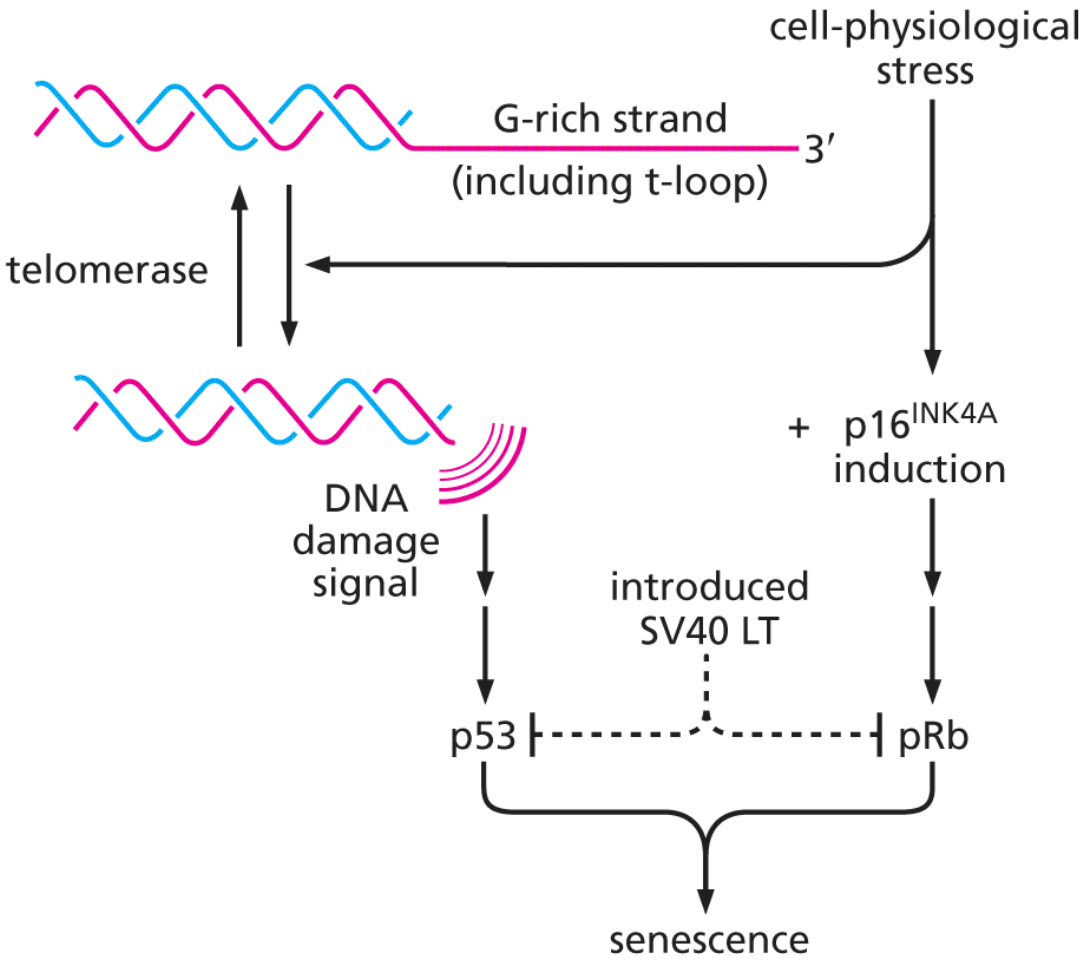
As described here, a diverse array of experimental data have converged on the conclusion that cells enter senescence in response to a variety of cell-physiological stresses, some sustained over extended periods of time. These include various types of

genetic damage, oncogene signaling, oxidative stress, and even metabolic stress. Replicative senescence—manifested by many cell types in response to being introduced into tissue culture—is largely and possibly entirely explained by the stresses that cells suffer from sub-optimal conditions of culture; this is underscored by observations indicating that replicative senescence can be delayed by improving the conditions of culture (see **Supplementary Sidebar 10.3**).

Once cells have entered into senescence, which is generally an irreversible step, they manifest DNA lesions that seem, for one reason or another, to be irreparable. Indeed, many of the stressors that induce senescence appear to function, directly or indirectly, to induce DNA damage, and the resulting unrepaired lesions seem to be responsible for emitting signals that induce senescence, thereby stably maintaining the cells around them in the senescent state. In human (but not in laboratory mouse) cells, the senescence-associated heterochromatic foci (SAHFs; see Figure 9.17) indicate a massive shutdown of the expression of thousands of genes, many of which are apparently essential for cell proliferation.

This scheme is difficult to reconcile with other solid observations demonstrating that in certain human cell types, senescence can be circumvented by forced expression of hTERT. Because such hTERT expression also allows a cell subsequently to circumvent crisis, this treatment effectively immortalizes cells. These observations have been incorporated into a scheme suggesting that when telomeres are eroded after short-term culture, some of the shortest telomeres have already eroded enough to lose their ability to protect the ends of telomeric DNA; these shortened telomeres release signals that induce senescence. In the event that senescence is circumvented, cells will then proceed to crisis, where far greater telomere erosion triggers the breakage–fusion–bridge cycles and the widespread apoptosis associated with crisis. Accordingly, telomere shortening acts as a clocking device to trigger both senescence and, later on, crisis.

These two mechanistic models are incompatible with one another: either the timing of senescence is triggered by telomere erosion or it is triggered by cell-physiological stress. A scheme to reconcile these two alternative mechanistic models is not obvious. One possible mechanism is the following (see Figure 10.17): when cells experience certain types of physiological stress, they actively degrade the ends of some or all of their telomeres; the resulting dysfunctional telomeres release a DNA damage signal that in turn triggers senescence. In the event that hTERT is present in significant amounts, such telomere degradation and resulting entrance into senescence is avoided. Yet other mechanisms by which hTERT acts independently of telomeres to prevent entrance into senescence have been proposed.



A sequence of events that begins with cell-physiological stress and proceeds along two pathways. In one pathway, the added induction of p16 INK 4A promotes the activation of p R b. In the other pathway, an overhanging single, G-rich strand, including the T-loop type, is degraded, leading to the emission of a D N A damage signal by the blunted double strand that remains. This signal activates p53. p R b and p53 Both promote senescence. However, telomerase can block the second pathway by reversing the effects of cell-physiological stress. It converts blunted double strand D N A into double-strand D N A with an overhanging single, G-rich strand. Also shown is the fact that although p R b and p53 normally promote senescence, the introduction of S V 40 L T inhibits the two proteins from doing so.

Figure 10.17 Replicative senescence and the actions of telomerase This diagram presents a speculative mechanistic model of how and why telomerase expression (achieved by ectopic expression of the hTERT catalytic subunit) can prevent human cells from entering into replicative senescence. The t-loop of the telomeric DNA (see Figure 10.11) is not illustrated here. The G-rich overhanging strand of telomeric DNA (*pink*, *top*), which forms the t-loop, has been found in

some studies to be largely degraded in cells that have entered replicative senescence. This loss may be triggered by certain cell-physiological stresses. The resulting blunted telomeric DNA may then emit a DNA damage signal that activates p53. Together with $p16^{INK4A}$ expression (see Section 8.4), which is activated by various cell-physiological stresses, this may impose a senescent state. By reversing this loss of the G-rich overhang (and a possible partial degradation of the dsDNA portion of telomeric DNA), the experimentally introduced telomerase prevents certain cell types, such as human fibroblasts, from entering into senescence. Of note, the demonstrated ability of SV40 large T antigen to circumvent senescence depends on its ability to sequester both pRB and p53, thereby neutralizing the cytostatic effects of increased expression of $p16^{INK4A}$ and p53 (see Figure 10.3).

OceanofPDF.com

Glossary

telomerase
: An enzyme specialized to extend telomeric DNA; those telomerases characterized to date carry an RNA subunit and a reverse transcriptase-like catalytic subunit. *See also* **telomere**.

holoenzyme
: A multi-subunit complex containing an enzyme and associated protein subunits that collaborate to mediate and regulate enzymatic activity.

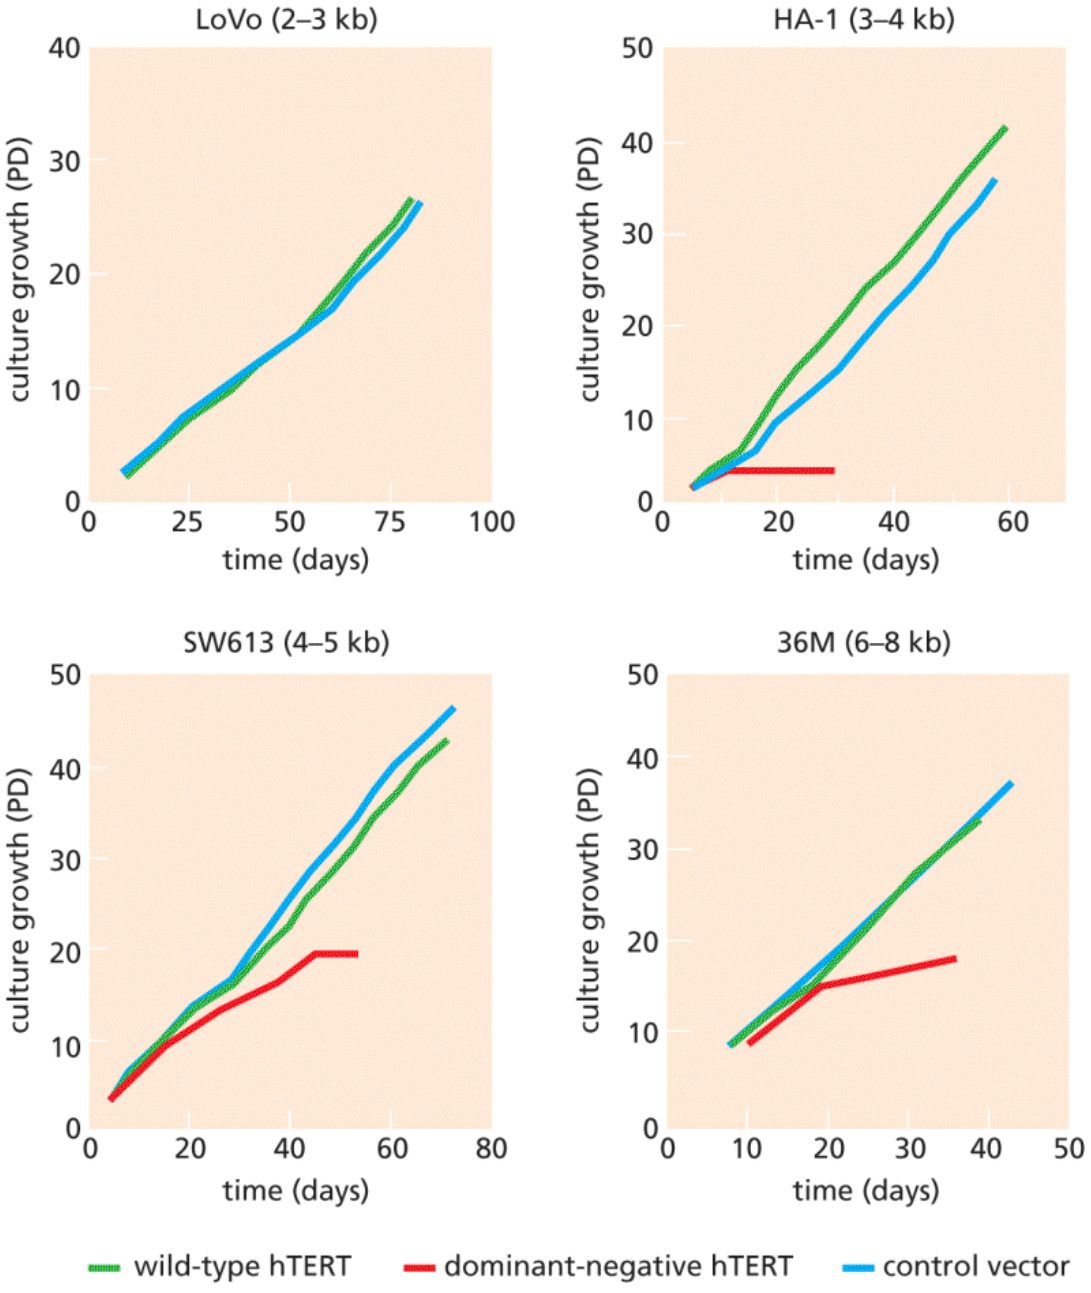
10.7 Telomerase plays a key role in the proliferation of human cancer cells

The experiments described above using pre-crisis human cells in culture suggest that the telomerase activity detectable in the great majority of human cancer cells plays a causal role in their immortalization and that such immortalization is a key component of the neoplastic growth state. This mechanistic model has been tested experimentally by suppressing the telomerase activity in cancer cells and following their subsequent responses. Telomerase activity can be reduced through the expression of antisense RNA in the telomerase-positive cells. For example, an RNA that is complementary in sequence to the *hTR* RNA subunit of the telomerase holoenzyme (see Figure 10.13) can be introduced experimentally into telomerase-positive human cancer cells. Such an antisense molecule is presumed to anneal to the *hTR* molecule, forming an RNA–RNA double helix, thereby blocking the ability of the *hTR* subunit to participate in the synthesis of telomeric DNA. In fact, it is difficult to achieve total inhibition of hTR function using this strategy. Nonetheless, such an antisense experiment performed with HeLa cells (from the line of human cervical carcinoma cells cited earlier) caused them to stop growing 23 to 26 days after they were initially exposed to the antisense RNA.

An alternative experimental strategy that is more effective derives from the use of a mutant hTERT enzyme carrying amino acid substitutions in its catalytic cleft; these alterations yield a catalytically inactive enzyme. When overexpressed in telomerase-positive cells, the mutant hTERT protein can act in a dominant-negative fashion (dn; see Section 9.4) to interfere with the existing endogenous telomerase activity of these cells. The dn hTERT, which can be expressed at levels vastly higher than the endogenous hTERT protein, is likely to associate with and thereby monopolize the other subunits that normally assemble to form the telomerase holoenzyme. As a consequence, when these other telomerase subunits associate with the dn hTERT protein, they become recruited into unproductive holoenzyme complexes.

Expression of the dn hTERT subunit in a number of different telomerase-positive human tumor cell lines causes them to lose all detectable telomerase activity and, with some delay, to enter crisis. The crisis occurs with a lag time from 5 to 25 days, depending on the length of the telomeric DNA in these cells at the time when the dn hTERT subunit was first introduced. Cells with telomeres that initially were 2 to 3 kb in length enter crisis almost immediately, whereas those with telomeres that were initially 4 to 5 kb in length require 30 days of further passaging in culture before

entering crisis (**Figure 10.18**). These delayed reactions suggest that after the dn hTERT is expressed in cancer cells, telomeres shorten progressively, and that crisis ensues after the initially present telomeric DNA erodes down to some threshold length that is incompatible with protecting the ends of chromosomal DNA.



Four line graphs, each with time in days on the horizontal axis and culture growth measured in population doublings on the vertical axis. The upper left graph, for the Lo Vo cancer cell line (2 to 3 kilobases) shows a blue line and a green one rising steadily from 2 doublings after 10 days to 80 doublings after 28 days. The

upper right graph, for the H A-1 line, 3 to 4 kilobases, shows a green line rising from 1 doubling after 5 days to 41 doublings after 58 days, a blue line rising from 1 doubling after 5 days to 35 doublings after 57 days, and a red line that starts at 1 doubling after 5 days and levels off at 2 doublings after 10 days before ending after 30 days. The lower left graph, for the S W 6 13 line, 4 to 5 kilobases, shows a blue line rising from 2 doublings after 4 days to 47 doublings after 70 days, a green line rising from 2 doublings after 4 days to 42 doublings after 70 days, and a red line that starts at 2 doublings after 4 days and levels off at 20 doublings after 42 days before ending after 52 days. The lower right graph, for the 36 M line, 6 to 8 kilobases, shows a blue line rising from 9 doublings after 9 days to 37 doublings after 42 days, a green line rising from 9 doublings after 9 days to 33 doublings after 39 days, and a red line that starts at 9 doublings after 10 days, rises to 14 doublings after 19 days, and then ends at 18 doublings after 35 days.

Figure 10.18 Suppression of telomerase activity and resulting loss of the neoplastic growth program Expression vectors specifying a mutant dominant-negative (dn) hTERT protein (*red lines*), a wild-type hTERT enzyme (*green lines*), or an empty control vector (*blue lines*) have dramatically different effects on four different human cancer cell lines. The respective lengths of their telomeric DNAs, as determined by TRF Southern blots (see Figure 10.8A) at the onset of the experiment, are indicated in kilobases (kb). The empty control vector and the hTERT-expressing vector permit the continued proliferation of these cells, as measured in population doublings (PD). However, introduction of the dn hTERT enzyme, which differs from the wild-type enzyme by a single amino acid substitution in its catalytic cleft and is presumed to shut down endogenous hTERT function, causes these cells to stop growing, doing so with various lag times (in days). Microscopic examination revealed that the cells that ceased proliferating entered into crisis and showed widespread apoptosis. Cells of the LoVo cell line (*top left*) entered crisis immediately after expressing the dn hTERT enzyme, and therefore no cells were available to count. (Because the TRFs also contain nonfunctional subtelomeric DNA that carries imperfect hexanucleotide repeats, the lengths of functional telomeric sequences are much shorter than the observed lengths of the TRFs.) (From W.C. Hahn et al., *Nat. Med.* 5:1164–1170, 1999. With permission from Nature.)

Importantly, the dn hTERT enzyme has no observable effect on the growth of telomerase-positive cells up to the point when they reach crisis. This rules out an alternative explanation: that the mutant enzyme is intrinsically cytotoxic and that its effects on the cell are attributable to some nonspecific toxicity. Taken together, such experiments lead to the conclusion that the continued activities of the telomerase enzyme are as important to the proliferation of these cancer cells as the actions of oncogenes and the inaction of tumor suppressor genes. This conclusion is strengthened

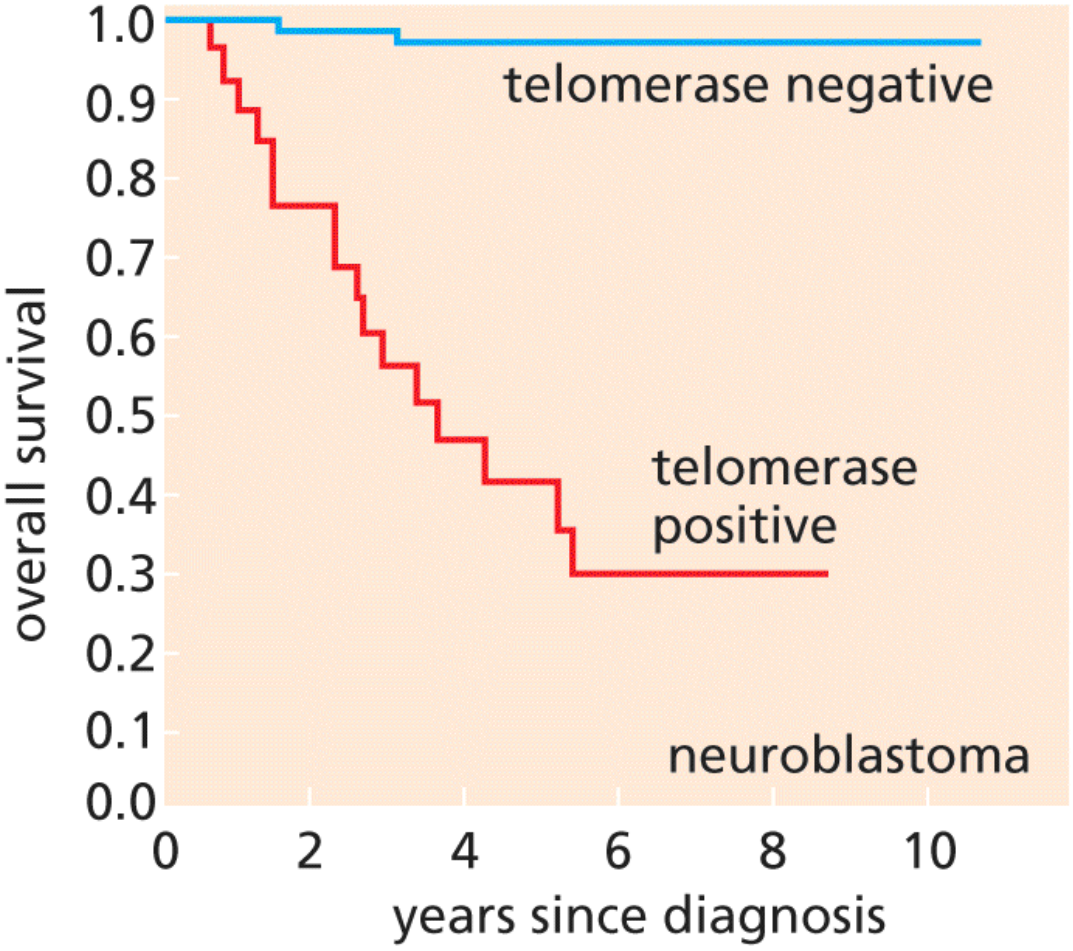
by the dramatic outcomes of studies of certain human pediatric tumors (**Sidebar 10.5**, **Figure 10.19**).

Sidebar 10.5 Telomerase fuels the growth of some pediatric tumors

Neuroblastomas are tumors of cells in the peripheral (sympathetic) nervous system and are usually encountered in very young children. These tumors have highly variable outcomes, with some regressing spontaneously and others progressing into invasive, metastatic tumors that ultimately prove fatal. As described in Section 4.4, the N-*myc* gene often undergoes amplification in these tumors, and greater copy numbers of N-*myc* indicate a worse prognosis for the patient. In fact, telomerase activity is an even more useful indicator of the eventual outcome of the disease. As shown in Figure 10.19A, children whose neuroblastomas are telomerase-negative (as judged by the TRAP assay; see **Supplementary Sidebar 10.5**) do very well in response to therapy, whereas those whose tumors are telomerase-positive do poorly. Expression of these two genes—N-*myc* and the telomerase-encoding *hTERT* gene—is likely to be functionally linked because N-*myc*'s cousin, *myc*, is already known to be a strong inducer of *hTERT* transcription (see Sidebar 10.3). Similar dynamics operate in another childhood

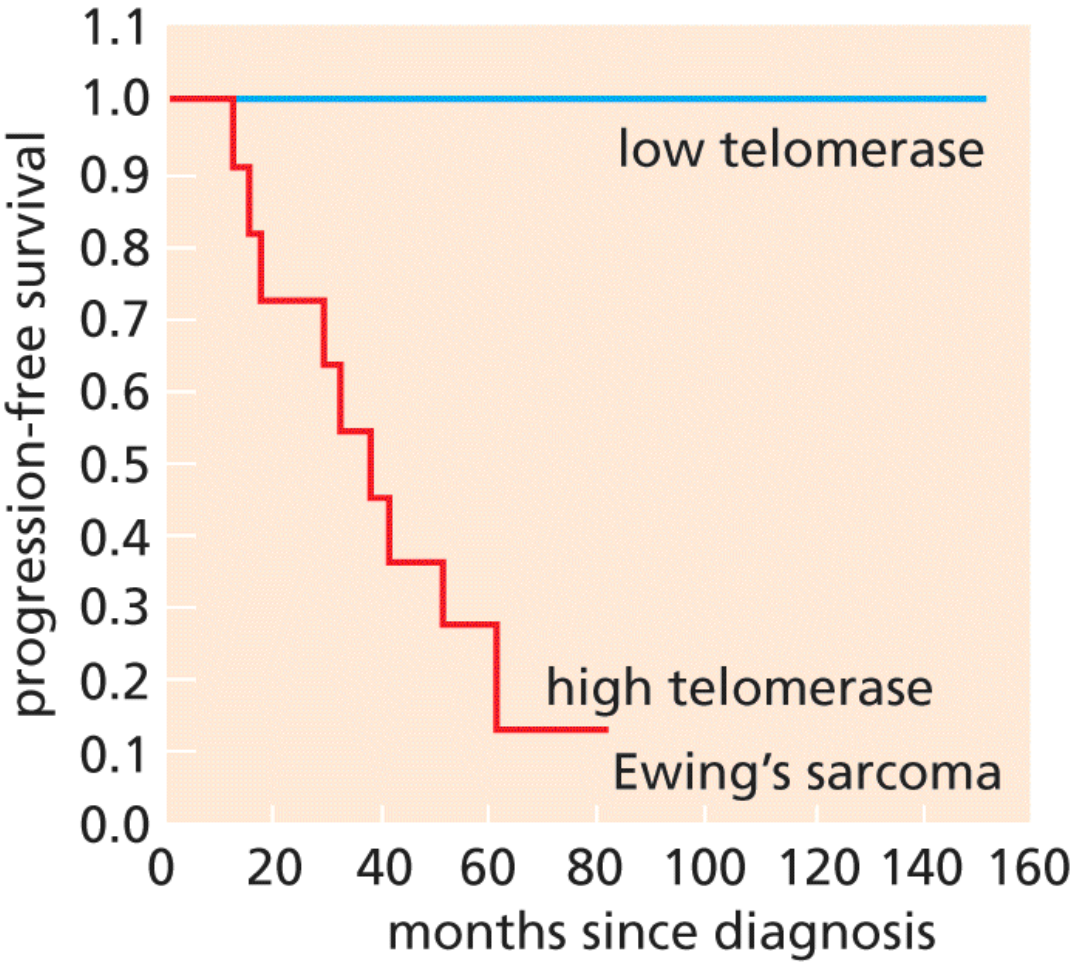
tumor—Ewing's sarcoma—which may arise from mesenchymal stem cells (Figure 10.19B).

Some pathologists argue that neuroblastomas are extremely common in children under the age of one year, and that almost all of these regress spontaneously and never become clinically apparent. The causes of this regression and the benign outcomes of many clinically detected neuroblastomas that respond well to treatment may now have found a molecular explanation: without significant hTERT expression, neuroblastoma cells lose telomeres and progress into crisis, from which they fail to emerge.



A line graph describing the overall survival rate of neuroblastoma patients as a function of time. About 95 percent of telomerase negative patients are still alive 10 years after diagnosis, whereas only about 30 percent of telomerase positive patients are alive after 6 years.

(A)



A line graph describing the overall survival rate of Ewing's sarcoma patients as a function of time. 100 percent of low telomerase patients are still alive 150 months after diagnosis, whereas only about 10 percent of high telomerase patients are alive after 60 months.

(B)

Figure 10.19 Telomerase activity and the prognosis of pediatric tumors (A) This Kaplan–Meier plot illustrates the survival of a group of pediatric neuroblastoma patients who had received no cytotoxic chemotherapy treatment and who were tracked for the time spans indicated (*abscissa*) following diagnosis. These patients were segregated into two groups—those whose tumors were telomerase activity–positive (*red*), and those whose tumors appeared to lack this activity (*blue*). The ordinate indicates overall survival, i.e., the proportion of patients who remained alive at various times after initial diagnosis. (B) A similar study of children with Ewing's sarcoma was undertaken, in which the patients were segregated into two groups, depending on whether their tumors had high

(*red*) or low (*blue*) telomerase activity. In this case, the ordinate indicates the proportion of children who experienced *progression-free survival,* i.e., those whose tumors had not advanced beyond the stage initially encountered in the clinic. (A, from C. Poremba et al., *J. Clin. Oncol.* 18:2582–2592, 2000. B, from A. Ohali et al., *J. Clin. Oncol.* 21:3836–3843, 2003. Both with permission from the American Society of Clinical Oncology.)

The key role of hTERT in human cell transformation is revealed by other data as well. Thus, as described in the next chapter, the experimental transformation of primary human cells into tumorigenic cells requires, among other introduced genes, the introduction of a vector expressing hTERT constitutively. Responding to these various discoveries, some researchers have used an automotive analogy to illustrate the growth of human cancer cells: activated oncogenes are said to be akin to accelerator pedals that are stuck to the floor; inactivated tumor suppressor genes are compared to defective braking systems; and telomerase is likened to an agent that ensures that the runaway car has an endless, self-replenishing supply of gasoline in its tank.

10.8 Some immortalized cells can maintain telomeres without telomerase

As noted earlier, 85 to 90% of human tumors have been found to be telomerase-positive. The remaining 10 to 15% lack readily detectable enzyme activity, yet the cells within this second group of tumors are presumably faced with the need to maintain their telomeres above some minimum length in order to proliferate indefinitely. In fact, many of these cells have learned to maintain their telomeric DNA using a mechanism that does not depend on the actions of telomerase.

This non-telomerase-based mechanism was first discovered in the yeast *Saccharomyces cerevisiae* following inactivation of one of the several yeast genes encoding subunits of its telomerase holoenzyme. Resulting mutant yeast cells soon entered into a state that is analogous to crisis in mammalian cells. The vast majority of the cells died, but rare variants emerged from these populations of dying cells that used the ALT (alternative lengthening of telomeres) mechanism, which is telomerase-independent, to construct and maintain their telomeres. The minority of human tumor cells that lack significant telomerase activity also use the ALT mechanism.

Details of the molecular mechanisms that ALT-positive human cells use to maintain their telomeres are poorly understood. An important clue, however, comes from an experiment in which a traceable molecular marker —a neomycin resistance gene—was introduced into the midst of the telomere repeat sequence of one chromosome carried by a mammalian cell in the ALT state. When the telomeric DNAs were examined in the descendants of this cell, copies of this molecular marker were found in a number of other telomeres as well. Hence, sequence information appears to be exchanged between the telomeres of cells in the ALT state. Some of the enzymes that are used by ALT-positive human cancer cells to maintain their telomeres have been identified while others remain elusive. For example,

certain enzymes involved in DNA mismatch repair, described in part in Chapter 12, appear to contribute to telomere maintenance in human ALT cells.

The existence of the ALT mechanism emphasizes that all types of human cancer cells must develop ways to maintain their telomeres above a certain threshold length in order to proliferate in an immortalized fashion. To summarize, most human cancer cells de-repress expression of the *hTERT* gene, but a small minority of incipient cancer cells find a way to activate the ALT mechanism.

The ALT state is associated preferentially with a specific subset of the tumors encountered in oncology clinics. These include perhaps half of osteosarcomas and soft-tissue sarcomas as well as one-quarter of glioblastomas, but only rarely carcinomas. Perhaps these correlations may one day be explained by the characteristic expression of a group of genes in mesenchymal cells that are also associated with repression of the *hTERT* gene, forcing the cancer cells that arise from these cell types to rely on ALT as a more accessible route to immortalization. Additional clues to understanding the origin of this mechanism may also come from observations that the ALT state operates in certain subclasses of normal lymphocytes.

At the moment, the precise reasons why one mechanism (involving hTERT) is usually favored over the other (ALT) remain obscure. Equally unclear are the mechanisms that cause the telomeric DNA of human cells in the ALT state to grow to heterogeneous lengths (often >30 kb) far greater than those usually seen in telomerase-positive cells (5–10 kb). Importantly, the dominant-negative hTERT enzyme (see Figure 10.18), which induces crisis in a number of telomerase-positive human cancer cell lines, fails to do so in a human ALT-positive tumor cell line, providing further support of the notions that (1) ALT-positive cells do not depend on telomerase for their growth, and (2) the dn hTERT enzyme is not intrinsically cytotoxic.

Of note, most of the telomeres in the ALT-positive cells are able to form the t-loops/lariats (see Figure 10.11) in the absence of telomerase function. These structures explain how these telomeres are protected from end-to-end fusion and BFB cycles. At the same time, it illustrates that these t-loops

form spontaneously and are directed to do so by the DNA sequences and associated proteins (see **Supplementary Sidebar 10.4**) found in human cells lacking hTERT function.

hTERT is a very attractive target for researchers who are intent on developing novel types of anti-cancer therapeutics. As we will learn in Chapter 17, the catalytic clefts of enzymes such as hTERT can often be blocked by highly specific therapeutic drug molecules. Significantly, hTERT is a distant relative of the reverse transcriptase of human immunodeficiency virus (HIV; see **Supplementary Sidebar 10.6**), against which effective drug inhibitors have been successfully developed. These existing successes increase the likelihood that anti-hTERT compounds will one day be produced as well. In addition, this enzyme is expressed in the great majority of human cancers, but is not present at significant levels in normal tissue. This offers the prospect of drug selectivity—being able to affect cancer cells, while leaving cells in normal tissues untouched. However, for reasons that remain unclear, the hTERT enzyme has proven time and again to be a formidable enemy, in that repeated screens for low–molecular-weight inhibitors of this enzyme have failed to yield attractive drug candidates.

The ALT state holds important implications for such drug development. Imagine that an inhibitor of hTERT were indeed developed. It is already clear that as many as 10% of human tumors will never respond to such an anti-telomerase drug, because they are ALT-positive and therefore do not depend on this enzyme for their continued proliferation. The remaining 90% of human tumors, which do indeed exhibit robust telomerase activity, may initially be susceptible to killing by this drug, but sooner or later may spawn variants that have activated the ALT mechanism of telomere maintenance. This might allow the newly arising ALT variants to evade the killing actions of the anti-telomerase drug. In this case, a back-up therapeutic strategy might come from the discovery that inhibitors of the ATR enzyme (see Section 9.7), which participates in DNA replication, recombination and repair, are highly effective in killing ALT cancer cells but not those that express high levels of hTERT.

10.9 Telomeres play different roles in the cells of laboratory mice and in human cells

Our descriptions of telomerase expression repeatedly refer to its actions in human cells, with good reason. Rodent cells, specifically those of laboratory mouse strains, control telomerase expression in a totally different way. These mice do not strongly repress mTERT expression, which seems to explain why the double-stranded region of telomeric DNA in laboratory mice is as much as 30 to 40 kb long—about five times longer than corresponding human telomeric DNA. In fact, laboratory mouse telomeres are so long that they are never in danger of eroding down to critically short lengths during the lifetime of a mouse, even when expression of mouse telomerase is suppressed experimentally.

The lengths of mouse telomeres permit cell lineages to pass through a far larger number of replicative generations than would seem to be required for tumor formation. This finding suggests that laboratory mice do not rely on telomere length to limit the replicative capacity of their normal cell lineages and that telomere erosion cannot serve as a mechanism for constraining tumor development in these rodents (see also Figure 10.16). Moreover, telomerase activity is detectable in the stem cells of certain tissues in the mouse, providing further indication of the absence of global repression of TERT activity in these animals.

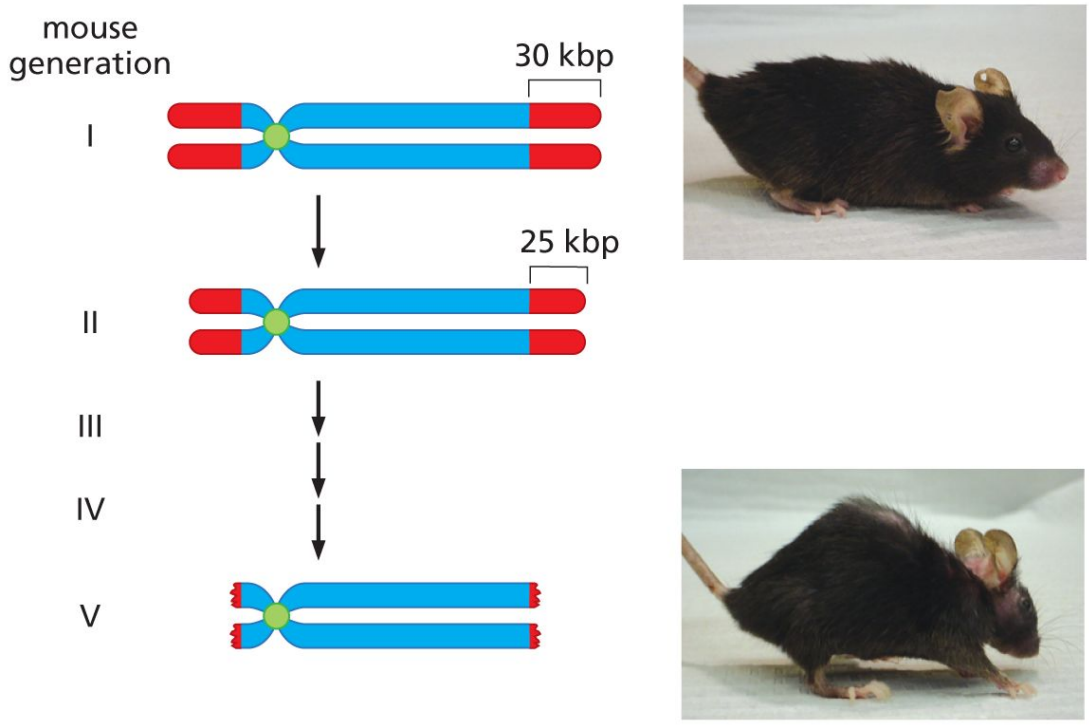
The long telomeres of laboratory mice hold additional implications: to the extent that cells derived from these mice show limited replicative ability *in vitro*, that ability is never determined by telomere shortening. In fact, mouse cells can be immortalized relatively easily following propagation in culture (which selects for cells that have avoided senescence and are spontaneously immortalized *in vitro*). Human cells, in contrast to their mouse counterparts, require the introduction of both the SV40 *large T* oncogene (to avoid senescence; see Figure 10.3) and the *hTERT* gene (to avoid crisis). As an aside, one reason for the reduced tendency of mouse cells to become senescent during *in vitro* culture may be that they fail to develop senescence-associated heterochromatic foci (SAHFs; see Section 9.11) in culture, whereas their human counterparts do so readily.

The role of telomeres in the lives of mice has been revealed dramatically by researchers who have inactivated the gene encoding the *mTR* RNA subunit of telomerase holoenzyme in the mouse germ line. As expected, the homozygous mutant

offspring of initially created heterozygous mice carrying the mutant *mTR* allele exhibit no telomerase activity in any of their cells. During their lifetimes, the telomeres of these telomerase-negative mice may shorten from approximately 30 kb down to about 25 kb; the latter length is still far longer than is required to protect chromosomal ends.

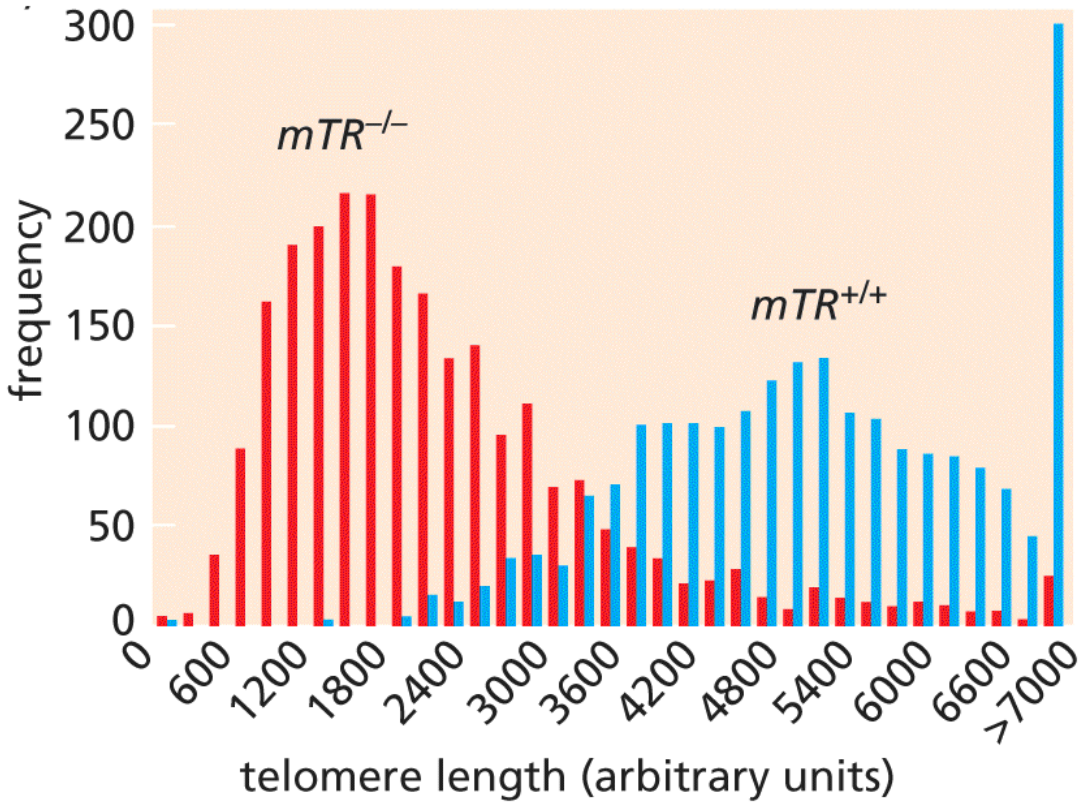
These *mTR*-negative mice are superficially indistinguishable phenotypically from wild-type mice. This absence of any readily observable mutant phenotype suggests that the telomerase holoenzyme plays no essential role in the tissues of these mammals beyond its task of maintaining telomeres. (However, detailed characterization of genetically altered mice that continue to express *mTR* but have been deprived of *mTERT* expression reveals a subtle morphogenetic defect—the conversion of a thoracic to a lumbar vertebra. This change may be caused by the association of the mTERT protein with other cellular proteins whose functions are totally unrelated to its actions on telomeres; one of these is, as an example, the complex of transcription factors that allow β-catenin to activate gene expression in response to Wnt signaling; see Figure 6.19B. The same association presumably holds true for hTERT.) Beyond this, there are several reports describing the actions of hTERT in protecting neurons against oxidative stress.

The homozygous telomerase-negative (that is, $mTR^{-/-}$) mice can be bred with one another through at least three more organismic generations without showing any discernible phenotype. Finally, however, in the fifth generation, telomerase-negative mice begin to show distinctive phenotypes—an indication that after five organismic generations without telomerase, their telomeres have eroded down to dangerously short lengths (**Figure 10.20**). These fifth-generation $mTR^{-/-}$ mice and, even more so, their progeny in the sixth generation are sickly and show a diminished capacity to heal wounds, indicative of the inability of their cells to respond properly to mitogenic signals. The sixth-generation $mTR^{-/-}$ mice suffer also from substantially reduced fertility.



An illustration of telomere shortening. In the first generation, all four telomeres on a chromosome are 30 kilobase pairs long. A normal looking mouse is shown. In the second generation, they are only 25 kilobase pairs long. By the fifth generation, they have shrunken to stubs. A hunchbacked mouse is shown.

(A)



Two overlapping frequency histograms, on a horizontal axis with telomere length ranging from 0 to 7000 in arbitrary units. Frequency ranges from 0 to 300. In wild-type mice, which are homozygous telomerase-positive, the most common telomere length is 5000 to 5200 units and there is a somewhat normal ditribution around that. In homozygous telomerase-negative mice, the most common telomere length is 1600 to 1800 units and the distribution is skewed to the right.

(B)

Figure 10.20 Erosion of telomeres over multiple generations in populations of *mTR*$^{-/-}$ mice (A) During the lifetimes of the first *mTR*$^{-/-}$ mouse generation, their telomeres, which are initially 30 kbp long (*red*), are reduced in size by about 5 kbp (*left*). These mice (*top*, *right*) are phenotypically normal, as are their descendants in the second and third generations. However, by the fifth organismic generation, the telomeres in their cells have eroded to the extent that they can no longer protect the ends of chromosomes; the tissues of these mice begin to lose their ability to renew themselves and heal wounds, and these mice begin to show symptoms of premature aging, including wasting away of muscle tissues and a hunched back (*bottom*, *right*). The relative sizes of the telomeres in these images have been exaggerated 1000-fold for the sake of illustration. (B) Telomere length

can be gauged by fluorescent *in situ* hybridization (FISH) using a probe that is specific for the telomere repeat sequence. Here the mTR^{-} allele has been bred into a strain of wild mice that normally have very short telomeres. Already in the first generation, the resulting homozygous $mTR^{-/-}$ mice (*red*) have far shorter telomeric DNA than their wild-type ($mTR^{+/+}$) counterparts (*blue*). These measurements also reveal the heterogeneous lengths of telomeric DNA within each population of mice, mirroring comparable heterogeneity within the individual cells of a mouse. Lengths are in arbitrary units. All telomeres longer than 7000 units are represented by a single bar (*far right*). (A, courtesy of R.S. Maser and R.A. DePinho. B, from L.-Y. Hao et al., *Cell* 123:1121–1131, 2005. With permission from Elsevier.)

The $mTR^{-/-}$ mice in this sixth generation already exhibit very short telomeres at birth, and their inability to subsequently maintain these telomeres, particularly in mitotically active tissues, results in widespread cell death and loss of tissue function. For example, highly proliferative tissues, such as the gastrointestinal epithelium, the hematopoietic system, and the testes, show substantial atrophy (loss of cells). These observations are striking and without parallel in the field of mouse genetics, because they demonstrate organismic phenotypes that only become manifest five or six organismic generations after a mutation has been introduced into the germ line of these animals.

Moreover, such observations dramatically demonstrate the differences between the telomeres of human cells and those of these mutant laboratory mice. Human telomeres begin relatively short, and loss of telomerase activity can lead, already in the *first* organismic generation, to severe organismic phenotypes (**Supplementary Sidebar 10.7**).

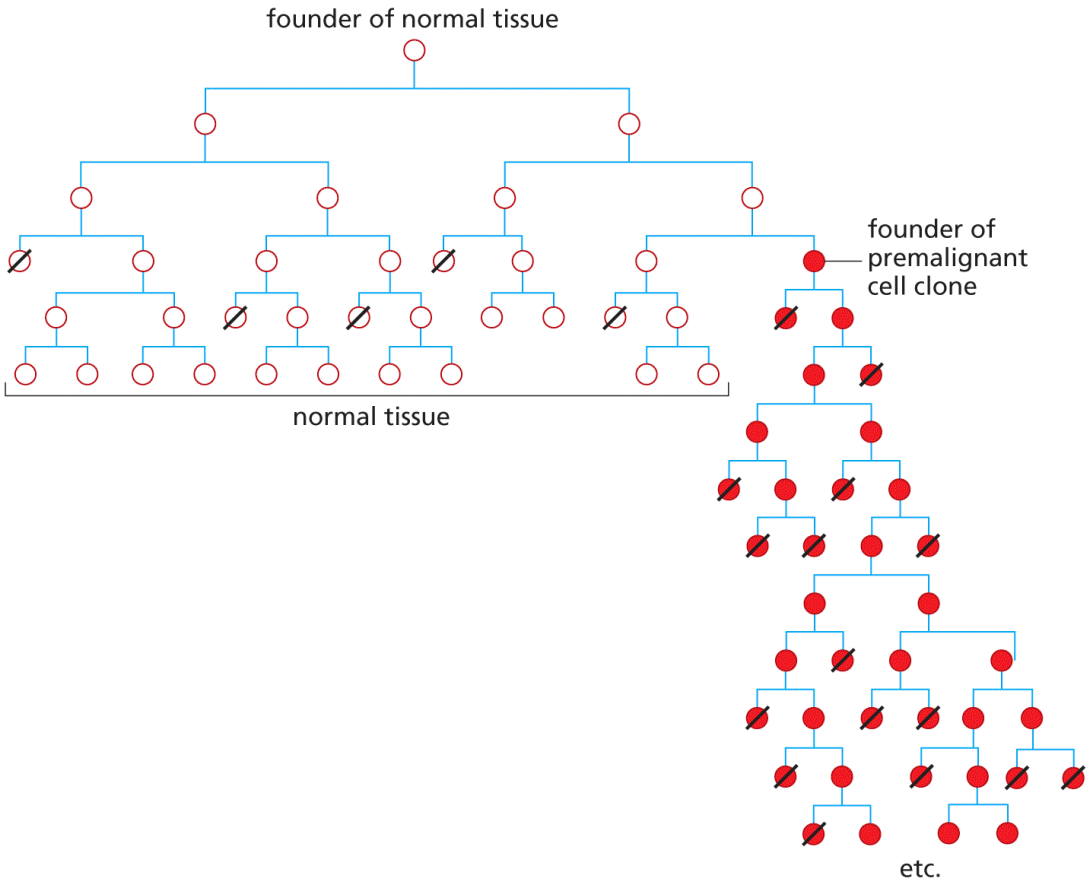
10.10 Telomerase-negative mice show both decreased and increased cancer susceptibility

Laboratory mice are susceptible to spontaneous cancers, largely lymphomas and leukemias. This background of susceptibility can be increased by experimentally introducing specific mutations into the mouse germ line that cause activation of proto-oncogenes or inactivation of tumor suppressor genes. These facts, when taken together, raise an interesting question: To what extent do the critically short telomeres in fifth- and sixth-generation telomerase-negative mice also affect the cancer rate in these animals?

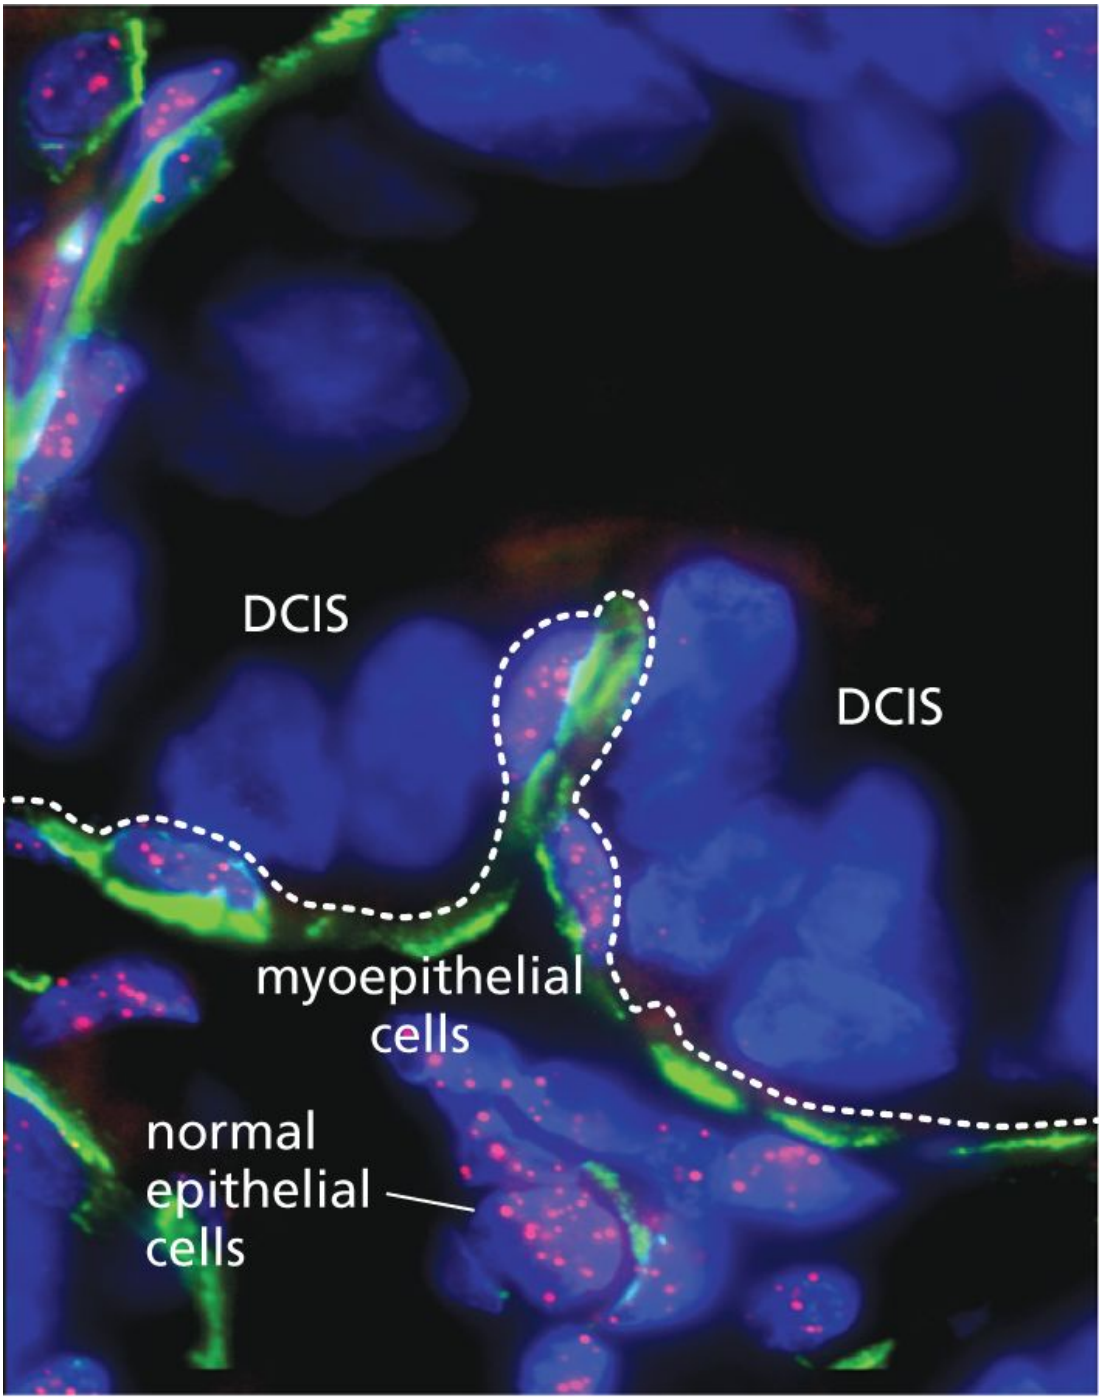
The response to this question would seem to be straightforward. We can imagine that the deterioration of cells in these *mTR*$^{-/-}$ mice leaves a barely adequate number of healthy cells to sustain tissue and organismic viability. Stem cells charged with the task of replenishing the pools of differentiated cells in these tissues will likely have great difficulty doing so.

Because the normal cells in these tissues are barely able to maintain themselves, incipient cancer cells should, by all rights, have an even more difficult time. The process of tumor development requires that clones of premalignant cells evolving toward malignancy must pass through a large number of growth-and-division cycles—a number substantially greater than those experienced by nearby normal cells (**Figure 10.21A**). Consequently, any tumor development that is successfully initiated by these cell clones is likely to be aborted long before it has reached completion (Figure 10.21B and C).



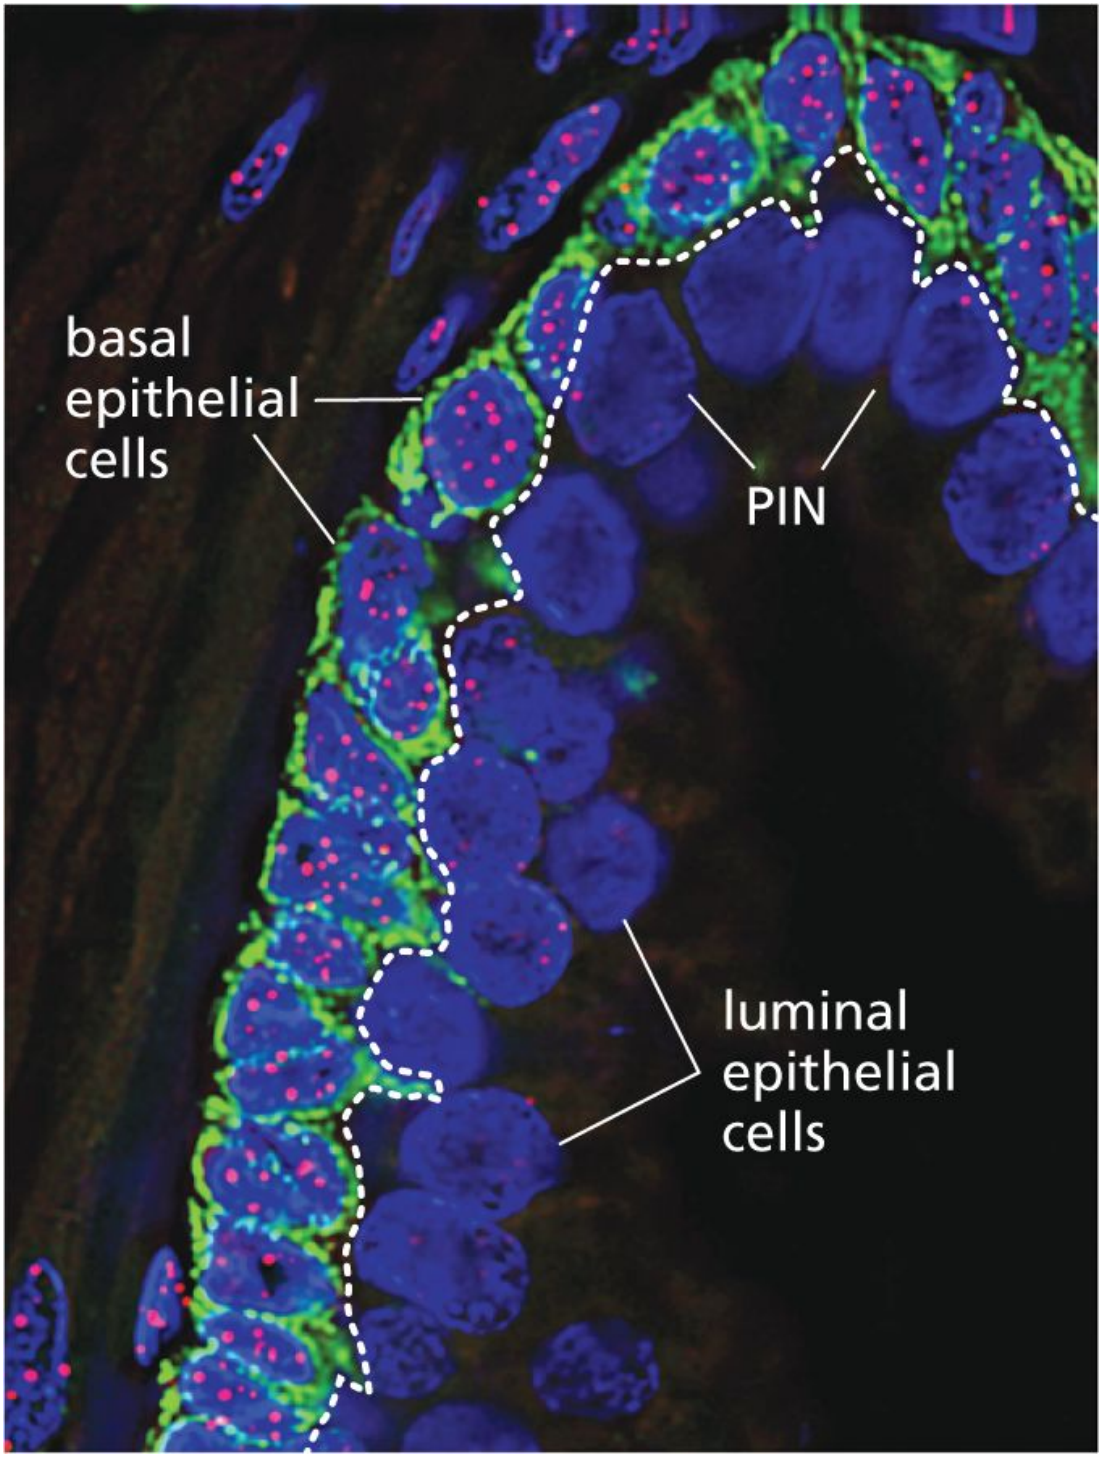
A pedigree chart that begins with a single normal-tissue founder cell. Five generations later, and with attrition, this cell has produced ten normal cells. The founder also produced, after three generations, a mutant cell that is the founder of a premalignant line. Ten generations later, and with a great deal of attrition, this mutant cell founder has produced three surviving premalignant cells.

(A)



A fluorescence microscopy image with a white dashed line undulating across it. Above the line, the only visible features are dark blue cell nuclei. This region is labeled D C I S. Below the line and running along it, bands of bright green are accompanied by many small pink dots; these bands are labeled myoepithelial cells. Farther below the dashed line is an area of pink dots without the green. This area is labeled normal epithelial cells.

(B)



A fluorescence microscopy image, with a white dashed line arcing through it. Below the line, inside the arc, the only visible features are dark blue cell nuclei, except for a few isolated green dots and pink dots. This region is

labeled P I N and also luminal epithelial cells. Above the line and following its arc is a layer of cells labeled basal epithelial cells. Each of these cells has bright green around the perimeter, enclosing a region of dark blue with many pink dots.
(C)

Figure 10.21 Normal and neoplastic cell lineages in *mTR*$^{-/-}$ mice and in humans (A) This diagram indicates the pedigree of normal cells (*open circles*) in a small patch of tissue. A founder cell in the embryo becomes the ancestor of all the cells in this tissue, e.g., all the epithelial cells. At one point, one of these epithelial cells suffers changes that make it the ancestor of the cells (*closed red circles*) that develop into a precancerous cell clone. This clone of cells must pass through many more replicative generations in order to eventually form a tumor mass. Slashes indicate the substantial attrition of cells through apoptosis or necrosis that occurs in almost every cell generation. (B) The large number of cell generations through which premalignant cells must pass en route to neoplasia results in considerable telomere erosion. In these images, telomeres are revealed by fluorescence *in situ* hybridization (FISH, *pink dots*). In normal human mammary ducts (*not shown*), telomeres are apparent in both the luminal epithelial cells and the myoepithelial cells. However, in ductal carcinoma *in situ* (DCIS), the luminal epithelial cells, which constitute the neoplastic cell population (*above dotted line*), have lost all detectable telomeric DNA, whereas the nearby normal myoepithelial cells (*below dotted line*), which have been stained for α-smooth muscle actin (*green*), still carry strongly staining telomeres. Similar behavior is seen in the normal epithelial cells (*lower left*). (In all cases, cell nuclei are stained *blue*.) (C) Similar dynamics apply in the case of prostatic intraepithelial neoplasia (PIN)—a precursor lesion to prostatic carcinoma—in which many of the luminal epithelial cells lining ducts (*below dotted line*) have lost telomeric DNA staining, while the keratin-positive (*green, above dotted line*) basal epithelial cells continue to display a strong telomeric DNA signal. (B and C, courtesy of A.K. Meeker; see also A.K. Meeker et al., *Cancer Res*. 62:6405–6409, 2002.)

In order to test these predictions, mice were first made cancer-prone by inactivating tumor suppressor genes in their germ line, in this case the locus encoding both the p16^{INK4A} and p19^{ARF} tumor suppressor proteins (see Sections 8.4 and 9.8). Such mice, as might be expected, are highly susceptible to cancer; indeed, they frequently develop lymphomas and fibrosarcomas relatively early in life. This susceptibility is manifested even more dramatically when they are exposed to carcinogens. In one set of experiments, sequential exposure to dimethylbenz[*a*]anthracene (DMBA), a potent carcinogen, followed by repeated exposures to ultraviolet-B (UV-B) radiation, led after

20 weeks to a 90% tumor incidence in the ($p16^{INK4A}$/$p19^{ARF}$-negative) mutant mice, whereas a control group of similarly treated wild-type mice had no tumors.

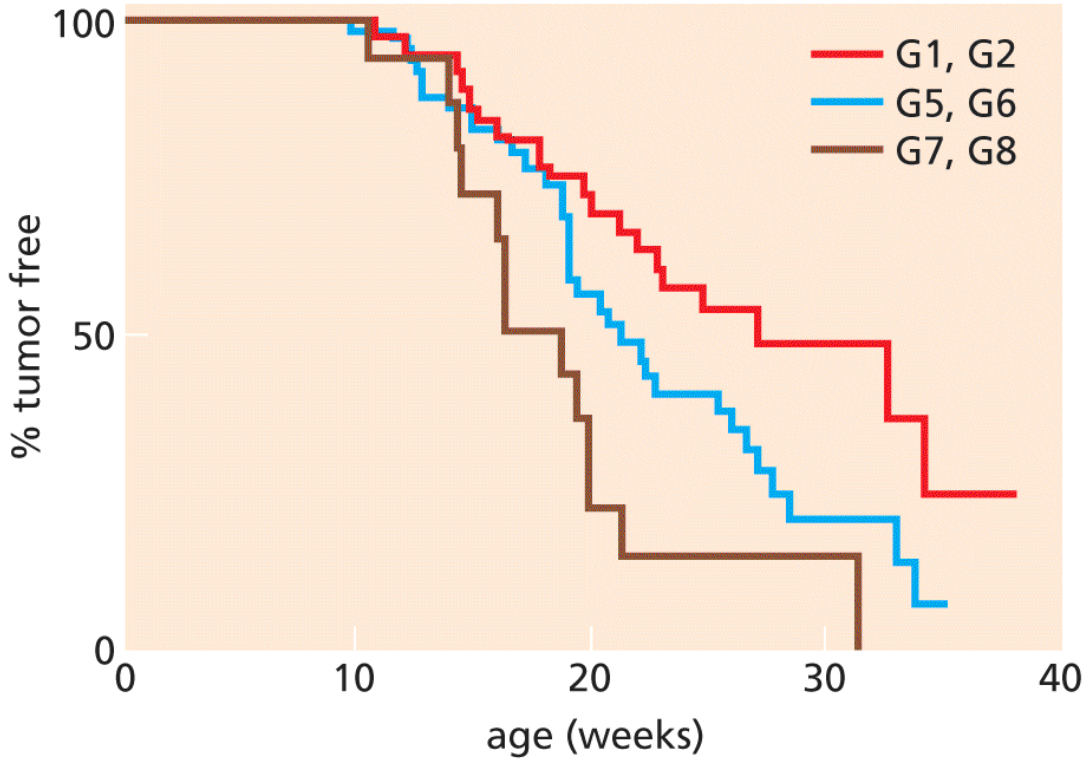
This experiment was extended by introducing the $p16^{INK4A}$/$p19^{ARF}$ germ-line inactivation into mice that also lacked *mTR*, the gene that is the counterpart of human *hTR* and therefore encodes the RNA subunit of the mouse telomerase holoenzyme (see Figure 10.13). The results were that 64% of control, telomerase-positive, $p16^{INK4A}$/$p19^{ARF}$-negative mice contracted tumors, whereas only 31% of the generation 4 and 5 $mTR^{-/-}$ $p16^{INK4A}$/$p19^{ARF}$-negative mice developed tumors. These results were even more dramatic when survival of mice after 16 weeks was measured: 88% of the telomerase-positive mice had been lost to cancer, whereas only 46% of the fifth-generation telomerase-negative mice had been lost to this disease.

This reduced rate of cancer in telomerase-negative mice fulfills the prediction that the normal tissues of $mTR^{-/-}$ mice have exhausted most of their endowment of replicative generations even before tumorigenesis has begun (see Figure 10.20B). Once tumors are initiated in these mice, incipient tumor cell populations must pass through many additional doublings before they can create macroscopic tumors. However, relatively early during the course of tumor formation, these aspiring cancer cells will be driven into crisis by telomere collapse and their agenda of forming tumors will be aborted. Indeed, in human tissues, premalignant cells that are poised to become fully neoplastic already show drastically truncated telomeres; this truncation ostensibly arises because these cell populations have passed through many more successive cell cycles than nearby normal cells (see Figure 10.21B and C).

A very different and ultimately far more interesting outcome was seen when mice were used that instead had been deprived of *p53* gene copies in their germ line (that is, rather than having had their $p16^{INK4A}$/$p19^{ARF}$ locus inactivated). Ordinarily, germ-line inactivation of the *p53* gene in mice leads, on its own, to an increased tumor incidence and resulting mortality, mirroring aspects of the Li–Fraumeni syndrome of humans (see Section 9.3). The mutant *mTR* locus was then introduced into the $p53^{+/-}$ genetic background of these mice. [The $p53^{+/-}$ genotype was used to forestall the early-onset sarcomas and leukemias that are known to arise in $p53^{-/-}$ mice; hence, loss-of-heterozygosity (LOH) and resulting conversion into the $p53^{-/-}$ genotype could be postponed for multiple organismic generations.]

When the $p53^{+/-}$ genotype was present in the genomes of fifth- and sixth-generation telomerase-negative $mTR^{-/-}$ mice, something totally unexpected was observed: the rate of cancer formation was significantly *increased* above that created by the $p53^{-/-}$ genotype alone. In addition, the spectrum of tumors, namely, lymphomas and angiosarcomas, which are commonly seen in $p53^{-/-}$ mice, was shifted in favor of

carcinomas—just the types of tumors commonly seen in humans. These trends became even more apparent in the seventh and eighth generation of telomerase-negative mice (**Figure 10.22**).



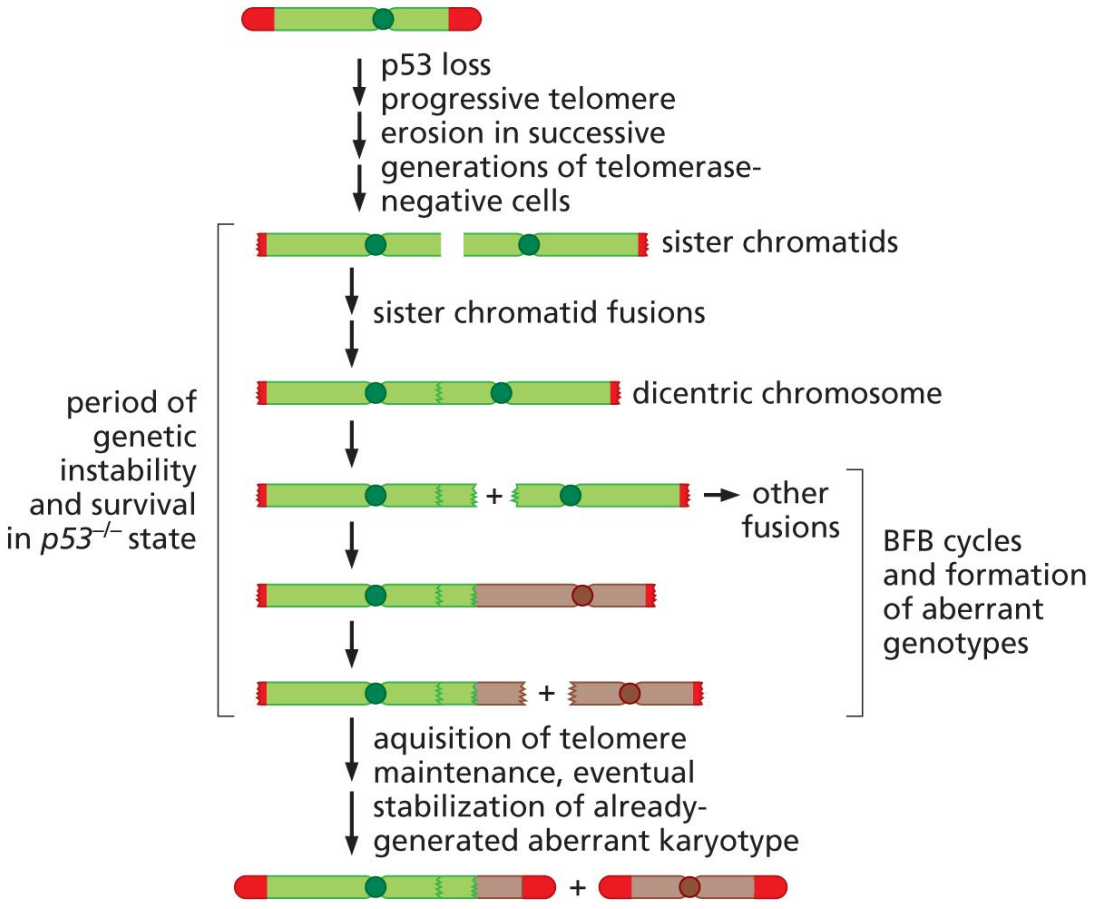
A line graph depicting percent tumor free as a function of time for three different generational cohorts of mice. In all three cohorts, tumors start to appear at age 10 weeks, but the lines descend at different rates. The time required for the line to drop to 50 percent is 17 weeks for generations 7 and 8, 20 weeks for generations 5 and 6, and 24 weeks for generations 1 and 2.

Figure 10.22 Rate of tumor formation in cancer-prone *mTR*$^{-/-}$ *p53*$^{-/-}$ mice These Kaplan–Meier plots reveal that tumor incidence actually increases with increasing organismic generation (G) in mice that lack both the *p53*- and *mTR*-encoding genes in their germ line. In generations 1 and 2 (*red*), about 50% of the mice had readily detectable tumors by the age of 24 weeks, but in generations 5 and 6 (*blue*), the mice developed tumors more rapidly. In generation 7 or 8 (*brown*), about 50% of the mice already exhibited tumors by the age of 17 weeks. (Adapted from L. Chin et al., *Cell* 97:527–538, 1999.)

How can these intriguing results be explained? We can imagine that as fifth- and sixth-generation mice exhaust their telomeres, their cells will begin to experience

chromosomal breakage–fusion–bridge (BFB) cycles (see Figures 10.9 and 10.10) and thus crisis. We already know that double-strand DNA breaks, which are formed in BFB cycles, can provoke apoptosis through a p53-dependent pathway (see Section 9.10). Hence, cells that carry functional *p53* genes and experience BFB cycles are likely to be rapidly eliminated from tissues.

As cells of fifth- and sixth-generation $mTR^{-/-}$ $p53^{-/-}$ mice experience BFB cycles, they may well struggle to stay alive because of the repeated breakage of their chromosomal DNA. However, many of these cells may manage nevertheless to survive, because a key component of their pro-apoptotic response machinery—p53—is missing. These cells will now limp through a number of growth-and-division cycles in spite of the ongoing karyotypic chaos that afflicts their genomes. All the while, their chromosomes will participate in multiple successive BFB cycles (**Figure 10.23**).



A model of how breakage-fusion-bridge cycles might promote carcinoma formation. p53 loss and progressive telomere erosion in successive generations of telomerase negative cells produce chromosomes in which each of two sister chromatids is entirely missing a telomere at one end. This begins a period of genetic instability and survival in the homozygous p53-negative state. The sister

chromatids fuse end-to-end to form a dicentric chromosome. They then break apart at a different point, and one of the parts fuses to a different broken chromatid to form a new dicentric chromosome. Again there is a break at a fresh point, leading to the B F B cycle and formation of aberrant genotypes. Finally, there is acquisition of telomere maintenance, and eventual stabilization of the already generated aberrant karyotype.

Figure 10.23 A mechanistic model of how BFB cycles promote human carcinoma formation During the early steps of tumor progression, inactivation of the *p53* tumor suppressor gene is often favored, because it allows incipient cancer cells to escape apoptotic death from oncogene activation, insufficient trophic signals, anoxia, and poisoning by metabolic wastes caused by inadequate vascularization. As tumor progression proceeds, the telomeric DNA (*red*) of evolving premalignant cell populations eventually erodes below the level needed to protect chromosomal ends. Breakage–fusion–bridge (BFB) cycles (see Figure 10.9) ensue, leading to increasing chromosomal rearrangements and the amplification and deletion of chromosomal segments adjacent to breakpoints (*not shown*); only one BFB cycle is shown here. Centromeres are *dark green* and *dark brown.* Cells undergoing BFB cycles would normally be eliminated by p53-induced apoptosis. In the absence of p53 function, however, such cells may survive, albeit with scrambled karyotypes that slow their proliferation. Emerging from such cell populations will be variants that have learned how to regenerate telomeres and thereby stabilize their karyotype; such cells can once again grow rapidly. In cells of the mutant $mTR^{-/-}$ mice, this stabilization may be achieved through the activation of the ALT telomere maintenance system, whereas in wild-type (e.g., $mTR^{+/+}$) organisms (including human cancer patients), de-repression of hTERT expression allows reconstruction of telomeres to proper length. Once telomeres have been regenerated in all chromosomes, further karyotypic disorder resulting from BFB cycles will be halted. However, any karyotypic aberrations generated previously will be perpetuated in descendant cell populations.

These cycles may continue for many cell generations because p53 will not be on watch to trigger apoptosis and eliminate these cells. As a consequence, the genomes of such cells will become increasingly scrambled by the nonreciprocal chromosomal translocations generated by the BFB cycles. In addition, and perhaps even more important, there is evidence that dsDNA breaks lead to the amplification or deletion of the chromosomal regions adjacent to these breaks. Thus, the areas of densely concentrated genomic damage termed chromothripsis and nearby focal areas of point mutations termed kataegis (see Section 12.11) have been ascribed to the localized breakdown of genomic order triggered by anaphase bridges.

Although these BFB cycles will not prove to be immediately fatal for the p53-negative cells, the cycles will surely compromise their proliferative ability. As a result, individual cells in these populations will be under great selective pressure to escape these BFB cycles and to reacquire karyotypic stability; once they do so, they will be able to grow more rapidly. In these mouse cells, however, the acquisition of telomerase activity is not an option (because of the germ-line knockout of both *mTR* gene copies). For this reason, they will be forced to resort to activating the ALT telomere maintenance system (see Section 10.8). Having done so, these cells will stabilize whatever aberrant karyotypes arose since the time when their ancestors first lost functional telomeres and will begin to grow robustly again.

Clearly, the scrambled karyotypes that these cells have acquired generate novel combinations of genes (including many translocated, deleted, and amplified genes), and among the novel genotypes that are created, there will likely be some that fortuitously *favor* neoplastic proliferation. Stated differently, the period of genetic instability appears to *increase* the probability that cancer-promoting genetic configurations will be produced. Such reasoning explains how collapsing telomeres in a p53-negative background can actually promote the development of tumors (see Figure 10.23).

These $mTR^{-/-}$ mice have human counterparts: as described in **Supplementary Sidebar 10.7**, patients suffering the dyskeratosis congenita syndrome involving germ-line mutations in one or another gene involved in telomere maintenance often go on to develop cancer once their collapsing hematopoietic systems have been successfully reconstructed by bone marrow transplantation. Some develop hematopoietic malignancies (myelodysplasia and acute myelogenous leukemia) or carcinomas of the gastrointestinal tract. These neoplasias arise in those tissues that undergo constant, intense proliferation—precisely the sites where telomeres might become rapidly eroded in the absence of telomerase activity, resulting in repeated breakage–fusion–bridge cycles.

10.11 The mechanisms underlying cancer pathogenesis in telomerase-negative mice may also operate during the development of human tumors

These observations of genetically altered mice, when taken together, lead us to consider a most interesting mechanistic model (see Figure 10.23) that explains why aneuploidy is seen in the great majority of human carcinomas. Imagine that relatively early in the long process of human tumor development, cells in premalignant cell populations are able to jettison their *p53* gene copies. The selective pressure favoring this particular genetic loss might occur, for example, because cells in the early premalignant cell populations experience anoxia and, in turn, suffer from p53-induced apoptosis. Alternatively, *p53* gene copies may have been shed by incipient cancer cells in order to escape oncogene-triggered apoptosis.

Some time after the loss of p53 function, as tumor progression proceeds, cells in these premalignant populations will begin to experience substantial telomere erosion (see Figure 10.21) and eventually telomere collapse because, like most types of normal human cells, they lack significant levels of telomerase activity. Repeated BFB cycles will ensue and result in aneuploidy. However, because these cells also lack functional p53, they will be able to survive and even continue to proliferate, albeit slowly.

Sooner or later, in this population of cells suffering BFB cycles, a cell will emerge that has acquired the ability to de-repress *hTERT* gene expression and, having done so, has gained the ability to prevent further BFB cycles, thereby stabilizing whatever karyotype it acquired during the BFB cycles. With telomerase on hand, we can imagine that this cell will repair the frayed ends of its chromosomal DNA molecules and once again enjoy robust growth. Of course, the belated appearance of telomerase on the scene cannot unscramble the considerable aneuploidy that accumulated during the time window that began with telomere collapse and ended with the acquisition of *hTERT* expression. (The same arguments will apply in the event that the ALT mechanism, rather than telomerase activation, is exploited to protect the genomes of these cells from further BFB cycles.)

Observations of human pancreatic cancer progression provide support for this model. Relatively early in the long, multi-step process of tumorigenesis in the pancreas (see **Supplementary Sidebar 11.3**), the mitotic cells in low-grade adenomas have few of the anaphase bridges that are characteristic of BFB cycles. However, more advanced, highly dysplastic adenomas show large numbers of these bridges. Still later, the even more advanced, *in situ* carcinomas once again exhibit lower levels of anaphase bridges. This behavior reinforces the model, described above, that proposes that BFB cycles and associated chromosomal instability are found only in a defined window of time during the course of multi-step tumor progression.

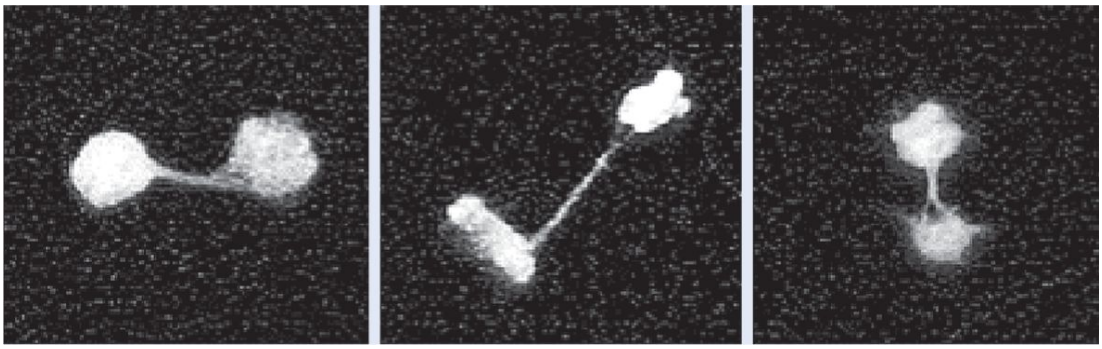
Additional support for this model comes from a study of human carcinomas of the esophagus, colon, and breast. In each case, tumors possessing relatively short telomeres are strongly associated with poor long-term prognosis, whereas tumors carrying long telomeres are associated with a far better prognosis, including greater long-term survival. Here, once again, we can imagine that the chromosomes of cancer cells with sub-optimal telomere lengths undergo relatively frequent breakage–fusion–bridge cycles, perhaps because they express hTERT at levels that are barely adequate to maintain telomeric DNA. These BFB cycles will create an ongoing chromosomal instability that continues throughout the life of the tumor to generate novel, scrambled genotypes, some of which may happen to favor advantageous phenotypes, such as more rapid proliferation and increasing aggressiveness. Certain human chronic inflammatory conditions, which are associated with increased risks of cancer, may also be attributable to eroded telomeres and BFB cycles (**Sidebar 10.6**).

Sidebar 10.6 Telomere collapse may contribute to cancer in organs affected by chronic inflammation

In Chapter 11, we will read about a number of human tumors arising in tissues that suffer continuous loss of cells resulting from chronic infections or inflammation. Such ongoing attrition of cells, which may occur over a period of decades, occurs in tissues affected by, for example, ulcerative colitis, Barrett's esophagus, and hepatitis B or C virus infection. In response to losses of differentiated cells, the stem cells in these tissues are continually producing replacements to ensure maintenance of tissue functions. These stem cells are therefore forced to pass through many more cycles of growth and division than are the corresponding stem cells of normal tissues. The resulting repeated cell cycles may tax the regenerative powers of the stem cell pools and lead eventually to telomere collapse, to the triggering of breakage–fusion–bridge cycles, and to the generation of karyotypes that favor neoplastic cell proliferation.

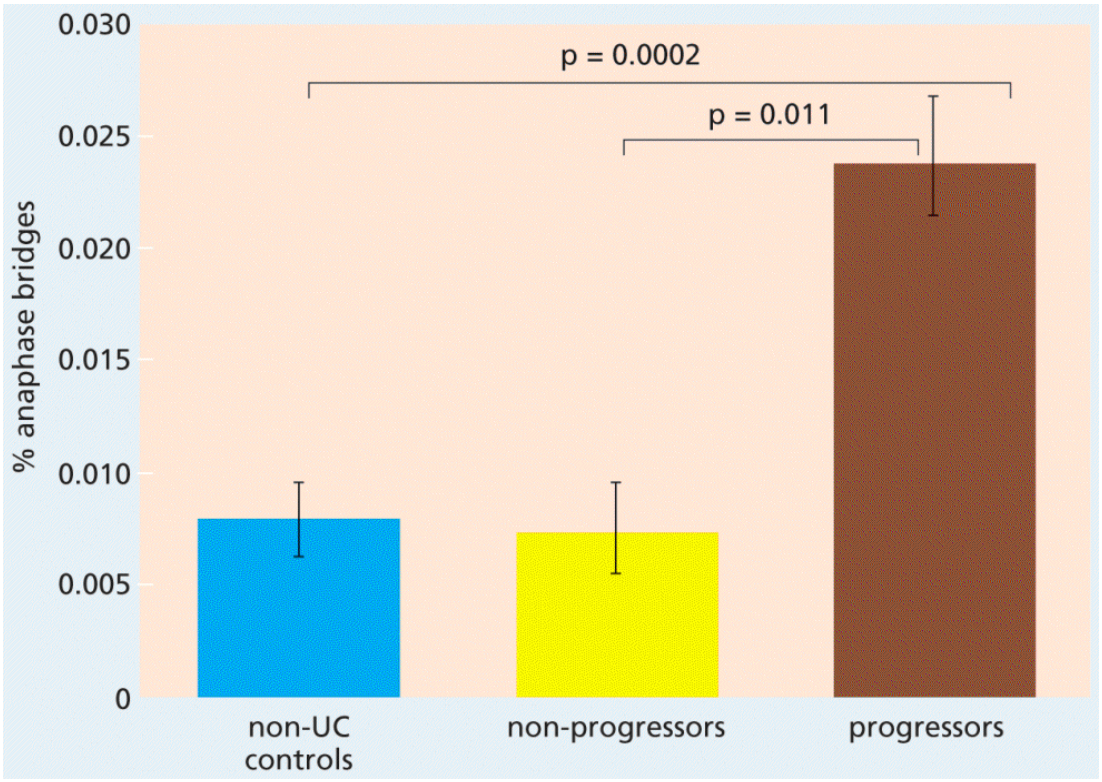
Such a mechanism may well account for the observed high rates of cancer in individuals suffering from these inflammatory and infectious diseases. In fact, in the intestinal epithelial cells of individuals suffering from ulcerative colitis, one can often

find the anaphase bridges that are telltale signs of BFB cycles and hence of telomere collapse—precisely what we would expect if telomere collapse were contributing to the formation of the colon carcinomas seen in these patients (**Figure 10.24**). Similarly, anaphase bridges have been documented in the cells of Barrett's esophagus (see Figure 2.12), a condition in which the reflux of stomach acid causes a high turnover of esophageal epithelial cells that leads, with significant frequency, to esophageal carcinomas.



Three images of cell pairs connected by thin anaphase bridges.

(A)



A bar graph showing the percent with anaphase bridges for three types of cells. For the non-U C control cells, the percent is 0.008. For non-progressors, it is 0.0075. For progressors, it is 0.024, with a p value of 0.002 compared to non-U C controls and a p value of 0.011 compared to non-progressors.

(B)

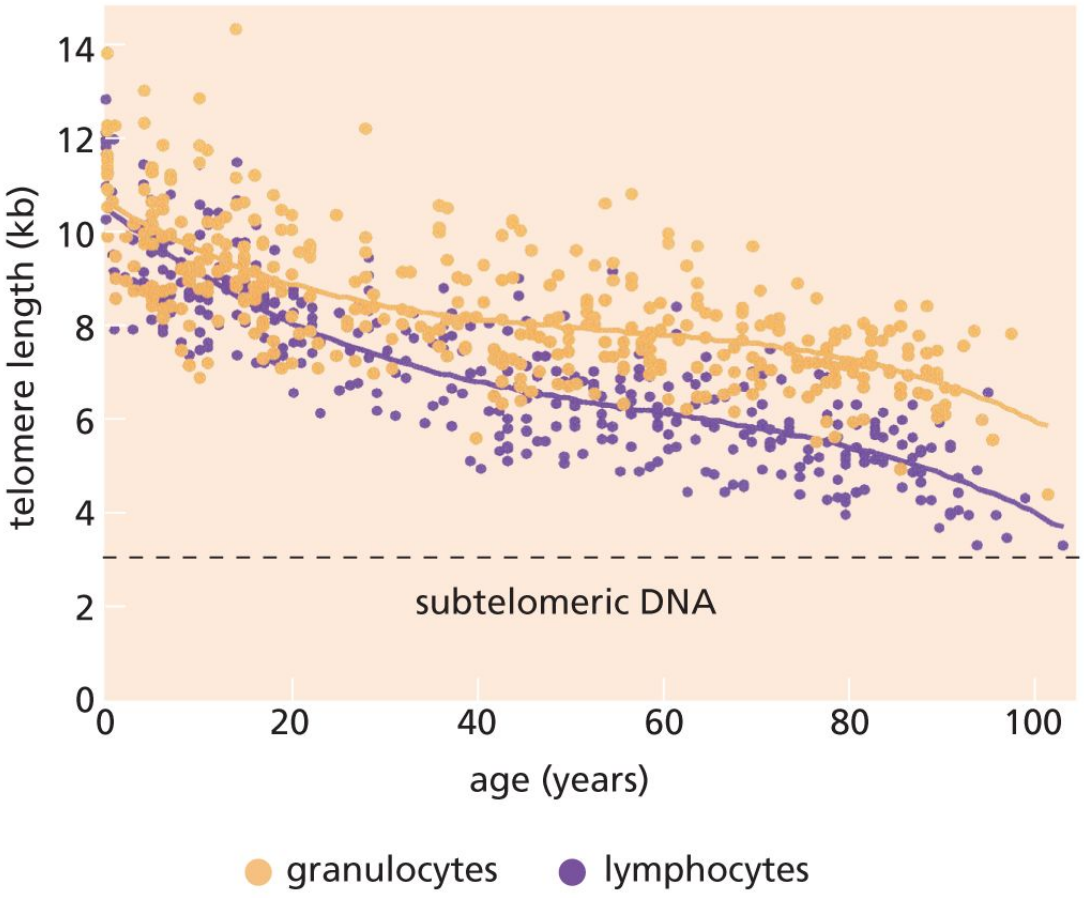
Figure 10.24 Ulcerative colitis and anaphase bridges Ulcerative colitis (UC) involves chronic irritation and inflammation of the colonic epithelium. These provoke ongoing turnover of colonic epithelial cells that can continue for several decades. UC leads, with significant frequency, to the development of colon carcinomas. (A) UC patients can be separated into “progressors,” whose colitis has led to the appearance of one or more carcinomas, and “non-progressors,” who show no evidence of intestinal tumors. The colonic epithelial cells of progressors frequently display the anaphase bridges characteristic of BFB cycles seen here (see also Figure 10.10), as well as extensive shortening of telomeres and numerous karyotypic aberrations (*not shown*). (B) Colon tissue samples from normal control individuals and UC non-progressors show relatively few anaphase bridges, but much greater numbers are found in the inflamed epithelium of the progressors. This indicates a correlation between the occurrence of anaphase bridges and the onset of tumor development. The p values indicate the probability of these differences arising by chance. (From J.N. O’Sullivan et al., *Nat. Genet.* 32:280–284, 2002. With permission from Nature.)

This model provides an attractive mechanism that explains how many types of human tumor cells acquire highly aneuploid karyotypes. Although not directly demonstrated, it is widely assumed that the resulting aneuploid genomes confer growth advantages on these cells by creating novel oncogenes through translocations, by increasing the dosage of growth-promoting proto-oncogenes, and by eliminating tumor suppressor genes that have been holding back cell proliferation. Hence, these BFB cycles may be instrumental in accelerating tumor progression because they increase genomic mutability and allow evolving, premalignant cells to explore a multitude of novel, potentially advantageous genotypes.

Yet other observations are consistent with this thinking but hardly prove it. For example, the leukemia cells in about two-thirds of acute myelogenous leukemia (AML) patients exhibit a normal karyotype, whereas cells from the remainder exhibit various types of karyotypic disarray. Those AML tumors with normal karyotype exhibit significantly longer telomeres than do those with a scrambled karyotype, consistent with the notion that eroded telomeres are associated with and possibly responsible for the derangement of normal karyotype. Of additional interest, a hypomorphic allele of *hTERT*—one that specifies reduced enzyme function—is

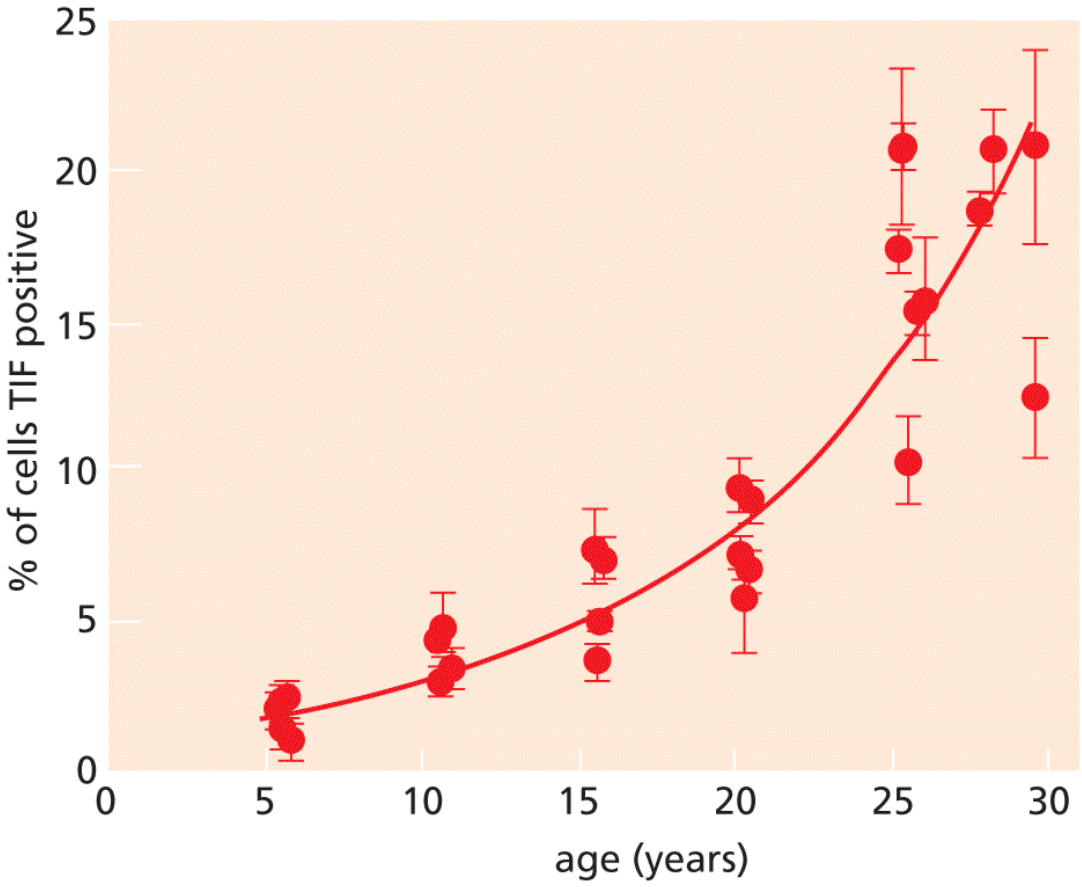
carried by as many as 1% of individuals in the general population. Significantly, individuals inheriting this allele—which confers only 60% of normal hTERT function—are overrepresented by a factor of 3 among AML patients. This finding suggests that normal cells throughout the bodies of these patients have a reduced ability to maintain normal telomere lengths, which in turn may predispose these people to the development of this form of leukemia. Indeed, those afflicted with dyskeratosis congenita (see **Supplementary Sidebar 10.7**) have a greatly increased risk of developing myelodysplastic syndrome, which in turn leads, with significant frequency, to AML.

These observations of premature, pathological shortening of telomeres lead to another question: Is the significantly increased cancer-associated incidence and mortality among the elderly (see Figure 11.1) attributable, at least in part, to *normal* telomere shortening? Exhaustive measurements of telomere lengths in normal humans do indeed indicate marked telomere erosion with increasing age. The data from measurements, such as those provided in **Figure 10.25A**, yield three conclusions: (1) In some (and perhaps most) human tissues, telomeres shorten progressively with increasing age. (2) The rate of shortening differs in different tissues, ostensibly because of differing mitotic activity in the cell lineages and differing expression of telomerase function in various stem cell compartments. (3) The scatter on each curve indicates substantial inter-individual variability in the lengths of telomeric DNA early in life or rates of telomere shortening during a lifetime. (In addition, the telomeres within a single cell exhibit differing, chromosome-specific lengths.)



A line graph depicting telomere length as a function of time. At birth, the average telomere length in both granulocytes and lymphocytes is about 10 kilobase pairs. This number immediately begins to decline, although it levels off somewhat in middle age, at roughly 8 k b p in granulocytes and 6 k b p in lymphocytes. Decline accelerates again in later life, so that at age 100, telomere length averages roughly 6 k b p in granulocytes and 4 k b p in lymphocytes. A dashed line runs across the bottom of the graph at about 3 k b p. This line is labeled subtelomeric D N A.

(A)



A line graph depicting percent of cells that are T I F positive as a function of time. The concave-up curve starts at around 2 percent at age 5 and rises past 20 percent by age 30.

(B)

Figure 10.25 Telomere shortening, aging, and cancer (A) Telomeric DNA lengths were measured in the lymphocytes and granulocytes of 400 individuals. As is apparent, the length of telomeres decreased progressively with increasing age in both human cell types. Inaccuracy in measuring telomere lengths is ±0.5 kb. The horizontal line (*dashed*) represents the threshold length below which telomeric DNA can no longer protect chromosomal ends from end-to-end fusions. (B) TIFs (telomere dysfunction–induced foci) were scored in dermal fibroblasts from baboons of various ages. These TIFs were scored wherever there was a congruence within a cell between γ-H2AX, a marker of double-strand DNA breaks (see Chapter 12), and telomeric DNA; they represent unrepaired and ostensibly irreparable dsDNA breaks. Their accumulation suggests that telomere erosion (and resulting cell senescence) represents one force in driving the aging process in certain tissues and, quite possibly, an important source of the age-

related increase in cancer incidence in older humans. (A, courtesy of G.M. Baerlocher and P. Lansdorp. B, from U. Herbig et al., *Science* 311:1257, 2006. With permission from AAAS.)

Other research, not described here in detail, yields a highly relevant observation: individuals whose normal circulating lymphocytes exhibit relatively short telomeres are overrepresented in cohorts of patients suffering from head-and-neck, bladder, lung, and renal carcinomas. In this case, the lymphocytes are presumed to be representative of normal cells throughout the body, suggesting that short telomeres in one's normal tissues represent a lifelong increased risk for developing various types of carcinomas. This also raises the question of whether the behavior of $mTR^{-/-}$ mice described above is applicable to that of aged humans, or more specifically, whether it contributes to the greatly elevated cancer incidence observed in older humans (Figure 10.25B).

These speculations still do not address an issue raised by some observations cited earlier: the repeated BFB cycles in $mTR^{-/-}$ $p53^{-/-}$ mice affect the *types* of tumors that these mice exhibit, causing them to develop carcinomas, which are common in humans, rather than hematopoietic and mesenchymal malignancies, which are frequently seen in mice. Precisely how does telomere biology possibly help to explain why cancers tend to arise in some tissues and not others?

10.12 Synopsis and prospects

Telomeres are now known to be major determinants of the ability of cells to multiply for a limited number of growth-and-division cycles before halting proliferation and entering into crisis. The resulting circumscribed proliferative potential of normal human cells appears to operate as an important barrier to the development of cancers by limiting the proliferation of pre-neoplastic cell clones. This mechanistic model of cell immortalization and cancer pathogenesis is elegant, if only because it is so simple. Still, the simplicity of this model should not obscure the fact that much of telomere structure and function remains poorly understood, and some of the conclusions described in this chapter may one day require substantial revision.

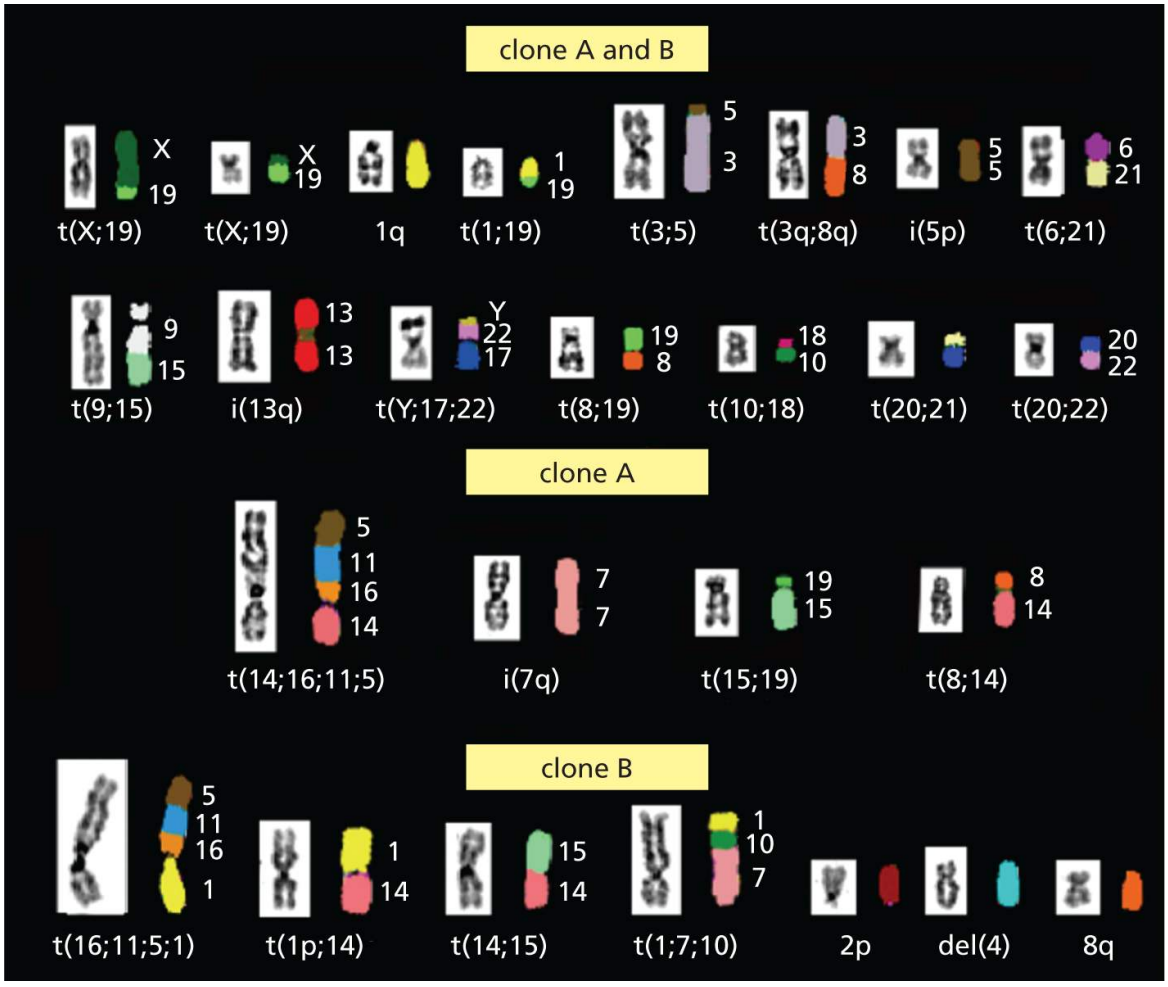
Among the many unresolved issues are the connections between the findings described in this chapter and a major problem of biomedical research: Does age-related telomere shortening contribute to the dramatically increased rates of cancer in the elderly? In the next chapter, we will examine the multi-step process of tumor formation and observe that each requisite step often takes years to complete; these kinetics, on their own, can be invoked to explain the age-related onset of cancer. However, now we may need to invoke an additional mechanism to explain the onset of tumors in aged individuals: perhaps their significantly eroded telomeres occasionally trigger the BFB cycles and genetic instability that fuels the formation of tumors.

These questions inevitably return to a focus on the telomerase enzyme and its function. Interestingly, during the earliest stages of development, specifically soon after egg fertilization, telomeres may be relatively short soon after fertilization. However, in the cleavage-stage embryo, a telomerase-independent, interchromosomal recombination mechanism similar to ALT generates the long telomeres that are present in the soon-to-be-formed blastocysts. Thereafter, telomerase is expressed in tissue-specific stem cells (which are committed to one or another differentiation lineage) and at very low levels in more differentiated cells (**Supplementary Sidebar 10.8**).

Although several types of stem cells have been found to express readily detectable levels of telomerase, this activity is apparently unable to maintain telomeres at a constant size. Evidence for this comes from the progressively shortening telomeres that are seen with increased life span. (Because the

differentiated cells that make up the great majority of cells in most tissues are generally a small number of cell generations removed from the stem cells within their respective tissues, the progressive telomere shortening seen in these differentiated cells must reflect the status of telomeres in the corresponding stem cell precursor.)

The experiments with the telomerase-negative mice described here underscore the consequences associated with the absence of telomerase and critically shortened telomeric DNA: in the presence of functional p53, such cells will enter crisis and die in large numbers—a mechanism that serves to obstruct the further expansion of clones of pre-neoplastic cells. However, without p53 on the job, critically shortened telomeres fail to trigger crisis and instead may lead the cell into multiple breakage–fusion–bridge cycles that create widespread genetic instability (**Figure 10.26**); this increased mutability can accelerate the progression of incipient tumors.



Three groups of chromosomes, shown in color beside their black and white micrograph images. The top group, containing 15 chromosomes, is labeled clones A and B. Below that, a group labeled clone A contains 4 chromosomes, and below that a group labeled clone B contains 7 chromosomes. Most of the chromosomes are shown in more than one color, indicating that parts from two different normal chromosomes have fused. The few chromosomes shown in a single color are the result either of truncation of a normal chromosome or the fusing of two copies of the same original part.

Figure 10.26 Karyotypic chaos Here, use of the SKY technique to "paint" each chromosome its own characteristic color revealed that numerous chromosomes belonging to two subclones (A and B) of a human bladder carcinoma cell line have participated in translocations. The translocations are indicated by the many chromosomes that carry segments originating from two or more normal human chromosomes. Each translocation is identified by a "t" followed by the number of each parental chromosome from which these arms derive. An "i" indicates an isochromosome, in which a single arm of a chromosome has been duplicated. The notation "p" and "q" indicates the short and long arms of normal human chromosomes, respectively; "del" indicates that a chromosomal segment has been deleted. The label "clone A and B" indicates aberrant chromosomes shared by the two subclones, while "clone A" and "clone B" indicate chromosomes that are present uniquely in one or another of these subclones. The translocations shared in common by the two subclones are likely to have occurred before these cells were introduced into culture, whereas those present in either one subclone or the other indicate ongoing chromosomal instability in culture. Comparable degrees of aneuploidy can be observed in cancer cells that have recently been introduced into culture. (From H.M. Padilla-Nash et al., *Genes Chromosomes Cancer* 25:53–59, 1999.)

There are still many puzzles associated with hTERT and telomeres that require clarification. Ectopic hTERT expression can operate to protect certain types of cells against p53-induced apoptosis. Provocatively, this protection is also afforded by a mutant of hTERT that lacks catalytic activity. Similarly, in zebrafish, knockdown of the *zTERT* gene results in compromised hematopoiesis (formation of various blood cells); this effect can be reversed by a mutant of zTERT that lacks the TERC-binding domain and therefore lacks bona fide telomerase activity. In addition, overexpression of a TERT mutant lacking reverse transcriptase activity stimulates hair growth in mice. Multiple reports indicate that hTERT

lacking its *hTR* subunit can be found in mitochondria, where it appears to have a role in conferring resistance to death triggered by reactive oxygen species (ROS). Yet another mystery is created by the discovery of TERRA (telomere repeat-containing RNA), a long noncoding RNA (lncRNA) of heterogeneous size that is transcribed from the C-rich strand of telomeric DNA and participates in some important fashion in the maintenance of the telomere-associated chromatin.

Certain non-telomerase-associated functions of hTERT may one day be associated with another biochemical activity of hTERT: it associates in the nucleus with the Brg-1 protein, a chromatin-modifying enzyme, and thereby amplifies Wnt-β-catenin–stimulated transcription. This function may explain why the use of immunofluorescence to localize hTERT protein demonstrates that it is distributed along the lengths of chromosomes rather than being concentrated at telomeres.

Cells that have been deprived of hTERT activity by siRNA-mediated knockdown have a markedly decreased ability to repair their DNA following exposure to several types of mutagens. This effect also cannot be easily related to any effects of hTERT on telomeric DNA. Recall as well that certain cells maintaining their telomeres via the ALT mechanism (which generates very long telomeres) cannot be readily transformed by an introduced *ras* oncogene but can readily be transformed if they are supplied with an ectopically expressed hTERT. Diverse observations like these indicate that maintenance of telomere length is only one facet of the function of the apparently multi-talented hTERT protein.

Replicative senescence, as controlled by telomere erosion, has been portrayed as one mechanism whereby the unlimited replicative power of cell lineages is constrained. In recent years, this thinking has been challenged by two types of findings. First, the onset of this process can be affected, sometimes dramatically, by altering conditions of *in vitro* cell cultures. From this perspective, the timing of replicative senescence can no longer be viewed as a cell-autonomous process that counts the number of cell generations separating cells from their ancestors in the early embryo. Second, as cited above, various lines of research indicate that hTERT has multiple functions that are clearly distinct from telomere maintenance. Taken together, these findings raise the question of whether the ability of the hTERT protein to allow cells to circumvent senescence is tied to one of its functions that is unrelated to elongating telomeric DNA.

Importantly, these findings do not jeopardize another key concept: that severe telomere erosion triggers crisis in human cells and that ectopic expression of

hTERT can prevent or allow escape from the ensuing, almost-certain death. Moreover, whether or not replicative senescence, as originally defined with cultured cells, is a real phenomenon, it is clear that certain forms of senescence (for example, oncogene-induced senescence) operate in living tissues, where they seem to serve as an impediment to the forward march of pre-neoplastic cells, as discussed in Chapter 9.

Arguably the most direct and compelling proof of the importance of telomeres and telomerase in cancer pathogenesis comes from experiments that will be described in detail in the next chapter: a clone of the *hTERT* gene has been found to be an essential ingredient in the cocktail of introduced genes that are used experimentally to transform normal human cells into tumorigenic derivatives. Without the presence of *hTERT*, experimental human cell transformation fails.

The central role of telomerase in fueling the growth of cancer cells has long suggested a novel, highly effective strategy of anti-cancer therapy. Telomerase inhibitors should prove to be potent in killing cancer cells that carry relatively short telomeres—the situation observed in many telomerase-positive human tumor cells. Such drugs, if developed, should at the same time have little if any effect on normal cells throughout the body, which express relatively low levels of telomerase and then only transiently during S phase. Although attractive in concept, this plan may be derailed by certain realities. First, attempts by a number of pharmaceutical companies to develop novel low–molecular-weight inhibitors of hTERT catalytic function have repeatedly failed to yield potent, highly specific drug molecules. The reasons for these failures are still obscure. Second, no one knows whether the relatively low levels of telomerase enzyme detectable in certain types of normal cells throughout the human body play a significant role in the proliferative capacity and viability of these cells. Consequently, the side effects of anti-telomerase drugs, should these agents be developed, are unpredictable.

The failures to generate drug-like inhibitors of hTERT function have led some to embrace an alternative strategy—the construction of a chemically modified 13-nucleotide-long RNA molecule that is complementary to the template region of the *hTR* RNA subunit of the holoenzyme (see Figure 10.13). This potent inhibitor of the telomerase holoenzyme yields rapid responses in telomerase-positive cancer cells propagated in culture, reducing detectable telomerase activity by 90 to 95%; the testing of its clinical efficacy is under way. Nonetheless, the therapeutic utility of this very promising agent, specifically its ability to elicit durable clinical responses, may be frustrated by one of the realities of telomere

biology cited above: short-term decreases in tumor burden may be followed by the emergence of cancer cells and thus tumors that have switched to the ALT state of telomere maintenance, thereby becoming hTERT-independent. Accordingly, the goal of exploiting the widespread expression of hTERT in human tumors to generate novel, cancer-specific therapeutics may continue to prove elusive.

OceanofPDF.com

Key concepts

- Two barriers prevent cultured cells from replicating indefinitely in culture—senescence and crisis.
- Senescence involves the long-term residence of cells in a nongrowing but viable state; crisis involves the apoptotic death of cells.
- Senescence is provoked by a variety of physiological stresses that cells experience *in vitro* and also *in vivo*, where it seems to play a significant role in constraining neoplastic progression.
- Crisis is provoked by the erosion of telomeres, which results in widespread end-to-end chromosomal fusions, karyotypic chaos, and cell death.
- Most premalignant cells escape from crisis by activating expression of hTERT, the telomerase enzyme, which is specialized to elongate telomeric DNA by extending it in hexanucleotide increments.
- A minority of incipient cancer cells escape crisis by regenerating their telomeric DNA through the ALT mechanism.
- Cells that have stabilized their telomeres through the actions of telomerase or the ALT mechanism can then proliferate indefinitely and are therefore said to be immortalized.
- Cell immortalization is a step that appears to be a prerequisite to the development of all human cancers.
- The end-to-end chromosomal fusions that accompany crisis lead to repeated breakage–fusion–bridge (BFB) cycles, which appear to be responsible for much of the aneuploidy associated with the karyotypes of many kinds of solid human tumors.
- These BFB cycles may prove to be an important means by which incipient cancer cells acquire mutant alleles, thereby expediting the formation of fully neoplastic cells.

Thought questions

1. Why is the acquisition of an immortalized proliferative potential so important for human tumors?
2. What types of evidence connect telomeres and telomerase to enter into the senescent state, and what alternative mechanisms are responsible for entrance into this state?
3. What complications and side effects might result from the shutdown of telomerase activity by anti-cancer drugs that may be developed in the future and function as specific inhibitors of this enzyme?
4. How does the molecular configuration of the t-loop protect the ends of telomeric DNA?
5. How does the telomerase-associated *hTR* RNA molecule facilitate the maintenance of telomeric DNA by the hTERT enzyme?
6. Precisely how do breakage–fusion–bridge cycles confer an advantage on populations of premalignant cells?

Supplementary Sidebars

Supplementary Sidebar 10.1 Differentiated cell lineages pass through dramatically different numbers of cell generations

All the cells in the body trace their ancestry back to a fertilized egg. In principle, these cells are members of cell lineages that exhibit diverse differentiation programs but nonetheless have all passed through comparable numbers of cell generations since their origins in the early embryo. Metazoan biology complicates this scheme, because the functions of some differentiated tissues require continual cell divisions (to replace ongoing attrition of cells), whereas other tissues or cell types do not require continuous replacement and therefore pass through a relatively small number of cell cycles during a human lifetime; neurons in the brain are examples of such cells that are largely quiescent during a human lifetime. These differences in proliferation can be gauged through various techniques, one of which is illustrated in **Figure S10.1**.

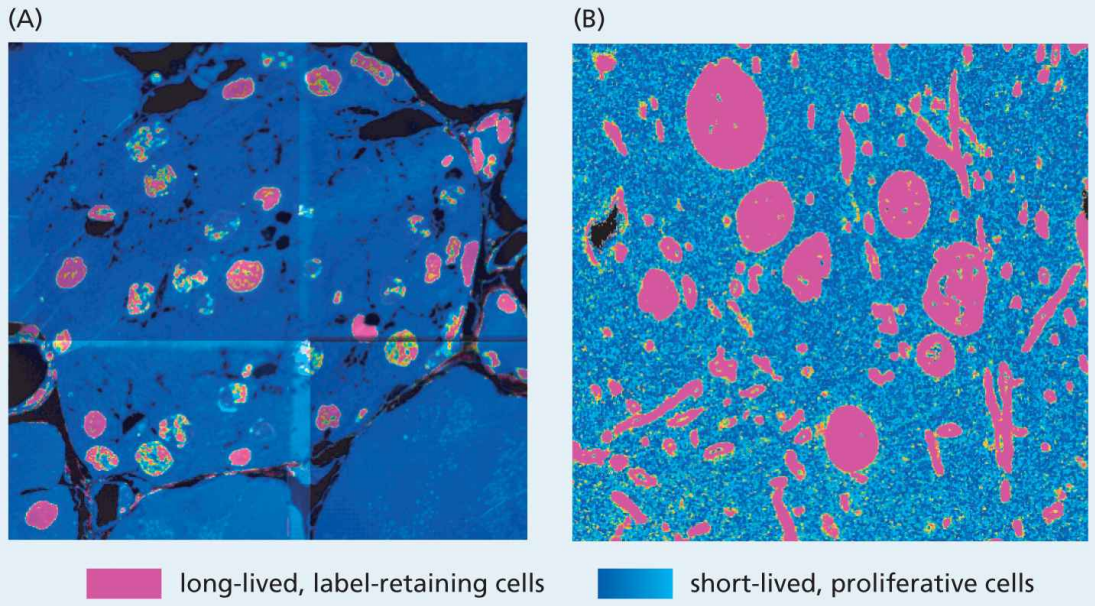

Figure S10.1 Differences in cell turnover within individual tissues The turnover of cells within living mouse tissues can be estimated by exposing mice to feed containing ^{15}N isotope for a period of time, halting such exposure after a period of time, and examining the ratio of ^{15}N vs. ^{14}N (the more abundant N isotope) in cells many months after the isotopic labeling was initially performed. Cells that retain a high ratio of $^{15}N/^{14}N$ are those that have not proliferated significantly since the initial labeling and therefore have not diluted the initially

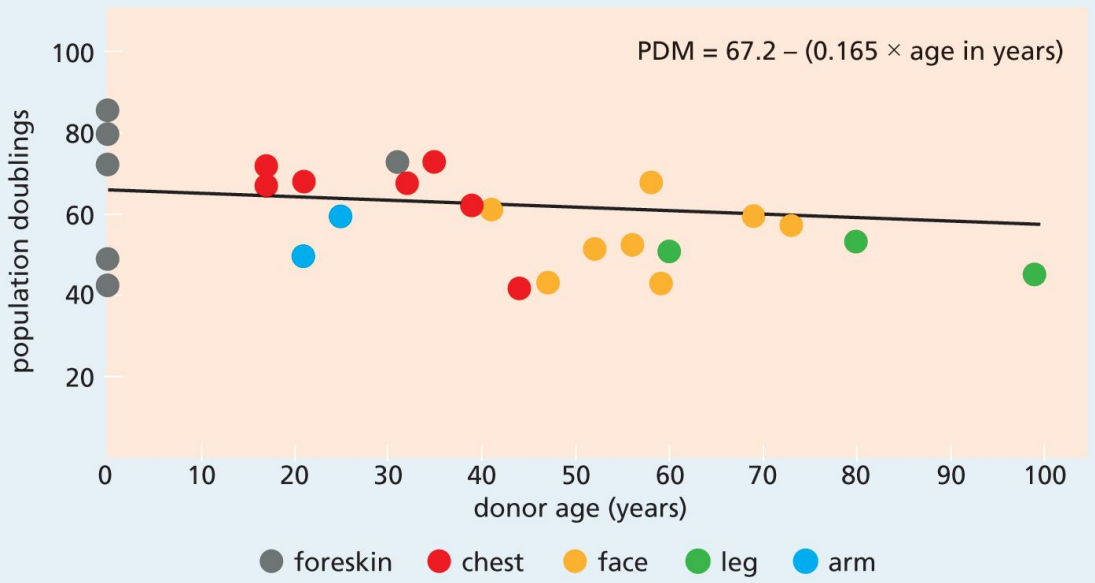
incorporated ^{15}N label. These cells and their ratios can be monitored and visualized using the techniques of scanning electron microscopy and multi-isotope imaging mass spectrometry. (A) Cells in the pancreatic islets of Langerhans of a mouse exposed to ^{15}N label for the first 45 days of life (a "pulse" label) followed by 18 months without further isotope labeling (a "chase"). (B) Neuronal cells in the mouse cortex of a mouse exposed for the first 45 days of life to ^{15}N isotope followed by 6 months without further isotope labeling. *Pink* indicates a high $^{15}N/^{14}N$ ratio indicating retention of ^{15}N label over extended periods of time and thus absence of extensive proliferation, whereas *blue* indicates a low $^{15}N/^{14}N$ ratio, indicating extensive proliferation and loss of ^{15}N label. (Reprinted from *Cell Metabolism*, Volume 30, Arrojo e Drigo, et al., Age Mosaicism across Multiple Scales in Adult Tissues, Fig. 3, Copyright 2019 with permission from Elsevier.)

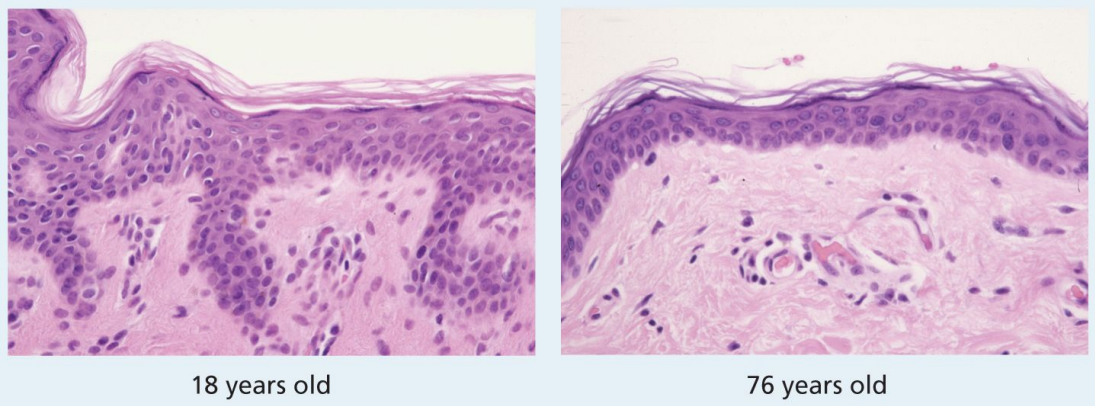
The profound differences in proliferation hold important implications for the development of cancer. Thus, certain types of differentiated cells that are effectively post-mitotic during a lifetime are unlikely or less likely to be the sources of tumors because (1) they may have developed, during the course of their differentiation, powerful regulatory controls that effectively preclude their entrance into the active growth-and-division cycle as discussed in Chapter 8, and (2) in the absence of proliferation, they are far less likely to acquire the somatic mutations that are critical to drive tumor formation forward. Arguably the most dramatic example of this phenomenon is provided by the epidemiology of retinoblastoma, which rarely occurs after the age of five; the end of the time window for disease diagnosis appears to occur relatively early in life, when most cells in the retina enter irreversibly into a post-mitotic state.

Supplementary Sidebar 10.2 The proliferative capacity of cells in aging tissues

As illustrated in **Figure S10.2A**, the proliferative ability *in vitro* of cells taken from humans is influenced in part by the age of the donor from whom the cells were prepared. The causes of this may be complex. Among them may be the cumulative genetic damage that lineages of cells have sustained over the course of many decades of time and cumulative oxidative damage to other critical cell constituents. Yet other mechanistic explanations can be entertained, including the main topics of this chapter —telomere and telomere shortening. In addition, as seen in Figure S10.2B, the cellular composition of the human skin changes, with the loss of the keratinocyte-regenerating stem cell niche, contributing to the outer appearance of the skin associated with aging.



(A)



(B)

Figure S10.2 Loss of proliferative capacity with age (A) The proliferative capacity of cells can be gauged by determining the number of times they will double in culture (mean population doublings, PDM). Here, doublings of dermal fibroblasts from various anatomical sites were measured as a function of the age of the donors. (Because of inter-individual variability in cell proliferative capacity, the data points show substantial scatter around the mean at each age.) (B) As the keratinocyte stem cells in the skin lose proliferative capacity with increasing age, the overall ability of the skin to regenerate itself declines, leading to a thinning of the keratinocyte layer of the skin (*dark pink*) and a loss of the ridge architecture seen in the younger skin. The sun-protected skin of an 18-year-old female (*left*) is compared here with that of a 76-year-old female (*right*). (A, courtesy of J.G. Rheinwald and T.M. O'Connell-Willstaedt. B, courtesy of T. Brenn.)

Supplementary Sidebar 10.3 Replicative senescence—a tissue culture artifact?

The phenomenon of replicative senescence has been portrayed as a physiological mechanism whose purpose is to limit the number of successive cell generations that a cell lineage can pass through. According to this logic, this cap on the number of cell generations should constrain and block the further expansion of cell populations beyond the normal needs for tissue assembly and maintenance, stopping their proliferation long before they have had the opportunity to grow into large, life-threatening tumors. Indeed, as the work of Leonard Hayflick (see Figure 10.2) showed in the 1960s, normal cells propagated in tissue culture halt their proliferation after 40 to 60 doublings, entering into a state that he termed "senescence"; the resulting senescent cells remain viable but lose the ability to ever re-enter the active growth-and-division cycles described in Chapter 8.

However, as tissue culture conditions have improved in the half-century since Hayflick's pioneering studies, the relevance of replicative senescence to the proliferative abilities of cells in living tissues has come into question. Thus, several lines of research have indicated that changes in growing conditions in Petri dishes can have profound effects on the timing of replicative senescence. As an example, some experimenters have altered the ambient oxygen tension to which cultured cells are exposed by reducing from ~21% (the ambient level of O_2 that is present both in the general atmosphere and in most tissue culture incubators) to the 1–3% O_2 that is more representative of the physiologic oxygen tensions encountered in living tissues; this change results in a substantial increase in the replicative life span *in vitro*. In one set of experiments, cells passed through 50% more doublings when cultured in 3% rather than 21% O_2 (**Figure S10.3A**). Thus, these lower oxygen tensions more closely reflect those that most cells experience in living tissues, rather than the ambient tension that is most conveniently provided to cells growing in a tissue culture incubator.

Figure S10.3 Influence of culture conditions on the onset of senescence (A) The proliferative capacity of cell populations (*ordinate*) has been measured here when they are exposed in culture to either 3% or 20% O_2. The 3% oxygen concentration is far more physiological, because it reflects the oxygen concentration that many cells actually experience in living tissues. (B) The normal dependence of epithelial cells in living tissues on stromal support creates stresses when such cells are propagated *in vitro*. When grown as pure cultures directly on the bottom plastic surface of a tissue culture dish, human foreskin keratinocytes rapidly induce expression of the $p16^{INK4A}$ tumor suppressor protein (*green line*), which imposes growth arrest and senescence on these cells. However, when these epithelial cells are grown above a feeder layer of fibroblasts (*brown line*), they can proliferate for an extended period of time without experiencing a strong induction of $p16^{INK4A}$ and resulting senescence. (C) The composition of both tissue culture medium and tissue culture plates can also have a dramatic effect on the longevity of cell populations in culture. The graph shows a population of human mammary epithelial cells (MECs) propagated either in the standard medium for human MECs (*brown line*) and in a standard plastic culture dish or in a specially devised medium (*green line*) on a special plastic surface. After 21 d in culture (*arrow*), $p16^{INK4A}$ and p53 levels were monitored by immunoblotting (*right panel*). Growth under standard conditions led to strong induction of these two growth-suppressing proteins, whereas cells in the special medium continued to proliferate without giving evidence of such induction. (A, from Q. Chen et al., *Proc. Natl. Acad. Sci. USA* 92:4337–4341, 1995. With permission from National Academy of Sciences, U.S.A. B, from B. Fu, J. Quintero and C.C. Baker, *Cancer Res.* 63:7815–7824,

2003. With permission from American Association for Cancer Research. C, from T. Ince et al., *Cancer Cell* 12:160–170, 2007. With permission from Elsevier.)

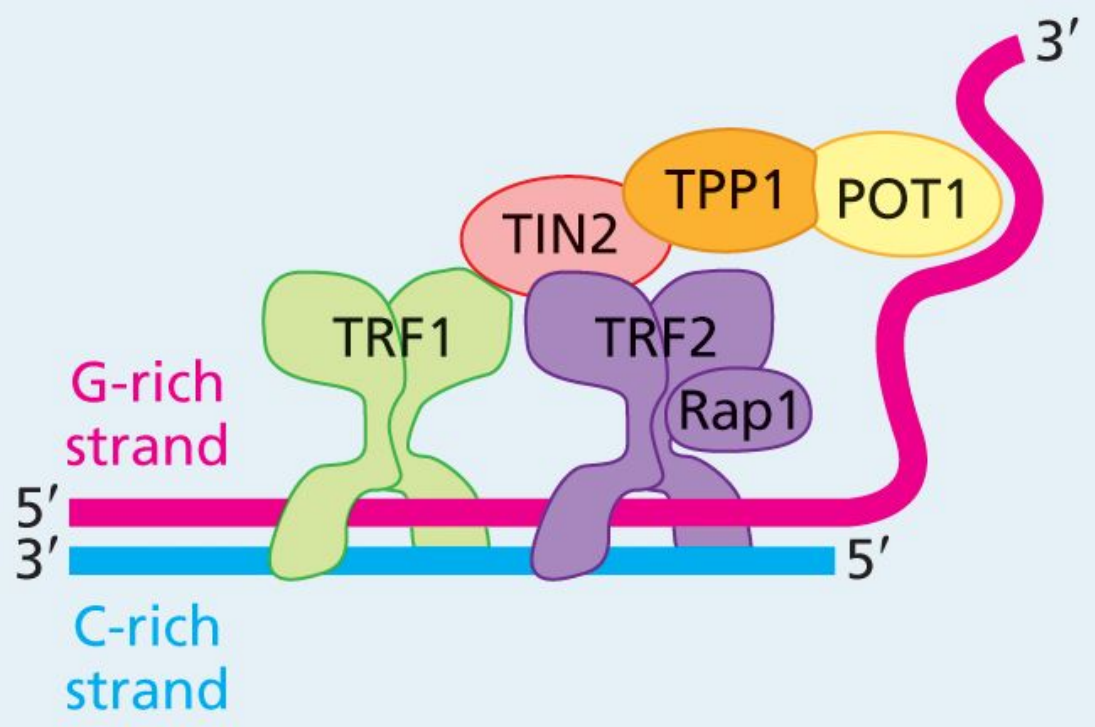
Yet other conditions of culture also have strong effects on the longevity of cell populations. In the case of epithelial cells, the presence of an underlying stromal feeder layer has profound effects on the ability of these cells to survive and proliferate in culture (Figure S10.3B). As discussed in Chapter 13, the normal epithelial cells within living tissues rely on continuous biological support from adjacent underlying stromal cells of various types; attempting to propagate such cells as pure epithelial populations in a Petri dish deprives them of this normal source of critical support. The composition of the medium in which cells are cultured also appears to be an important determinant of the schedule of induction of $p16^{INK4A}$ and p53 expression, which impose cell-cycle arrest once expressed (Figure S10.3C). When human mammary epithelial cells are propagated in a standard medium, they soon become senescent. However, if they are placed in a specially devised medium, the induction of $p16^{INK4A}$ and p53 and entrance into the senescent state can be postponed for many weeks (see Figure S10.3C). Indeed, as researchers have devised cell culture conditions that more closely approach the conditions experienced by cells within tissues, the life span of cell lineages in culture has increased progressively and senescence *in vitro* can be delayed and, in certain cases, avoided altogether. Hence, "replicative senescence" may only reflect stress that cells have sustained because of sub-optimal conditions of culture.

Experiments like these yield an important conclusion: the term "senescence" is actually misleading. Although originally invoked to imply the *aging* of cells in culture, entrance into this state may often have little to do with elapsed time or number of successive cell doublings. This raises the issue of whether replicative senescence is nothing more than an artifact of *in vitro* culture and thus whether it ever occurs *in vivo*. One response to this comes from discussions of another form of senescence that we already encountered in Section 9.11.

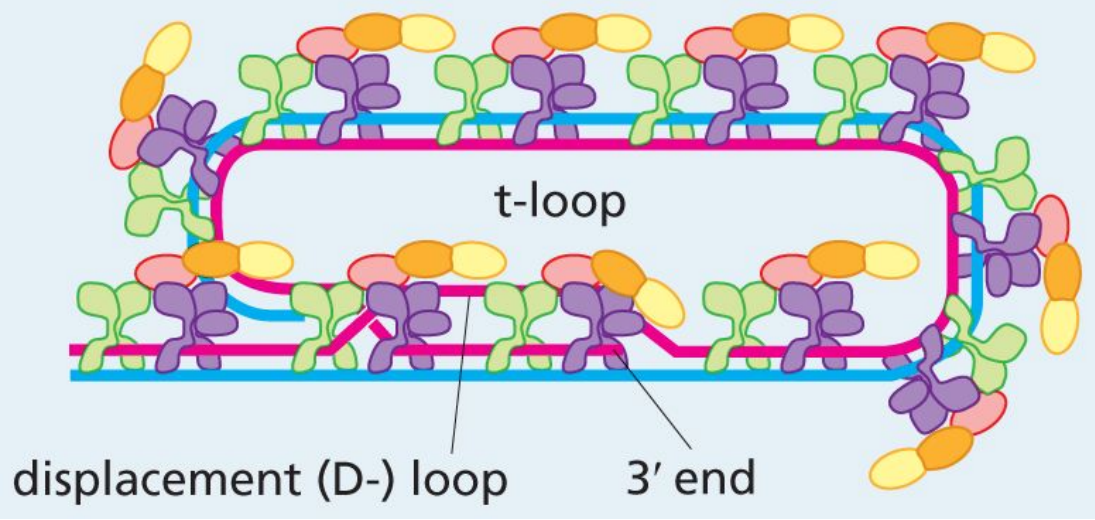
Supplementary Sidebar 10.4 Telomere-associated proteins

A complex of six proteins, which together has been termed shelterin, associates with telomeric DNA and is critical to the ability of telomeres to resist end-to-end fusions with other DNA molecules (**Figure S10.4**). Loss of one of these —TRF2— led to the single giant chromosome seen in Figure 10.6B. Importantly, the shelterin complex is found to be associated with the long telomeric DNAs present in cells that maintain their telomeres via the ALT complex (see Section 10.8), indicating that the intervention of telomerase is not critical for the association of shelterin proteins with telomeric

DNA. Moreover, the t-loops formed by telomeric DNA can also be found in ALT cells, indicating that their formation also does not depend on the actions of telomerase.



(A)



(B)

Figure S10.4 Multiple telomere-specific proteins bound to telomeric DNA (A) In addition to its complex structure (see Figure 10.11), telomeric DNA is protected from degradation by a group of physically associated proteins that constitute the

shelterin complex. Two of the latter's proteins—TRF1 and TRF2—bind to the double-stranded DNA portion of telomeres, and a third protein—POT1—binds to both the single-stranded 3′ overhang created by the G-rich strand and the ssDNA in the displacement (D-) loop. (B) The shelterin complex is present in multiple copies per telomere and is responsible, in part, for maintaining the structure of the t-loop. As is indicated here, by binding to the D-loop, POT1 is able to stabilize this structure and thus the structure of the t-loop as a whole. (A and B, from T. de Lange, *Science* 326:948–952, 2009. With permission from AAAS.)

Supplementary Sidebar 10.5 TRAP assay for quantifying telomerase activity

The levels of hTERT in normal and neoplastic cells are relatively low, ostensibly reflecting the low amounts of the enzyme needed to service the small number (92) of substrate molecules per human cell. This complicated the development of assays for quantifying telomerase

activity and led, in turn, to the invention of an assay, termed the Telomeric Repeat Amplification Protocol, which depends on the actions of the polymerase chain reaction (PCR) to greatly amplify the signal through use of a telomeric DNA-derived primer and a second primer of arbitrary sequence (**Figure S10.5**).

Figure S10.5 Detecting telomerase activity (A) The telomeric repeat amplification protocol (TRAP) assay permits detection of minute levels of

telomerase activity in cell lysates by relying on the polymerase chain reaction (PCR) to amplify the products of the telomerase enzyme. A primer consisting of arbitrary nontelomeric sequences (*black*) and telomeric hexanucleotide sequences (from the G-rich strand; *light pink*) is added to a cell lysate in the presence of deoxyribonucleotide triphosphates. This primer is extended (*darker pink*) by any telomerase that may be present in a cell lysate. The thermostable Taq polymerase is then added together with a primer from the C-rich strand (*dark blue*), and the second strand is elongated (*light blue*). These two DNA strands are then denatured and recopied repeatedly by the PCR in the presence of appropriate primers. (B) The products of the TRAP reaction are analyzed by gel electrophoresis to resolve DNA molecules differing in size by hexanucleotide increments. As a negative control, brief heat treatment of a portion of the lysate is used at the beginning of the reaction to denature and inactivate any telomerase that may be present (*1st channel*); this heat treatment is done to determine whether any heat-resistant DNA polymerases are present in the lysate in addition to the telomerase itself. In this experiment, pre-crisis cells were infected with an expression vector that specifies hTERT, the catalytic subunit of the telomerase holoenzyme, thereby inducing high levels of telomerase activity that are readily detectable when both high (*2nd channel*) and low levels (*3rd channel*) of cell extract are tested. Supplementary Sidebar 10.6 Ciliates are a rich source of telomerase

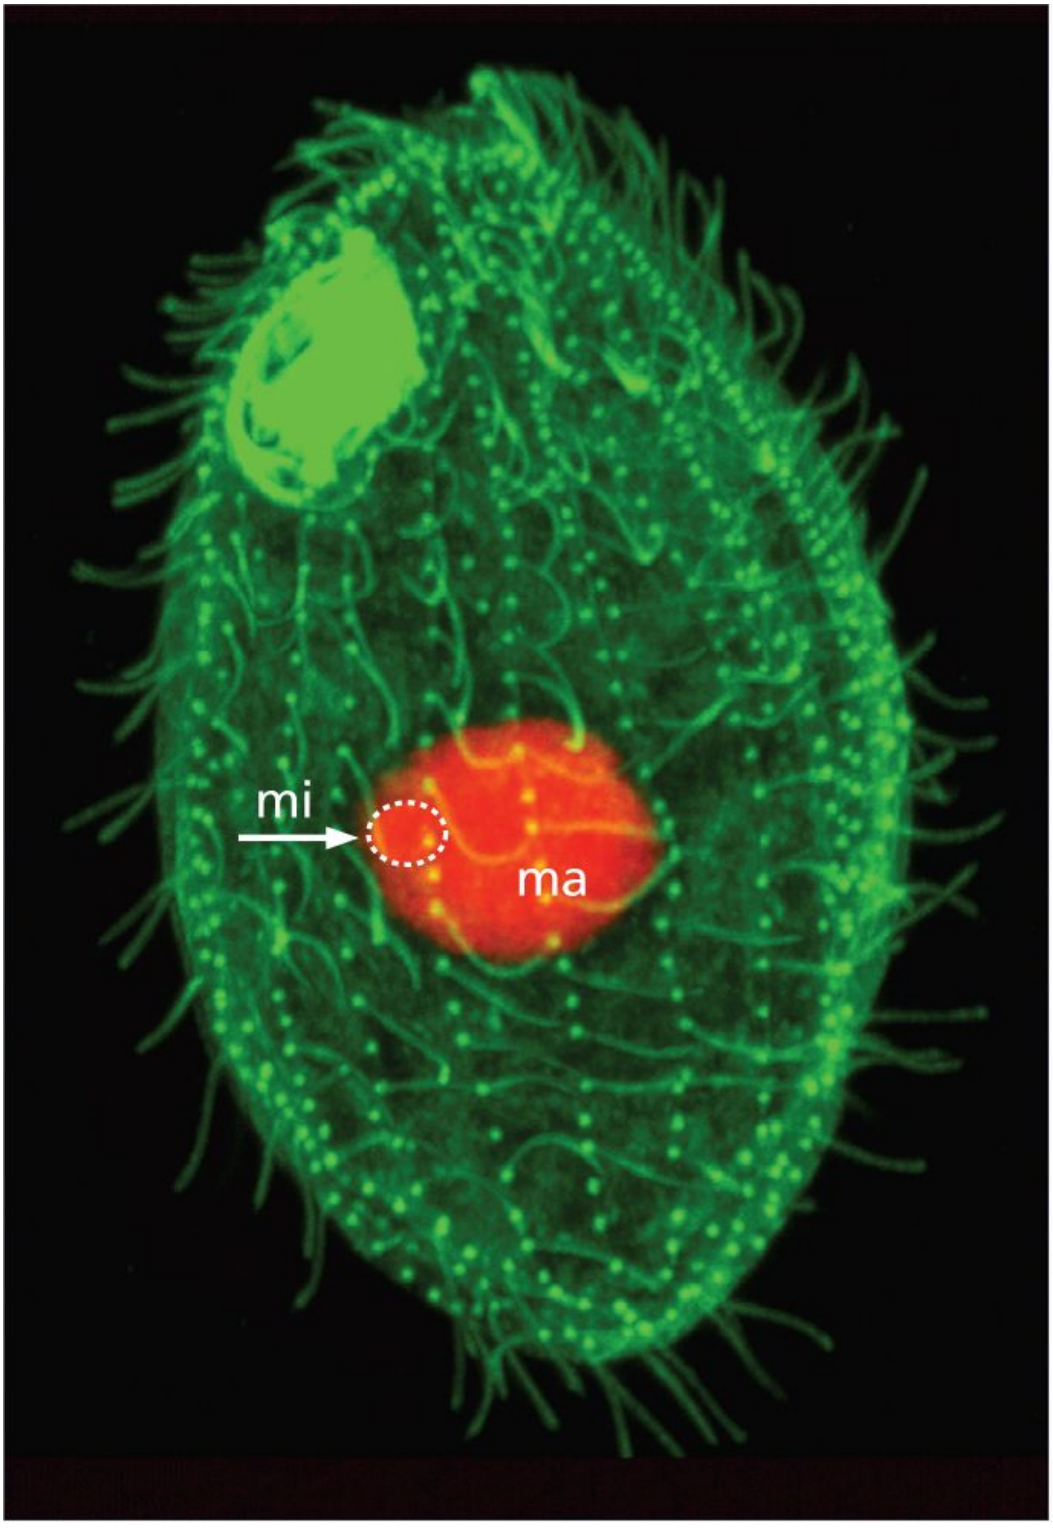
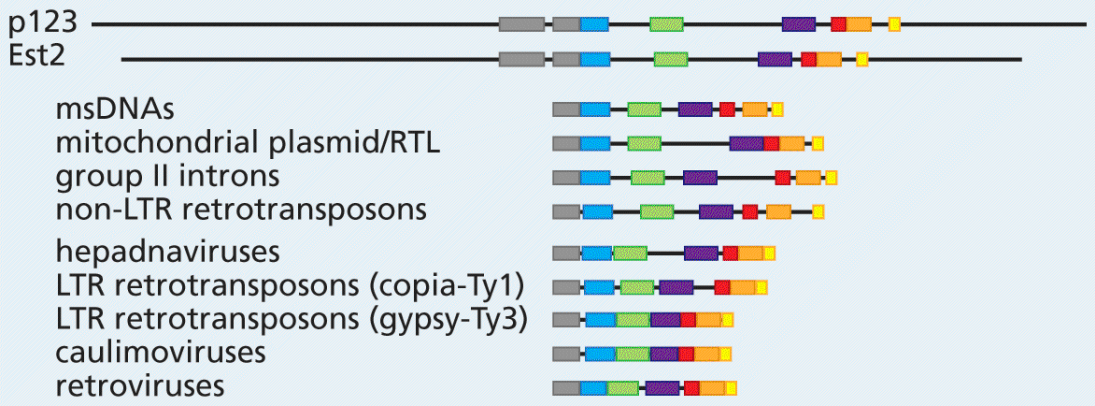
Ciliates are unicellular eukaryotes that belong phylogenetically to the diverse kingdom of Protozoa. Ciliates are very large cells, as such cells go, so they require proportionately greater gene expression in order to generate the large quantities of cellular components needed for cell doubling. Ciliates solve this problem by forming two nuclei. The micronucleus carries the entire genome in a diploid (2*N*) configuration, the state seen in the somatic cells of metazoa including mammals; this micronucleus is responsible for storing the genetic information of the ciliate cell and transmitting it to daughter cells (**Figure S10.6A**).

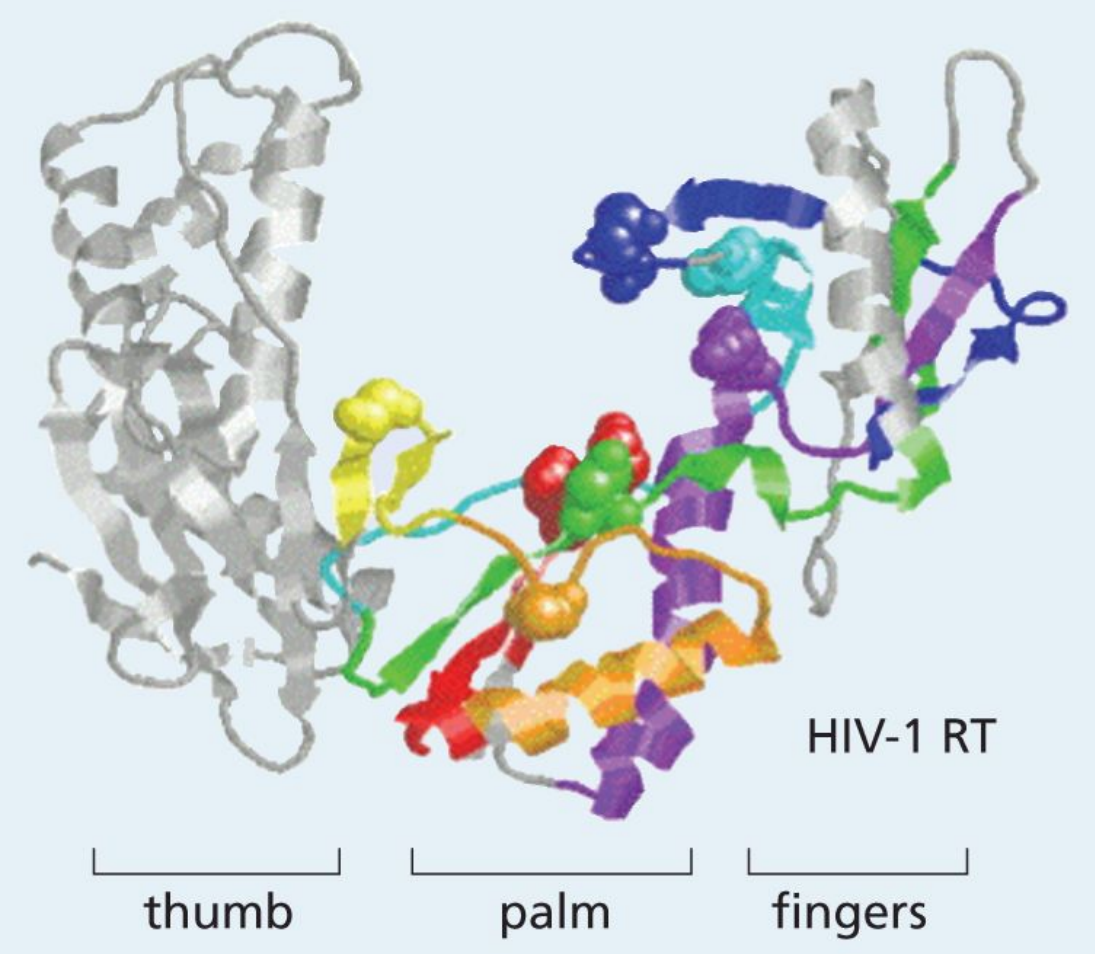


(A)

(B)



(C)



(D)

Figure S10.6 Isolation and origins of the telomerase enzyme (A) Ciliates of the hypotrichous class have a large macronucleus and a small micronucleus. The former carries genes required for the maintenance of biosynthesis of these large

cells, and the latter carries the germ-line copies of the genome. Shown here is a confocal immunofluorescent image of *Tetrahymena pyriformis*, a close relative of *T. thermophila*, in which the telomerase enzyme was first discovered and characterized. The microtubules of the cytoskeleton are revealed by anti-tubulin antibody (*green*), and the nuclei are stained *orange*. The micronucleus (mi, *dashed line*) is seen here as a small oval beneath the macronucleus (ma). (B) This micrograph reveals the appearance of *Euplotes aediculatus*, from which the telomerase catalytic subunit was purified; this purification allowed the determination of its amino acid sequence and in turn the cloning of the encoding *p123* gene. (C) This *p123* gene was found to be homologous to the gene encoding the catalytic subunit of the *Saccharomyces cerevisiae* (yeast) telomerase holoenzyme, termed *Est2* (ever-shorter telomeres). Further analysis revealed extensive sequence relatedness of the two catalytic subunits to the catalytic clefts of reverse transcriptases (RTs) specified by a variety of retrotransposons and by retroviruses such as human immunodeficiency virus (HIV). (D) The regions of homology are mapped in corresponding colors on the three-dimensional structure of the HIV reverse transcriptase (HIV-1 RT). (A, courtesy of D. Wloga and J. Gaertig. B, courtesy of A. Fleury-Aubusson. C, D from T.M. Nakamura et al., *Science* 277:955–959, 1997. With permission from AAAS.)

The macronucleus, in contrast, carries a polyploid genome; that of *Tetrahymena thermophila*, for example, carries the equivalent of approximately 45*N* copies of genomic DNA, and many genomic regions may be present in 1000 copies per macronucleus. The resulting increased gene dosage makes possible the large-scale biosynthesis required to form and maintain these cells. In addition, among the group of ciliates known as hypotrichs, the chromosomal DNA in the macronucleus is cleaved into relatively short, linear fragments, each of which carries a complete, functional gene. The ends of these gene-sized DNA molecules, like the ends of normal eukaryotic chromosomes, must be protected by telomeres. Consequently, a single hypotrichous ciliate cell, such as that of *Euplotes aediculatus* (from which the telomerase enzyme was purified and subjected to sequencing), may carry hundreds of thousands of telomeres instead of, for example, the mere 92 telomeres present in most human cells (Figure S10.6B). As might be expected, such ciliates must carry a proportionately high concentration of telomerase enzyme to service their abundant telomeres. This explains why ciliates were used for the biochemical purification of an enzyme that is otherwise present in vanishingly low amounts in the cells of metazoa.

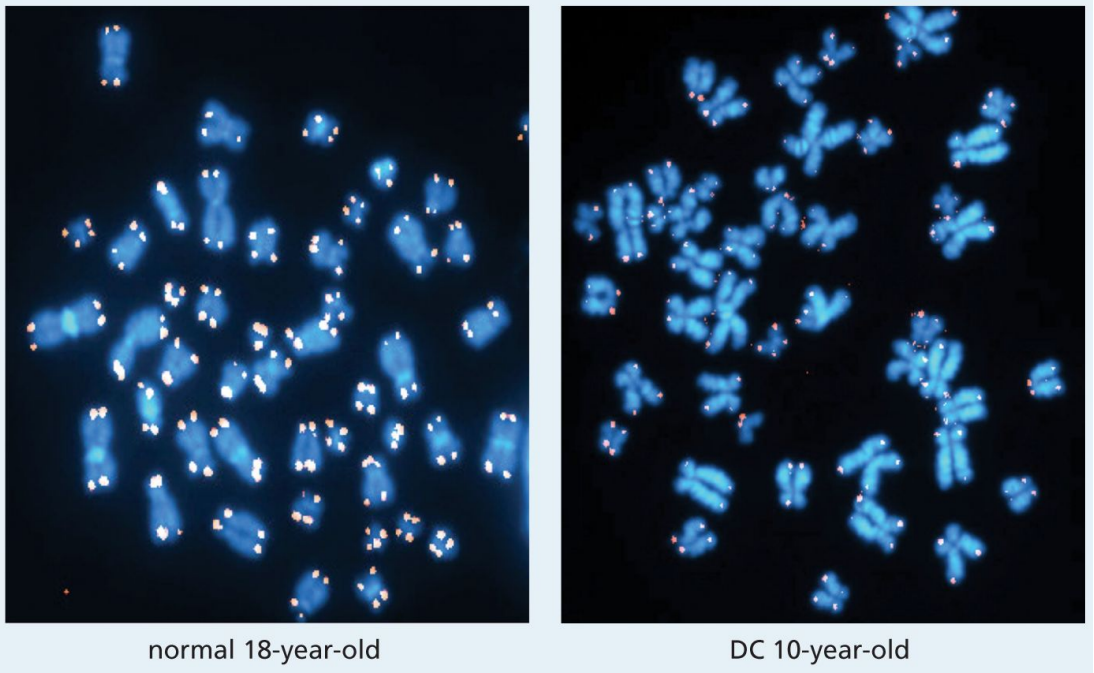
Analyses of the sequences of the ciliate and yeast catalytic subunits of telomerase enzymes revealed a clear homology, albeit distant, with a variety of known reverse transcriptases (Figure S10.6C and D). This pointed, in turn, to a possible evolutionary

origin of these telomerase subunits, specifically from a preexisting retrotransposon-encoded reverse transcriptase enzyme.

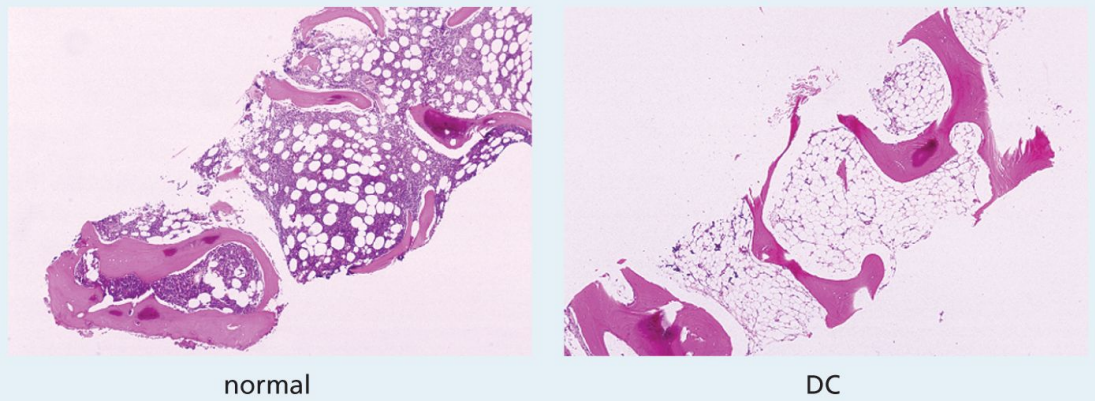
Supplementary Sidebar 10.7 Defective telomerase function explains a rare human familial syndrome

Humans suffering from the inherited condition known as dyskeratosis congenita (DC) exhibit defects in highly regenerative tissues, such as skin and bone marrow, as well as reduced chromosomal stability. In the X-linked form of the disease, a protein known as dyskerin is absent or malfunctioning. Dyskerin associates with the telomerase-associated RNA subunit (*hTR*) and helps *hTR* to assemble in the telomerase holoenzyme complex (see Figure 10.13). Autosomal dominant forms of the same disease

can be caused by the inheritance of mutant alleles of the *hTR*- and hTERT-encoding genes. Cells in proliferating tissues of affected individuals (**Figure S10.7**) exhibit dicentric chromosomes, which are indicative of interchromosomal fusions. Some affected individuals succumb to a collapse of their hematopoietic system due to the loss of regenerative capacity of the stem cells in their bone marrow; some of these patients may ultimately develop leukemia because of telomere collapse, similar to the mice described in Section 10.9.



(A)

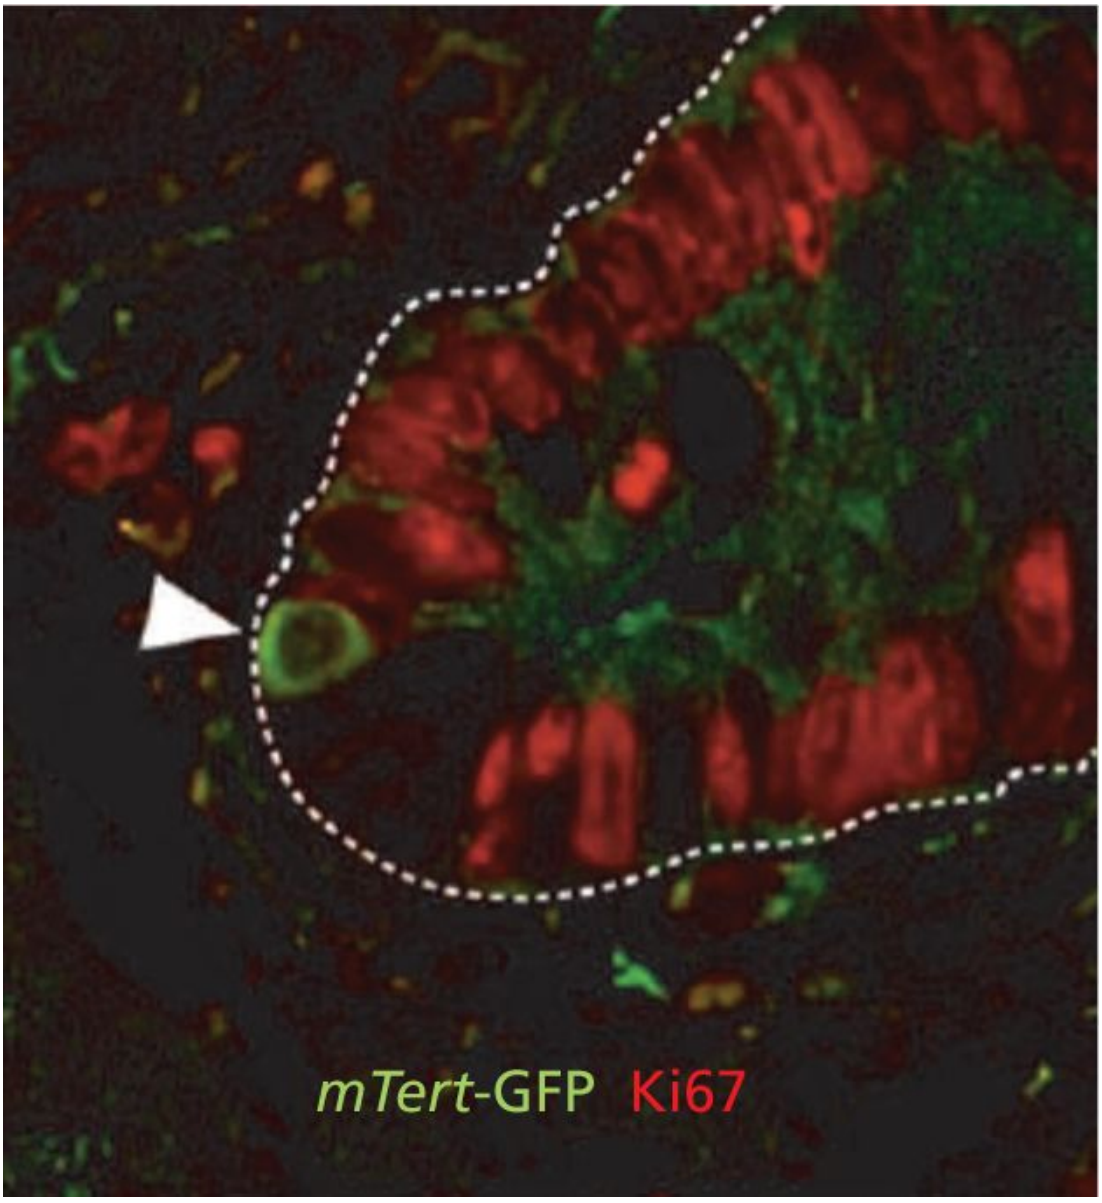


(B)

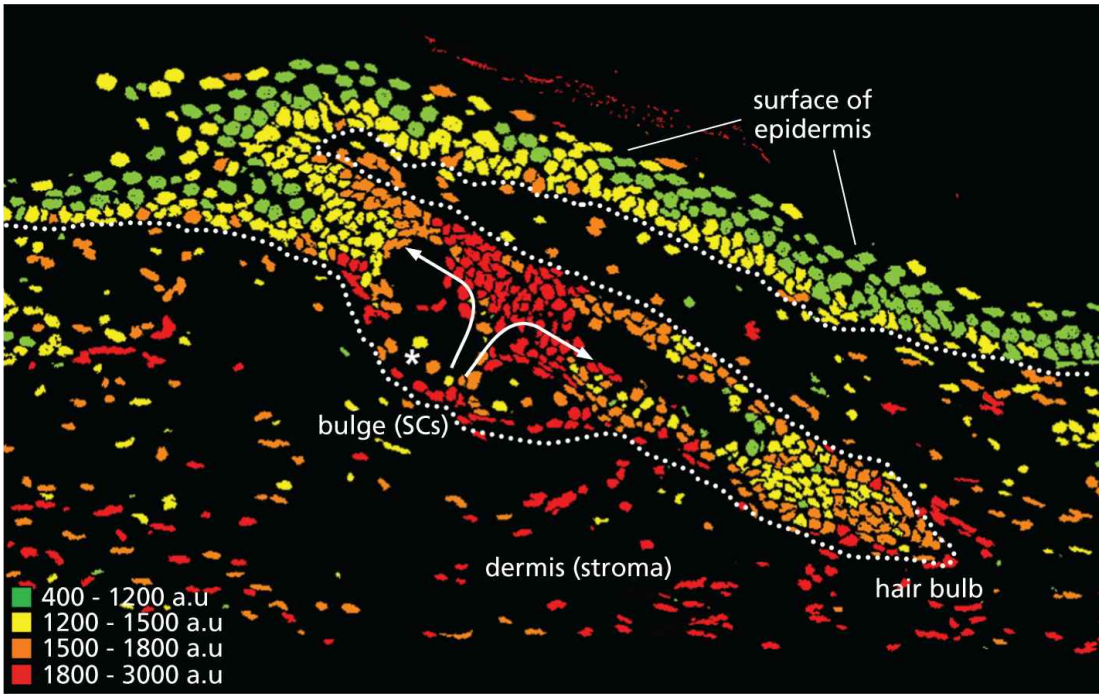
Figure S10.7 Telomere and bone marrow collapse of dyskeratosis congenita patients Humans suffering from dyskeratosis congenita (DC) experience atrophy of a number of tissues, which is traceable to the absence of functional telomerase and to the catastrophic collapse of their telomeres. (A) Fluorescence *in situ* hybridization (FISH) was used to detect the telomeres of metaphase chromosomes in a cell of a normal 18-year-old (*left*) as well as in a cell of a 10-year-old suffering from DC (*right*). Many of the chromosomes in the latter cell have telomeres that are so short that they are no longer detectable by FISH. (B) The most life-threatening tissue atrophy of DC patients occurs among the rapidly proliferating cells of the bone marrow. As indicated here, in normal bone (*left panel*), regions between mineralized bone (*pink*) are filled with hematopoietic cells of the marrow (*purple*). However, the marrow of a dyskeratosis patient suffering germ-line mutations in the *hTR* gene (*right panel*) is almost totally devoid of cells because the stem cells have lost the ability to maintain the various lineages of hematopoietic cells. (A, courtesy of S. Kulkarni and M. Bessler. B, courtesy of M. Bessler.)

Supplementary Sidebar 10.8 Evidence of telomerase activity in the normal stem cells of laboratory mice

The presence of telomerase-positive stem cells in mouse tissues helps to explain the long telomeric DNA in normal mouse tissues relative to the homologous sequences present at the ends of human chromosomes. In addition, telomerase activity (that is, that mediated by the mTERT enzyme) is detectable in a number of more differentiated cells of mouse tissues, whereas the activity of significant enzyme activity cannot be detected in corresponding human cells (**Figure S10.8**). The presence of hTERT activity in various types of stem cells in adult human tissues remains unclear.



(A)



(B)

Figure S10.8 mTERT function may be confined largely to adult stem cells
Most of the mTERT activity in adult mice may be traceable to its expression in the stem cells of various tissues; a similar dynamic may operate in the stem cells of humans, in which, however, such expression is poorly resolved. Two lines of evidence suggest this limited expression pattern in murine stem cells. (A) Transgenic mice were constructed in which the promoter of the *mTERT* gene drives expression of green fluorescent protein (GFP). In addition, cells in the crypts of the small intestine (see Figure 7.20) of these mice were immunostained with an antibody that recognizes Ki67, a marker of cells in the active growth-and-division cycle (*red*). This analysis indicates that the long-lived, slowly cycling cells in the crypt, which are located in the positions of stem cells (*arrowhead*), express readily detectable levels of mTERT, whereas their more differentiated, rapidly proliferating progeny do not. (B) Fluorescence *in situ* hybridization (FISH) using a probe that is specific for telomeric DNA reveals that telomeres are longer in the stem cells than in their more differentiated progeny. In this case, the telomeres in various locations in the hair root of the tail skin of a rat were measured; the intensity of hybridization to telomeric DNA is presented in arbitrary units (a.u.). These measurements translate to an average telomere length of ~43.9 ± 5.8 kb in the bulge region (in which stem cells, SCs, are concentrated) to 34.1 ± 3.2 kb in the interfollicular epidermis, i.e., the surface of the skin between hair roots. The arrows indicate the downward migration of the progenitor products of stem cells into the hair bulb, in which a hair shaft is produced, and, following

wounding, upward cell migration into the skin. In each case, migration is accompanied by increased differentiation and shortening of telomeres. (A, from R.K. Montgomery et al., *Proc. Natl. Acad. Sci. USA* 108:179–184, 2011. With permission from National Academy of Sciences, U.S.A. B, from I. Flores et al., *Genes Dev.* 22:654–667, 2008. With permission from Cold Spring Harbor Laboratory Press.)

OceanofPDF.com

Glossary

feeder layer
: A population of cells, usually grown as a monolayer, that continuously secretes factors that benefit the growth and survival of a second cell population that is propagated above this monolayer.

shelterin
: A complex of at least six proteins that binds to the ssDNA and dsDNA regions of telomeres and functions together with the telomeric DNA to protect the ends of chromosomal DNA from end-to-end fusions.

micronucleus
: (1) A small fragment of a nucleus that has its own nuclear membrane and results from certain aberrations in cell division or from damage inflicted on a cell; micronuclei often carry only a single chromosome and arise when this chromosome fails to be incorporated into the previously formed mitotic spindle, thereby escaping inclusion in the normal karyotypic array of a daughter cell. (2) Smaller of the two nuclei in many ciliate cells, which is used to carry and transmit the ciliate genome to progeny cells.

macronucleus
: Larger of the two nuclei in many ciliate cells, which carries multiple copies of each gene and is used for the production of mRNAs.

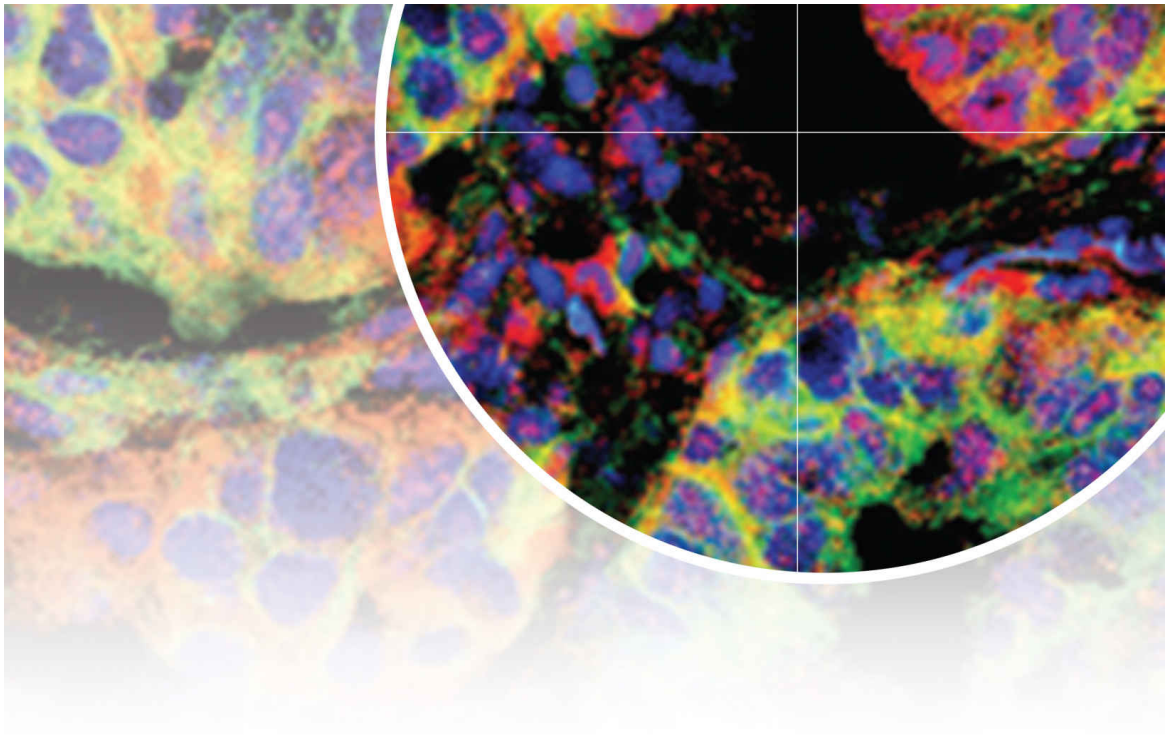
Chapter 11
Multi-Step Tumorigenesis



Cancer cells glow green, red and yellow in an immunofluorescence image.

In the survival of favoured individuals and races, during the constantly-recurring struggle for existence, we see a powerful and ever-acting form of selection.

Charles Darwin, biologist, 1859

Nothing in biology makes sense except in the light of evolution.

Theodosius Dobzhansky, geneticist, 1973

In the evolutionary diversification of mammals, enormous changes in cellular susceptibility to oncogenes have developed.

Richard Peto, epidemiologist, 1977

The chapter that follows is the longest of this book because it attempts to draw together diverse lines of evidence in order to create an overarching conceptual framework for understanding of human cancer formation. It draws on the contents of all preceding chapters and is worthwhile digesting in segments rather than swallowing the contents whole.

The formation of a human tumor is a complex process that usually proceeds over a period of decades. Normal cells evolve into cells with increasingly neoplastic phenotypes through a process termed tumor progression. This process takes place at myriad sites throughout the normal human body, advancing further and further as we get older. Rarely does it proceed far enough at any single site to make us aware of its end product, a clinically detectable tumor mass.

Tumor progression is driven by a sequence of randomly occurring mutations, epigenetic alterations of DNA, and epigenetically controlled cell-biological programs that affect the genes governing cell proliferation, survival, and other traits associated with the malignant cell phenotype. The complexity of this process reflects the work of evolution, which has erected a series of barriers between normal cells and their highly neoplastic derivatives. Accordingly, completion of each step of multi-step tumor progression within a tissue can be viewed as the successful breaching of yet another barrier that has been impeding the progress of a clone of normal cells toward the fully malignant state.

One might think that these barriers are the handiwork of relatively recent evolutionary processes. Perhaps, we might imagine, the forces of evolution initially worked to design the architecture and physiology of complex metazoan bodies and, having completed this task, then proceeded to tinker with these plans in order to reduce the risk of cancer.

An alternative scenario is far more likely, however: the risk of uncontrolled cell proliferation has been a constant companion of metazoans from their very beginnings, roughly 600 million years ago. By granting individual cells within their tissues the license to proliferate under certain conditions, even simple metazoans ran the risk that one or another of their constituent cells would turn into a renegade and trigger the disruptive, runaway cell multiplication that we call cancer. Consequently, the erection of multiple defenses against cancer must have accompanied, hand-in-hand, the evolution of organismic size and complexity.

Most of the preceding chapters have addressed one or another of the individual cellular control systems that defend against cancer and are subverted during the process of tumorigenesis. Now, we will begin tying these individual threads together and examine how alterations in these systems contribute to the end product—the formation of a primary tumor. We start by attempting to gauge the scope of the problem at hand: How many different sequential changes are actually required in cells and tissues in order to create a human cancer and how long do these processes take to reach completion?

OceanofPDF.com

Glossary

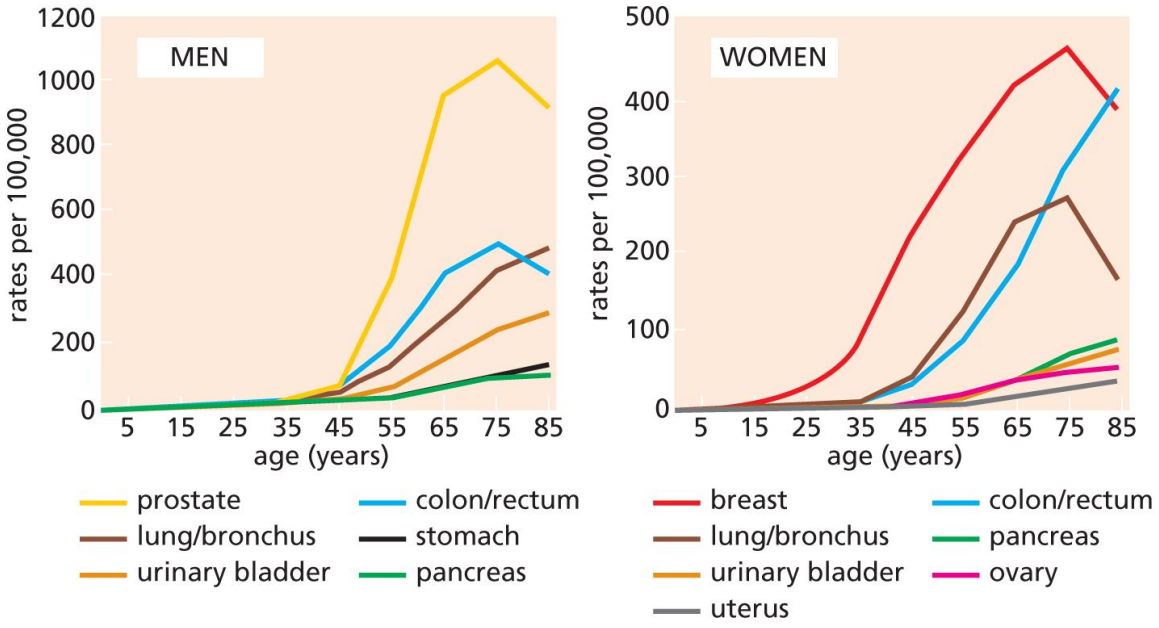
tumor progression

(1) Process of multi-step evolution of a normal cell into a fully neoplastic, malignant tumor cell. (2) Evolution of a benign into a malignant cancer cell or growth. (3) Evolution of a premalignant cell from a promoter-dependent to a promoter-independent state.

OceanofPDF.com

11.1 Most human cancers develop over many decades of time

Epidemiologic studies have shown that age is a surprisingly large factor in the incidence of cancer. In the United States, the risk of dying from colon cancer is as much as 1000 times greater in a 70-year-old man than in a 10-year-old boy. This fact, on its own, suggests that this type of cancer and, by extension, many other cancers common in adults (**Figure 11.1**), require years if not decades to develop (**Sidebar 11.1**).

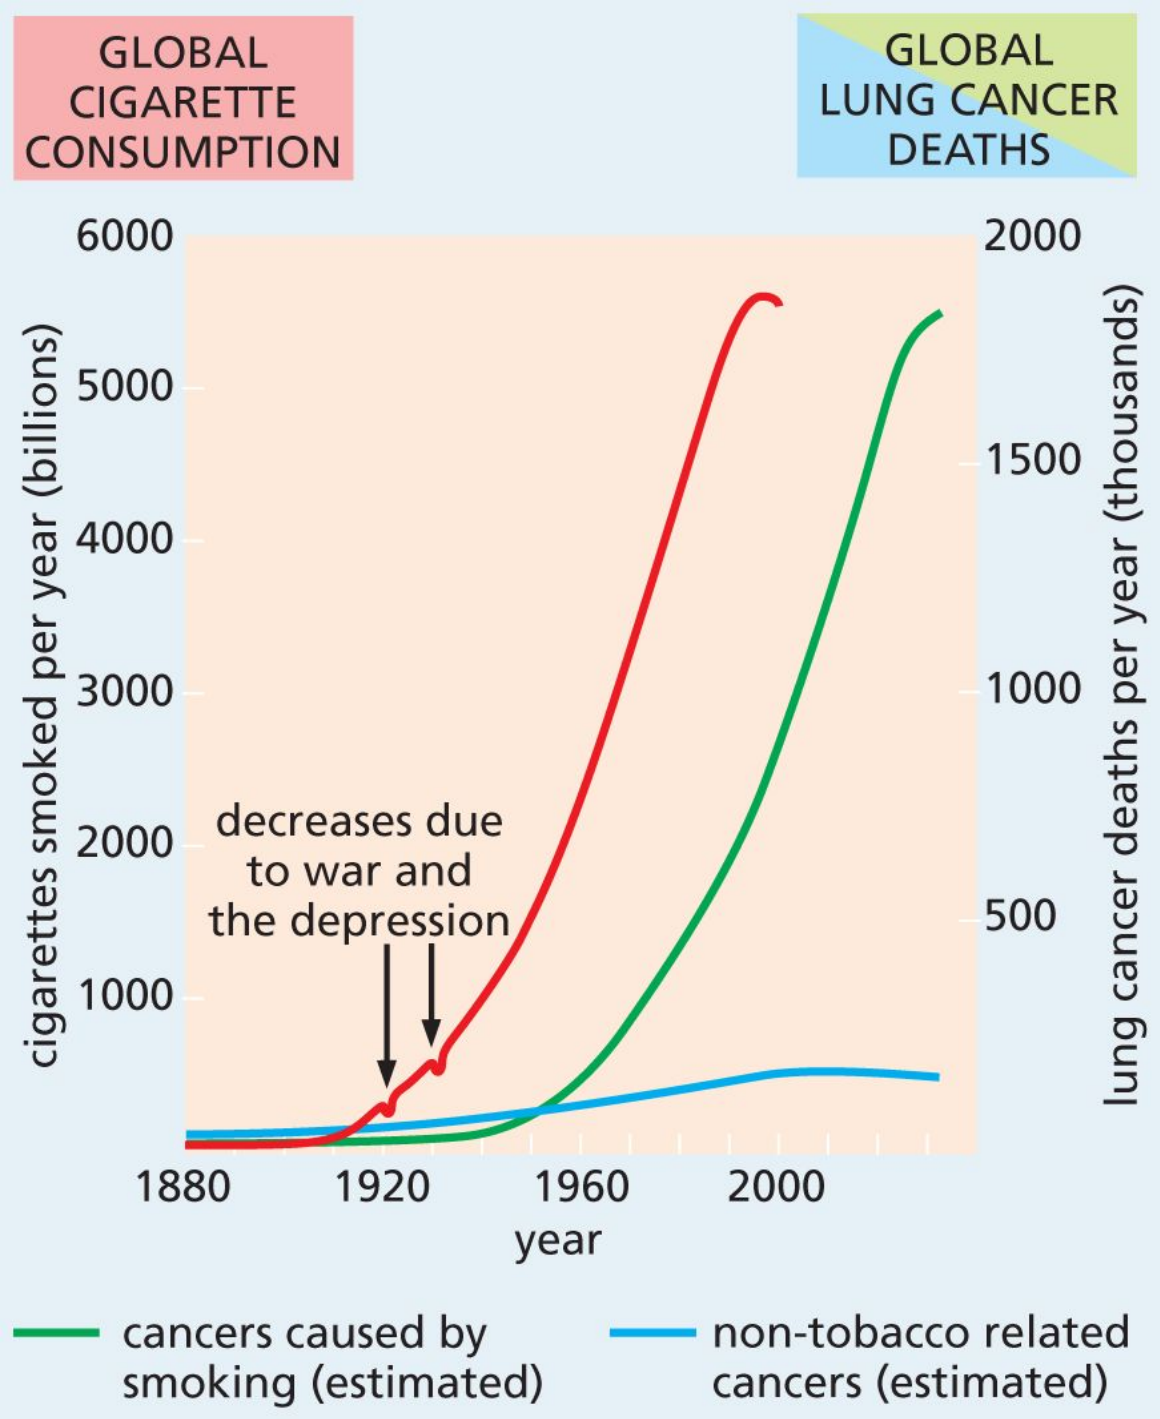


Two line graphs. The first one shows rates of various cancers per one hundred thousand of population as a function of age for men. The second does the same for women. Among men, cancer rates are low until age 45 and then rise steeply, especially for prostate cancer. Colorectal cancer is the next-most-frequent type, followed by lung and bronchial cancer. Among women, breast cancer rates start to rise fairly early life, at age 15, and breast cancer remains the most frequent cancer type into a woman's eighties, although it is about half as frequent as prostate cancer in men. Lung and bronchial cancer rates and colorectal cancer rates in women start to rise at about age 35.

Figure 11.1 Cancer incidence at various ages These graphs of diagnoses of various types of epithelial cancers show a steeply rising incidence with increasing age, indicating that the process of tumor formation generally requires decades to reach completion. (Courtesy of W.K. Hong, compiled from *SEER Cancer Statistics Review.*)

Sidebar 11.1 Estimates of time required for tumor development in humans

Attempts to gauge the latency of cancer development—the time window between initial exposure to a carcinogen and the eventual diagnosis of disease—are complicated by our inability in the case of most cancers to identify the timing of exposure to a known carcinogen and the time of subsequent diagnosis of disease. One compelling measurement comes from measures of the incidence of lung cancers among males in the United States. Cigarette smoking was relatively uncommon among this group until World War II, when large numbers of men first acquired the habit, encouraged in part by the cigarettes they received as part of their rations while serving in the U.S. armed forces. Thirty years later, in the mid-1970s, the rate of lung cancer began to climb steeply with kinetics that closely paralleled the increase in size of the smoking population in the U.S. (**Figure 11.2**). Another comparable measurement comes from the development of mesothelioma among British shipyard workers who were exposed to asbestos used in ship construction; in this case, the lag in cancer development could be gauged to be about 40 years after first exposure. In general, however, to the extent that many human cancers derive from chronic exposure to low levels of carcinogen over extended periods of time, it is impossible to estimate the lag period between exposure and disease development.



A line graph illustrating the relationship between cigarette smoking and lung cancer. One line displays the number of cigarettes smoked per year, worldwide. The line rises from practically zero in 1880 to about 5.6 trillion in the late 1990s. A curve of the exact same shape, but shifted forward by about 40 years, shows annual estimated deaths from smoking-caused lung cancer rising from practically zero in 1920 to about 1.8 million in the 2030s. A third

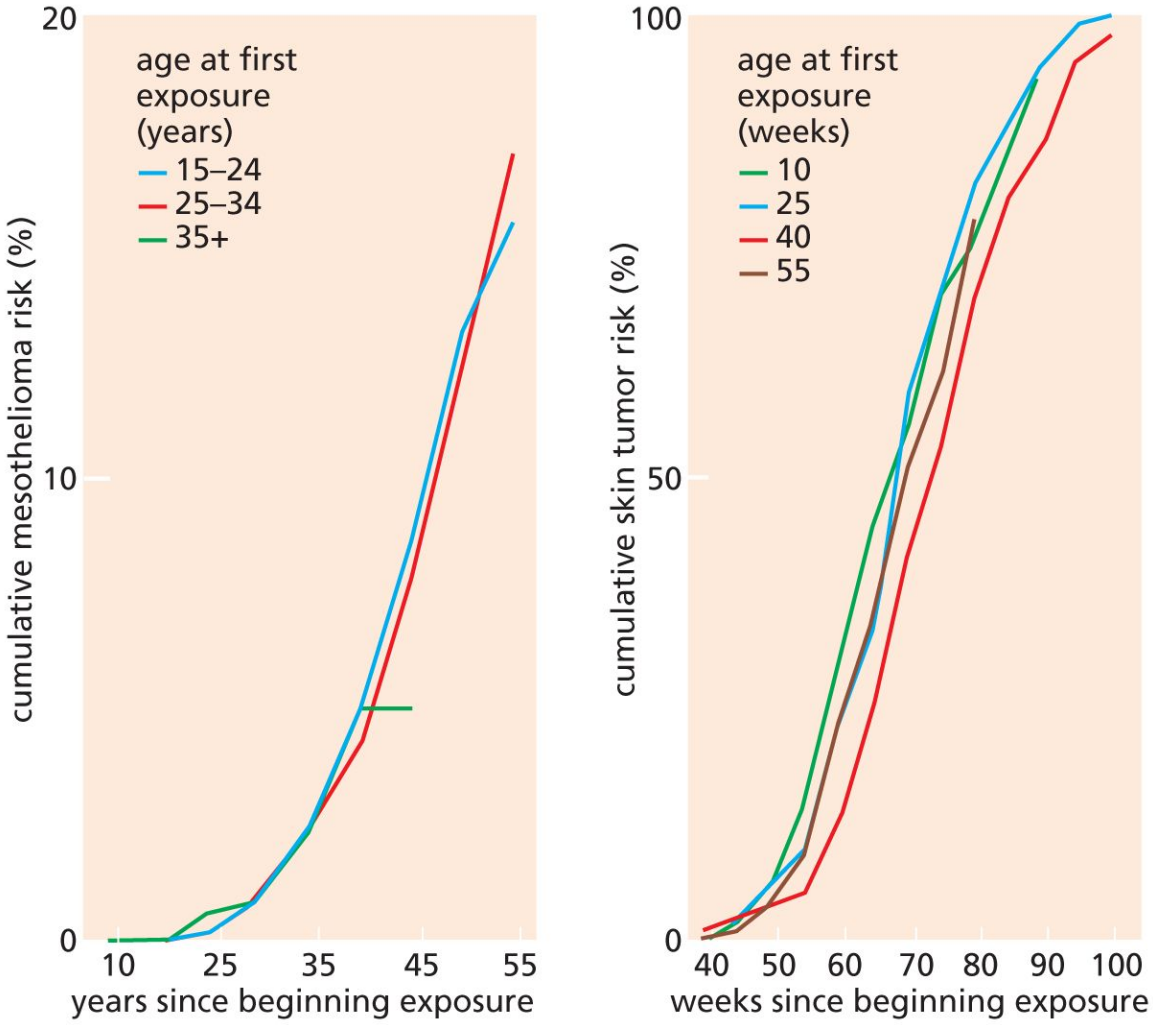
curve shows annual estimated deaths from non-tobacco-related cancers rising steadily over the years and peaking at about 200 thousand in the year 2000.
Figure 11.2 Cigarette consumption and lung cancer These curves compare the annual global consumption of cigarettes (*red curve*) with the recorded and predicted annual worldwide mortality from lung cancer (*green curve*). Annual mortality from tobacco-induced lung cancer (in thousands) is estimated to peak sometime in the fourth or fifth decade of the twenty-first century. During the twentieth century, there was an increase in what is judged to be "non-tobacco-related" lung cancer mortality (*blue curve*). The precise number of these cases is unclear, and there is some debate about how many of them are attributable to secondhand tobacco smoke. (From R.N. Proctor, *Nat. Rev. Cancer* 1:82–86, 2001. With permission from Nature.)

The various frequencies of cancers in diverse populations have led to a number of calculations that shed light on the complex processes of cancer formation (**Supplementary Sidebar 11.1**). In many cases, simple algebraic formulas, a^5 or a^6, may roughly predict cancer incidence as a function of elapsed lifetime (where a = years lived). Such dynamics imply a sequence of random, independent events that occur at comparable frequencies over extended periods of time. Such calculations can only be made when cancer incidence and age-of-onset of disease are averaged over a large human population. These independent events are likely to be rate-limiting, and their probability of occurring per unit of time may vary dramatically from one individual to another, being affected by inherited predisposition, diet, and lifestyle, among other variables. Independent of the measurements of event probability is the conclusion that cancer development is a multi-step process for most kinds of human cancer. (These calculations have limited utility for pediatric cancers, whose dynamics do not conform to this model of disease pathogenesis, as discussed later in this chapter.)

The conclusion that tumorigenesis is a multi-step process hints at another interesting idea. Assume that (1) a sequence of unlikely events is required in order for a tumor to appear and (2) many of these events happen at comparable frequencies in all of us. Together, these assumptions indicate that as we grow older, virtually all of us will carry populations of cells in many locations throughout the body that have completed some but not all of the steps of tumor progression. Because most of us will not live long enough for the full schedule of requisite events to be completed (because we will succeed in dying from accidents or other diseases), we will never realize that any of these tumor progressions had been initiated at various sites within our bodies. Indeed,

autopsies reveal that by life's end, 60 to 70% of individuals carry undiagnosed tumors, independent of the cause of death; these autopsies provide minimum estimates of the actual number of minor pre-neoplastic growths in the body. Viewed from this perspective, cancer is an inevitability; if we succeeded in avoiding the death traps set by all the other usual diseases and conditions, sooner or later most of us would become victims of cancer. Interestingly, the late onset of most human cancers dictates that curing all cancers will have relatively minor effects on overall life span (**Supplementary Sidebar 11.2**).

Epidemiology provides us with another important insight into the multi-step nature of tumorigenesis. If we examine the frequencies of mesothelioma in humans (caused largely by asbestos exposure plus increased incidence from cigarette smoking) and skin cancer in mice (induced by repeated benzo[*a*]pyrene painting), it becomes apparent that the formation of each of these tumors requires an extended period of repeated exposure to carcinogens and that it is the *duration* of this exposure (rather than the absolute *age* of exposed individuals or the age when exposure began) that determines the timing of the onset of detectable disease (**Figure 11.3**). In these particular cases, tumors are created by the actions of exogenous carcinogens rather than by processes operating entirely within the body's various tissues; these carcinogens increase the rate of tumor development, often by many orders-of-magnitude above the spontaneous background rate. The lion's share of the background rates of human cancers that seem to be formed spontaneously appear to result from the actions of *endogenou*s carcinogenic processes, notably (1) errors in DNA replication and repair, (2) accidents occurring during various steps of cell division, and (3) actions of mutagenic molecular species that are by-products of metabolism, notably energy metabolism in the mitochondria.



Two graphs each showing cumulative risk of cancer in percent, as a function of years since beginning exposure. The first graph, for mesothelioma, shows curves for three different ages at first exposure, namely 15 to 24 years, 25 to 34, and 35 and older. All three curves follow the same basic trajectory, from 0 at 17 or 18 years after first exposure, up to 10 percent at 45 years, up to 16 percent after about 55 years. The second graph, for skin tumors, shows graphs show curves for four different ages at first exposure, namely 10, 20, 45 and 55 weeks. All four curves follow the same basic trajectory, from 0 at 40 weeks since first exposure, up to 50 percent at 65 weeks, up to 100 percent after about 95 weeks.

Figure 11.3 Cancer incidence and duration of carcinogen exposure These graphs indicate that cumulative exposure to a carcinogenic stimulus, rather than the age at which this exposure began, determines the likelihood of developing a detectable tumor. The left graph presents the cumulative risk of

developing mesothelioma (a tumor of the mesodermal lining of the abdominal organs and the lungs) among insulation workers in the United States, many of whom were occupationally exposed to asbestos. The right graph presents the cumulative risk of developing a skin tumor among mice treated in an experimental protocol for inducing squamous cell carcinomas of the skin. (From J. Peto, *Nature* 411:390–395, 2001. With permission from Nature.)

These generalizations about cancer formation tend to overlook cancers in a minority of adults that occur at ages that do not conform to a simplified algebraic formula of multi-step tumorigenesis as described above. As we see in **Figure 11.4**, a pediatric cancer strikes only early in life, whereas testicular cancer strikes in early adult life. Kinetics like these demonstrate that biological forces operating in certain differentiated tissues may ultimately determine cancer onset, a point made as well in Figure 11.1 by examining the kinetics of breast cancer onset.

relative age adjusted incidence

Four graphs showing Cancer incidence as a function of age for four different cancers. Testicular cancer typically appears at a fairly young age, most commonly in men in their late twenties and early thirties. The incidence of brain cancer rises steadily until about age 70 and then declines steeply. The incidence of retinoblastoma is high at birth and plummets to essentially zero by age 10. The incidence of squamous skin carcinoma rises exponentially throughout one's lifetime.

Figure 11.4 Cancer incidence as a function of age These graphs show age-dependent incidence rates in a subset of cancers. The rates vary dramatically from the kinetics of appearance of most common cancers. With the exception of testicular cancer, the ordinates in all cases represent incidence relative to the highest incidence rate. Squamous cell skin carcinoma is included to illustrate the incidence kinetics of a cancer that is more typical of adult-onset neoplasias. (Courtesy of B. Westermark; from J. Li et al., *Pediatrics* 121:e1470–e1477, 2008.)

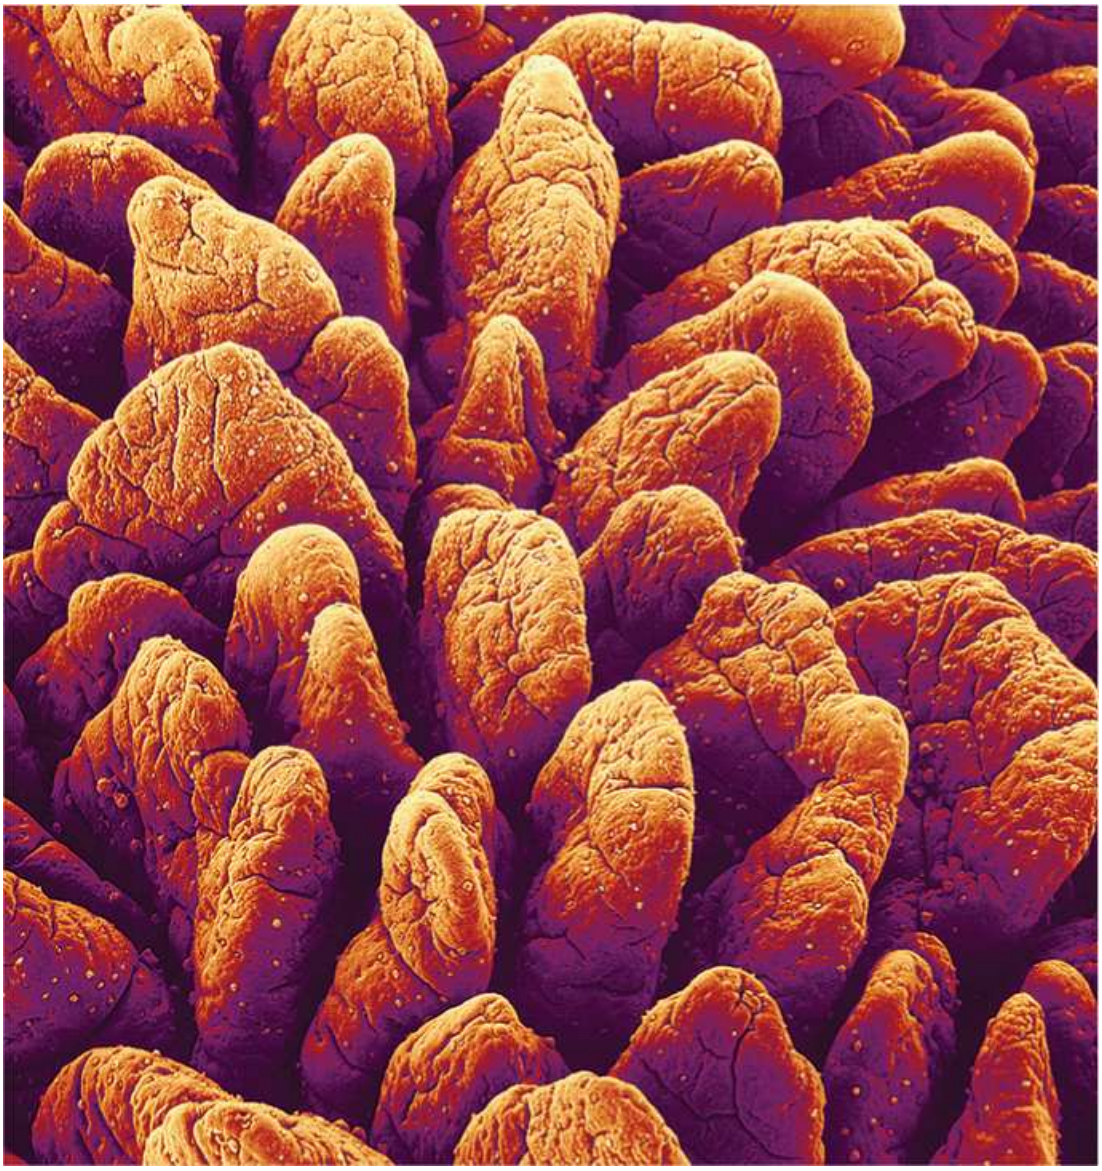
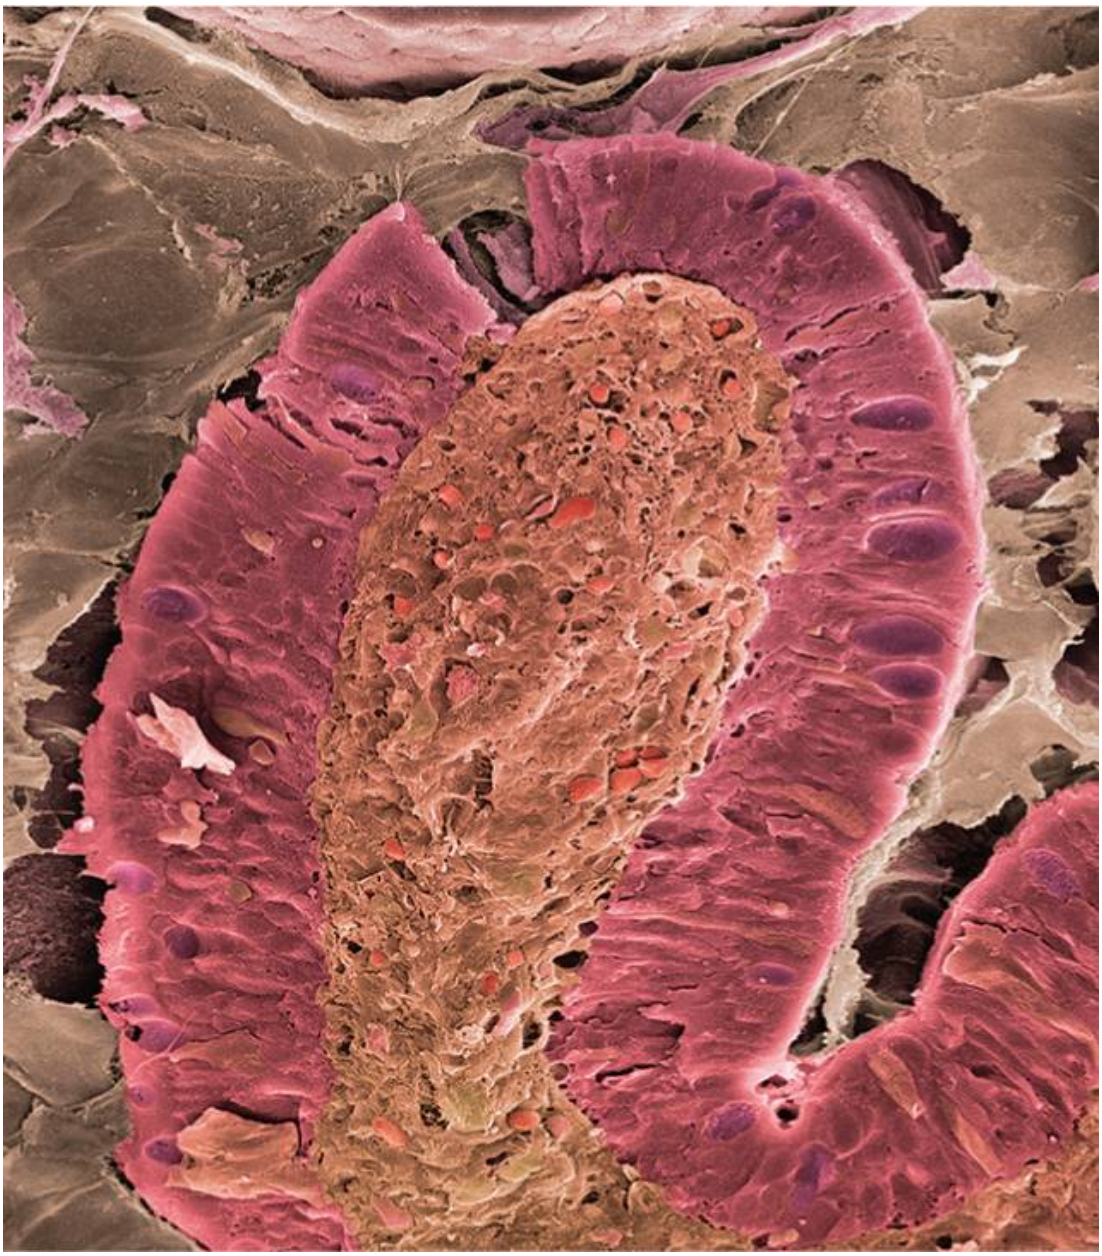
11.2 Histopathology provides evidence of multi-step tumor formation

The notion of human tumor development as a multi-step process has been histologically documented most clearly in the epithelium of the intestine. The intestinal epithelial cells, which face the interior cavity (lumen) of the gastrointestinal tract, form a layer that is only one cell thick in many places (**Figure 11.5**). These epithelial cell populations are in constant flux. Each minute, 20 to 50 million cells in the human duodenum and a tenth as many in the colon die and an equal number of newly minted cells replace them! These epithelial cells, rather than underlying mesenchymal cells, are the sources of cancers arising in the intestine.



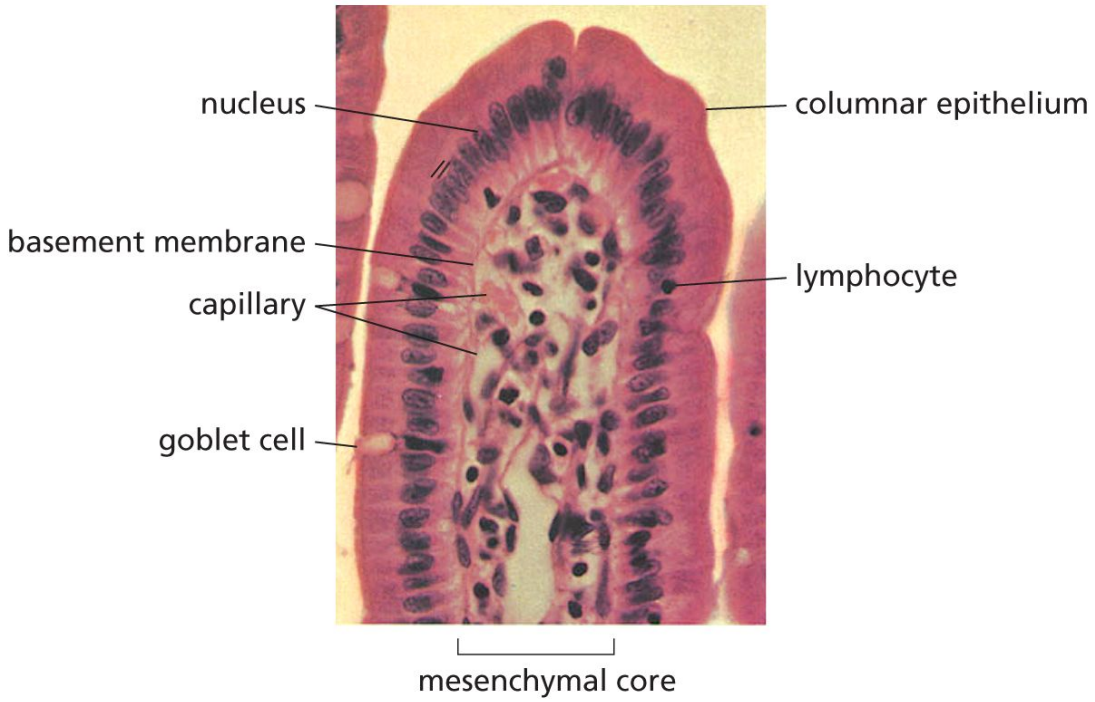
An electron micrograph of two or three dozen intestinal villi projecting upward. The image has been colorized to red and they look somewhat like chicken nuggets.

(A)



An electron micrograph of a single villum in cross section. The outer layer consists of columnar epithelial cells. The core is spongy in texture.

(B)



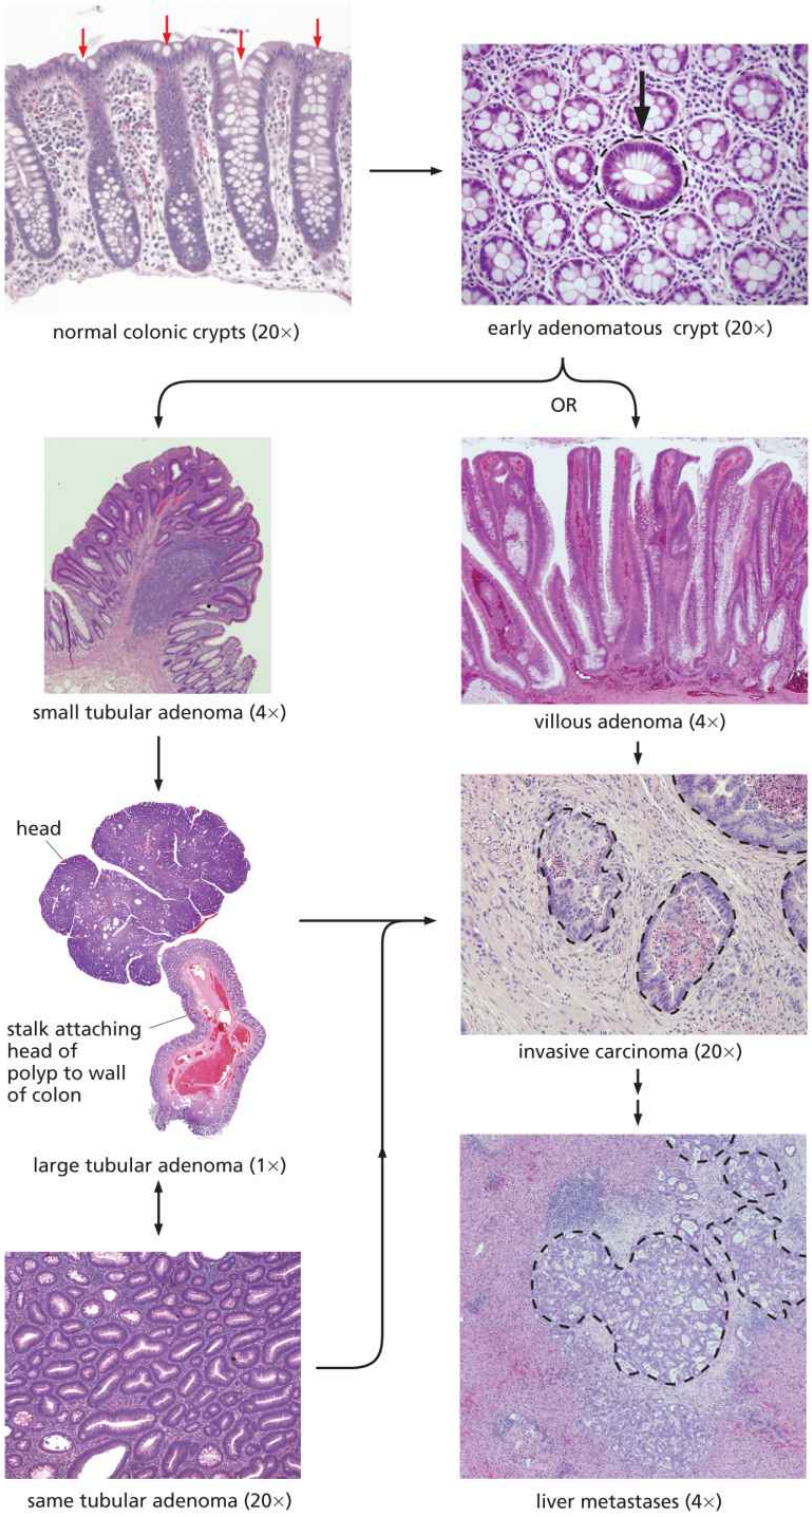
A histology image of a single villum in cross section. The outer layer consists of columnar epithelial cells. Their nuclei are stained dark and appear side by side in orderly progression. Within the epithelial layer, lymphocytes and goblet cells make an occasional appearance. The mesenchymal core is shown to contain capillaries.

(C)

Figure 11.5 Microanatomy of the normal intestinal wall The epithelial cells lining the small intestine and those lining the large intestine (colon) have a similar organization. However, the protruding villi visualized here are present only in the small intestine. (A) This scanning electron micrograph of epithelium of the small intestine shows villi (fingers) of the intestinal mucosa extending into the lumen at regular intervals. (B) Each villus is covered with a layer of epithelial cells. (C) The core of each villus, which is separated from the overlying epithelium by a basement membrane, is composed of various types of mesenchymal cells, including fibroblasts, endothelial cells, pericytes, and various cells of the immune system (*not indicated*). (A, © Susumu Nishinaga/Science Source. B, © SPL/Science Source. C, from University of Iowa Virtual Hospital, Atlas of Microscopic Anatomy, Plate 194.)

Analyses of human colonic biopsies have revealed a variety of tissue states, with degrees of abnormality that range from mildly deviant tissue, which is barely

distinguishable from the structure of the normal intestinal mucosa (the epithelial lining of the colonic lumen), to the chaotic jumble of cells that form highly malignant tissue (**Figure 11.6**). Like the normal intestinal lining, these growths are composed of various distinct cell types, indeed almost all of the cell types found in the normal tissue.



A sequence of histology images that shows the progression of cancer beginning in the colon. The first image is of normal colonic crypts in side view. The next image is of an early adenomatous crypt seen from above. The walls are thicker and contain many more cells than in a normal crypt. This crypt may develop into

either a villous adenoma, shown in side view with thick walls and irregular structure, or a tubular adenoma, shown first small, then large with a bulbous head at one end and at the other end a stalk that attaches to the colon wall. Either type of adenoma can develop into an invasive carcinoma that forms large sections of uneven tissue within the normal tissue. Eventually, as shown in the last image, the cancer can metastasize to the liver. The cancerous tissue is circles and is much less uniform, with more gaps than the surrounding tissue.

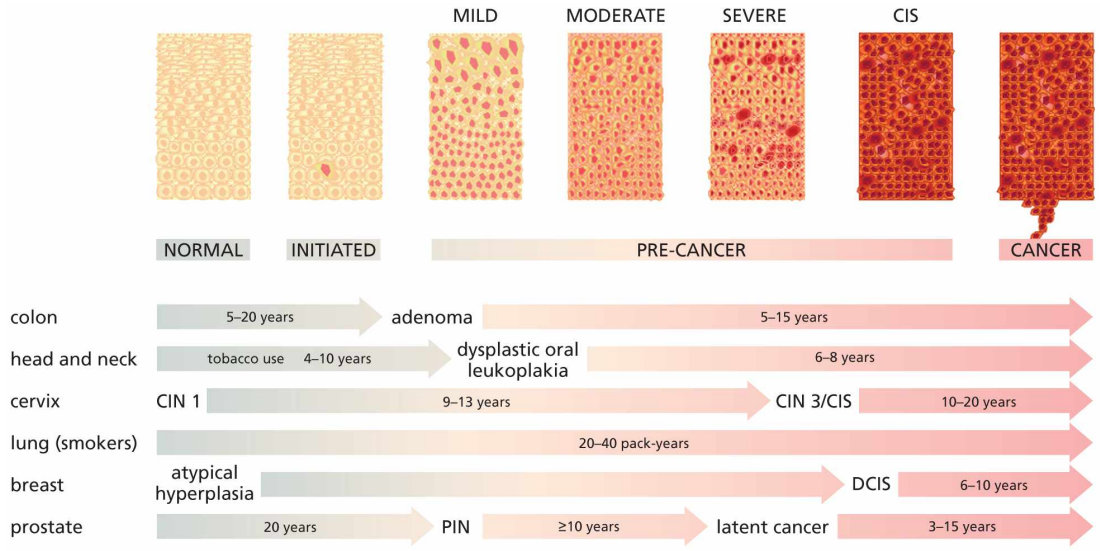
Figure 11.6 Histopathological alterations of the human colon The various types of abnormal tissues revealed by histopathological analyses of the human colon can be arrayed in a succession of ever-increasing abnormality. Normal colonic crypts are seen here in longitudinal section (*top left*). (Very similar crypts are found in the small intestine around the base of each villus.) A small adenomatous crypt (*arrow, circled*) is shown, together with normal crypts, in cross section (*top right*). The cells in this abnormal crypt are presumed to have the ability to develop into at least two distinct types of adenomas—tubular and villous. A small tubular adenoma is shown (*left, middle*). The larger tubular adenoma (*below*) is sometimes termed *pedunculated*, indicating its attachment via a stalk to the colonic wall. These two types of adenomas have the ability to evolve into a locally invasive carcinoma, whose presence here is indicated by small islands of carcinoma cells (*circled*) surrounded by extensive stroma (*right, lower middle*). Dissemination of these cells, usually to the liver (*bottom right*), can lead to metastases (*circled*), which are surrounded here by layers of recruited stromal cells. The histopathological progression indicated here would seem to be the most logical way by which normal tissue, in this case the colonic epithelium, is transformed through a series of intermediate steps into carcinomas and ultimately spawns metastatic growths. However, the evidence for most of these precursor–product relationships is actually quite fragmentary. (Courtesy of C. Iacobuzio-Donahue and B. Vogelstein.)

Some growths that are classified as hyperplastic exhibit an almost-normal histology, in that the individual cells within these growths have a normal appearance. However, it is clear that in these areas of hyperplasia, the rate of epithelial cell division is unusually high, yielding thicker-than-normal epithelia, often composed of multiple cell layers in an epithelium that is normally only one-cell-layer thick. Yet other growths show abnormal histology, with the individual epithelial cells no longer forming the well-ordered cell layer of the normal colonic mucosa and exhibiting a morphology that deviates in subtle ways from that of normal cells; these growths are said to be dysplastic (see Figure 2.13). A much larger and more deviant growth that has dysplastic cells and marked thickening is termed a polyp or an adenoma (see Figures 2.14A and 11.6). In the colon, several distinct types of polyps are encountered; some grow along the wall of the colon, whereas others are tethered to the colonic wall by a

stalk. Importantly, these growths are considered benign, in that none has broken through the basement membrane (see Figure 2.15A) and invaded underlying stromal tissue.

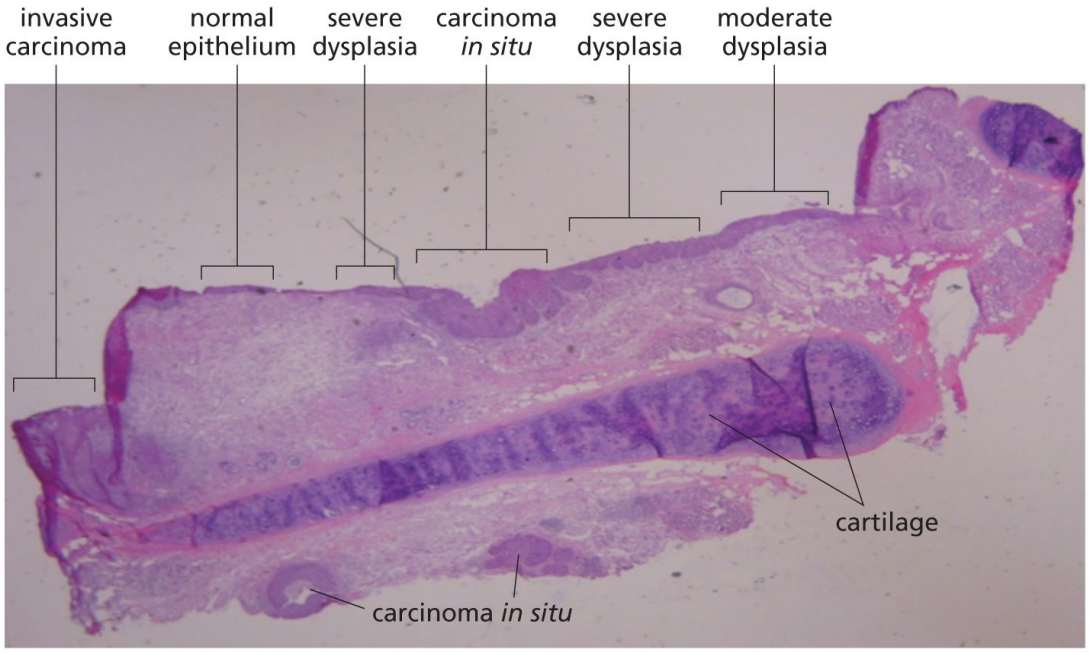
The more abnormal growths that have indeed invaded through the basement membrane and beyond have progressed from a previously benign to a malignant state. There are distinctions among these more aggressive colon carcinomas and associated cancer cells, depending on whether they have penetrated deeply into the stromal layers and smooth muscle and whether cells from these growths have migrated—metastasized—to nearby lymph nodes and anatomically distant sites in the body, where they may have succeeded in founding new tumor cell colonies.

Having arrayed these growths in a succession of tissue phenotypes that advance from the normal to the aggressively malignant (see Figure 11.6), we might imagine that this succession depicts with some accuracy the course of tumor development as it actually occurs in the human colon. In truth, the evidence supporting this scheme is quite indirect. Some tumors may well develop through a succession of intermediate growths, such as those arrayed here. Alternatively, it is possible that some of the tissue types depicted as intermediates in this sequence represent dead ends rather than stepping stones to more advanced tumors. In certain cases of colon cancer, it is also possible that the development of the tumor depends on the ability of early growths to leapfrog over intermediate steps, allowing them to arrive at highly malignant endpoints far more quickly than is suggested by this succession of steps. Similar successions have been proposed for various other epithelial cancers (**Figure 11.7A**). On rare occasions, one can actually find a tissue in which multiple stages of cancer progression coexist (Figure 11.7B); however, observations like these provide no direct evidence of precursor–product relationships between the various types of histologically abnormal growths.



A series of seven images across the top illustrates normal tissue; tumorigenesis initiated; pre-cancerous growth in mild, moderate, severe, and cancer in situ stages; and finally cancer, marked by escape of proliferating tissue from the site of initiation. Below that progression, the development of six types of cancer is described in more detail. Colon cancer takes 5 to 20 years to reach the mild pre-cancerous adenoma stage, and another 5 to 15 years to reach the cancerous stage. Head and neck cancer take, with tobacco use, 4 to 10 years to reach the mild to moderate pre-cancerous dysplastic oral leukoplakia stage. It takes another 6 to 8 years to reach the cancerous stage. Cervical cancer takes 9 to 13 years to reach the severe pre-cancerous carcinoma in situ stage, and another 10 to 20 years to reach the cancer stage. Lung cancer, in smokers, takes 20 to 40 pack-years to reach the cancer stage. After breast cancer, starting with atypical hyperplasia, reaches the ductal carcinoma in situ stage, it takes another 6 to 10 years to reach the cancer stage. Prostate cancer takes 10 years to reach the mild pre-cancerous prostatic intraepithelial neoplasia stage, another 10 or more years to reach the severe pre-cancerous latent cancer stage, and finally another 6 to 10 years to reach the cancer stage.

(A)

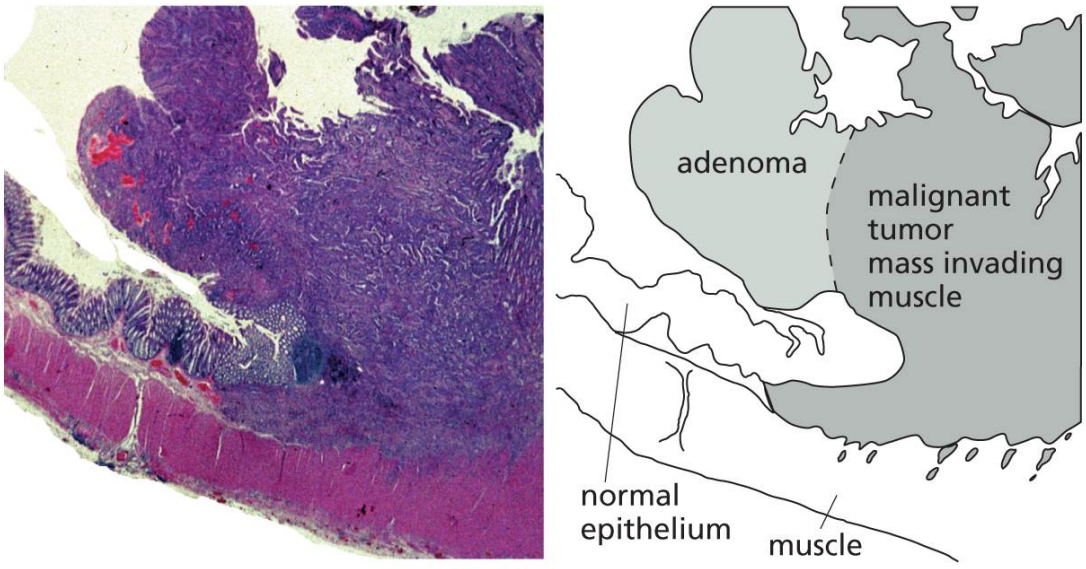


An image of a sample of stained lung cancer tissue. Along the upper edge, one can see, left to right, invasive carcinoma cells, normal epithelium, severe dysplasia, a carcinoma in situ, severe dysplasia, and moderate dysplasia. Two

more carcinomas in situ are visible at the bottom, and a shaft of cartilage tissue runs across the middle.
(B)

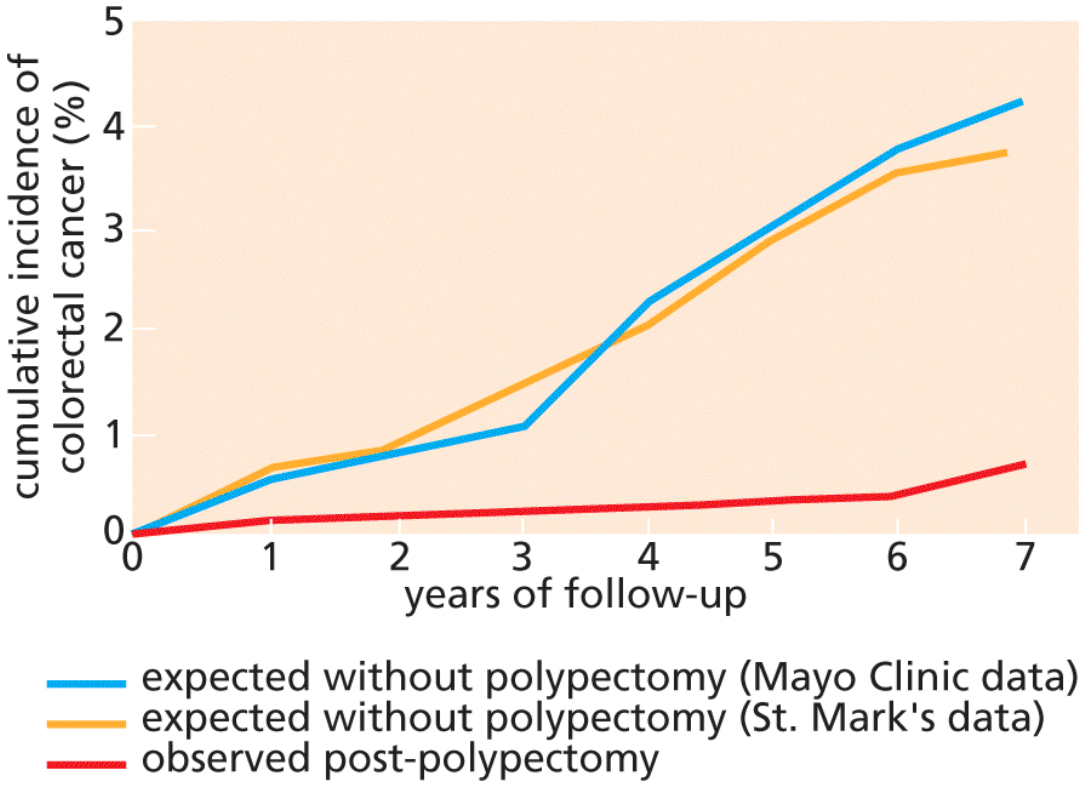
Figure 11.7 Multi-step tumorigenesis in a variety of organ sites (A) The pathogenesis of carcinomas is thought to be governed by very similar biological mechanisms operating in a variety of epithelial tissues. Accordingly, multi-step tumorigenesis involving similar histological entities has been proposed to progress along parallel paths in these various organ sites. These similarities are obscured because the nomenclature is quite variable from one tissue to another. CIS, carcinoma *in situ*; CIN, cervical intraepithelial neoplasia; DCIS, ductal carcinoma *in situ*; PIN, prostatic intraepithelial neoplasia. (B) Because more aggressive growths often overgrow their more benign precursors, it is rare to see the multiple states of tumor progression coexisting in close proximity, as is the case in this lung carcinoma. Importantly, although the close juxtaposition of the aberrant growths suggests some relationship among them, an image like this provides no definitive evidence of precursor–product relationships between these various abnormal tissues. (A, courtesy of W.K. Hong and adapted from J.A. O'Shaughnessy et al., *Clin. Cancer Res*. 8:314–316, 2002. With permission from the American Association for Cancer Research. B, courtesy of A. Gonzalez and P.P. Massion.)

In the case of colorectal tumors, at least three types of evidence strongly support the precursor–product relationship between adenomas and carcinomas. First, on rare occasions, one can actually observe a carcinoma growing directly out from an adenomatous polyp (**Figure 11.8A**). We can surmise that outgrowths like these occur routinely during the development of virtually all colon carcinomas and that, more often than not, the rapid expansion of the carcinoma soon overgrows and obliterates the adenoma from which it arose.



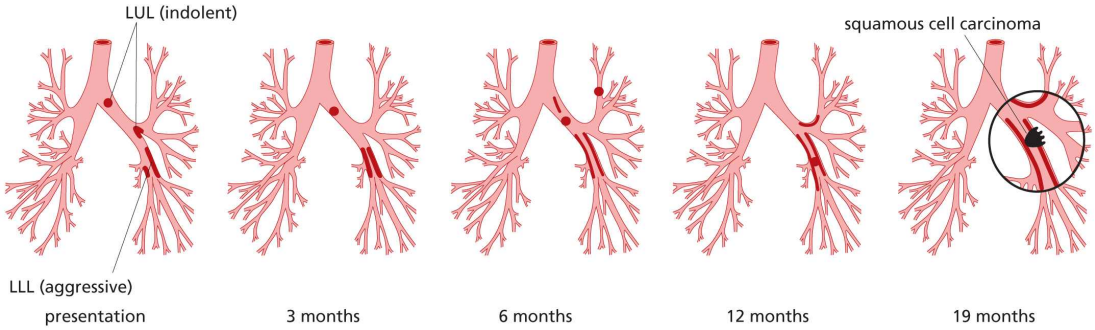
A histology image and beside it a diagram explaining what the image shows, namely a malignant tumor mass that is larger than the adenoma it is attached to, and is sending offshoots into nearby muscle tissue.

(A)



A graph with time on the horizontal axis and cumulative incidence of colorectal cancer on the vertical axis. Studies by the Mayo clinic and by Saint Mark's both suggest that with no polypectomy, the cumulative cancer incidence rises linearly from 0 at the time of the initial visit to about 4 percent 7 years later, and that with a polypectomy, the cumulative incidence remains remains very low for 6 years and remains below 1 percent even after a rise in year 7.

(B)



Five diagrams depicting lung cancer progression. The cancer begins as two indolent regions in the patient's left upper lobe and one aggressive lesion in the left lower lobe. Diagrams for 3, 6, 12 and 19 months show the indolent lesions disappearing and the aggressive lesion growing bigger and eventually sprouting a squamous cell carcinoma.

(C)

Figure 11.8 Evidence for adenoma-to-carcinoma progression The evidence for precursor–product relationships between premalignant growths (adenomas and *in situ* carcinomas) and frank carcinomas comes from at least three types of clinical observations. (A) On occasion, carcinomas are observed to be growing directly out of adenomas. As seen here, the demarcation between the two can sometimes be drawn with some precision. (B) A second line of evidence derives from clinical studies in which colonoscopy is used to screen large cohorts of patients. Any polyps that are discovered are removed by *polypectomy* (i.e., surgically). As seen in the graph, two independent studies (*yellow-orange, blue lines*) predict a certain expected number of carcinomas in such cohorts on the basis of historical experience. However, in patients who have undergone polypectomy, the number of colorectal cancers diagnosed in subsequent years has been reduced by more than 80% (*red line*). (A more conservative estimate of reduced risks gives the extent of reduction at 60%.) (C) As diagrammed here, three apparently significant premalignant carcinomas *in situ* were detected by *bronchoscopy* in the lungs of a patient upon initial clinical presentation. By 19 months, the lesion in the left lower

lobe (LLL; the left side of the lung is depicted here as might be seen from the front of the patient and is located from this perspective in the right side of the lung) had developed into a frank squamous cell carcinoma (*circle*), whereas the two indolent lesions in the left upper lobe (LUL) were no longer apparent. Interestingly, the three initially characterized lesions bore the same relatively rare *p53* mutation, indicating a common origin in spite of their physical separation; this mutation was also present in the subsequently arising carcinoma. (A, courtesy of Paul Edwards. B, courtesy of W.K. Hong, data from S. Winawer et al., *N. Engl. J. Med.* 329:1977–1981, 1993. C, from N.A. Foster et al., *Genes Chromosomes Cancer* 44:65–75, 2005. With permission from John Wiley & Sons.)

Second, clinical studies have been performed on large cohorts of patients who have undergone colonoscopy, which is performed routinely to survey the colon for occasional adenomatous polyps and to remove any that are detected (see also Figure 7.19). At present, it is estimated that those patients whose polyps are removed experience, in subsequent years, more than a 60% reduction in the incidence of colon carcinomas (Figure 11.8B). This finding indicates that in this patient population, conservatively, at least 60% of colon carcinomas derive from preexisting, readily detectable adenomas; because colonoscopy often misses polyps, especially those in the right side of the colon, the actual proportion may be higher. (These observations still do not prove that every single colon carcinoma arising in humans must arise from a preexisting adenoma.)

A third type of evidence supporting precursor–product relationships between premalignant and frankly malignant growths comes from longitudinal studies of individual patients over a period of time. This is occasionally possible in patients developing sporadic tumors in organs that are accessible to repeated surveillance, such as the skin, colon, and lungs (Figure 11.8C). Familial cancer syndromes also offer a demonstration of such progression in individual patients. Recall, for example, the disease of familial adenomatous polyposis (FAP; see Section 7.10), in which an individual inheriting a mutant form of the *APC* tumor suppressor gene is prone to develop anywhere from dozens to more than a thousand polyps in the intestine (see Figure 7.19). With a certain low but measurable frequency, one or another of these polyps will progress spontaneously into a carcinoma. (The multiplicity of polyps in these patients and the low conversion rate of individual polyps to carcinomas—estimated to be ~2.5 events per 1000 polyps per year—effectively preclude association of a carcinoma with a particular precursor polyp.). This evidence has been garnered through studies of the colon and its proclivity to generate the relatively common intestinal tumors. Indeed, these studies appear to indicate comparable processes operating in a variety of epithelial tissues throughout the body (**Sidebar 11.2**).

Sidebar 11.2 Parallel multi-step pathogenesis in multiple tissues

The development of carcinomas in other organ sites throughout the body is thought to resemble, at least in outline, the multi-step progression observed in the colon (see, for example, Figure 11.7A). Many of these other tissues, such as the breast, stomach, lungs, prostate, and pancreas, also exhibit growths that can be called hyperplastic, dysplastic, and adenomatous, and these growths would seem to be the benign precursors of the carcinomas that arise in these organs. However, the histopathological evidence supporting multi-step tumor progression in these tissues is, for the most part, less well developed than for the colon—a consequence of the accessibility of the colon through colonoscopy and the relative inaccessibility of these other tissues. (An exception to this rule is tumor formation in the pancreas, discussed below.) In the case of nonepithelial tissues, including components of the nervous system, the connective tissues, and the hematopoietic system, the histopathological evidence supporting multi-step tumor progression is even more fragmentary.

Importantly, and as we will discuss again later in this book, the early stages of progression in a tissue do not inevitably progress to later stages, and certain subtypes of early-stage tumors are unlikely to ever evolve into later, more aggressive stages. This has profound implications for clinical medicine and diagnostic screening, because many patients bearing early-stage tumors may be treated unnecessarily.

OceanofPDF.com

Glossary

mucosa
: Epithelial cell layer that secretes a mucus-like substance that forms a protective layer above the secreting cells.

hyperplasia
: (adj., - **plastic**) (1) Accumulation of excessive numbers of normal-appearing cells within an otherwise normal-appearing tissue. (2) An increase in the size of a tissue or organ, usually due to increased cell number rather than increased size of constituent cells.

hyperplasia
: (adj., - **plastic**) (1) Accumulation of excessive numbers of normal-appearing cells within an otherwise normal-appearing tissue. (2) An increase in the size of a tissue or organ, usually due to increased cell number rather than increased size of constituent cells.

polyp
: A tumor, usually presumed to be premalignant, protruding into the lumen of an organ, such as gut or bladder, often equated with an adenoma. *See also* **adenoma, polyposis**.

adenoma
: (adj., - **omatous**) Any of a series of premalignant, noninvasive growths in various epithelial tissues, many of which have the potential to progress further to carcinomas. *See also* **polyp**.

benign
: (1) Describing a growth that is confined to a specific site within a tissue and gives no evidence of invading adjacent tissue. (2) Referring to an epithelial growth that has not penetrated through the basement membrane.

malignant
: Describing a growth that shows evidence of being locally invasive and possibly even metastatic.

colonoscopy
: Clinical procedure used to visually survey the wall of the colon via insertion of an optical tube through the rectum, employed used to detect previously undiagnosed polyps.

longitudinal

Referring to the repeated, successive monitoring of a single patient or a group of patients over an extended period of time.

dysplasia

(adj., - **plastic**) A premalignant tissue composed of abnormally appearing cells forming a tissue architecture that deviates from normal.

metastasis

(pl., - **es**; adj., **metastatic**; v. **metastasize**) A neoplastic growth forming at one site in the body, the cells of which derive from a malignancy located elsewhere in the body, such as the site of primary tumor formation. (2) The process leading to the formation of metastases. *See also* **primary tumor**.

OceanofPDF.com

11.3 Cells accumulate genetic and epigenetic alterations as tumor progression proceeds

The forces driving tumor progression in various tissues are hardly obvious from the histopathological descriptions cited above. The progressive changes in cell and tissue phenotypes observed as a tumor develops may arise entirely from changes in various gene expression programs. For example, some or possibly all of the steps in tumor progression might recapitulate specific changes in cell behavior that occur during normal embryogenesis. Because such cell-biological changes are known to depend on changes in gene expression programs rather than alterations in genomic sequences, they are considered to be epigenetic in origin. However, the logic of cancer pathogenesis dictates that somatic mutations, that is, genetic changes, must be involved in important ways as major rate-limiting determinants of the formation of most human tumors (**Sidebar 11.3**).

Sidebar 11.3 Our large size and long lives has forced the erection in our cells of barriers to cancer formation

Given the huge number of cell growth-and-division cycles in an average human lifetime ($\sim 10^{16}$) and the opportunity during each of these cycles for disaster, our own species and indeed all large, long-lived animal species have needed to evolve robust defense mechanisms in order compensate for the countless genetic and epigenetic accidents that inevitably occur in tissues during a normal life span. These randomly occurring changes inevitably lead to progressive degradation of the genomes and epigenomes of the cells in these tissues, the latter referring to the entire set of the epigenetic mechanisms that govern the lives of individual cells. Among the consequences of increasing disorder is, inevitably, the runaway proliferation of neoplastic cells.

As argued earlier, we might propose that each of the discrete steps of multi-step tumor pathogenesis represents the successful breaching of one or another functional barrier that has been installed in our cells and designed specifically to impede the forward march of cancer progression. In fact, ever-increasing numbers of such barriers seem to have been needed as our metazoan ancestors evolved from small, short-lived organisms to contemporary long-lived, large animals like ourselves.

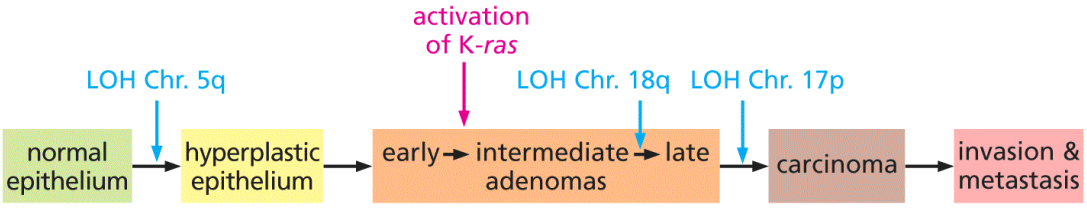
This logic dictates that the successful breaching of each functional barrier must have been rendered as improbable as possible, that is, such barriers, once erected, are as resistant to change as possible. In fact, the barriers that are most capable of resisting changes inflicted by random accidents are present in the nucleotide sequences of the genomes of our cells. Thus, the somatic mutations that corrupt cellular genomes occur with extraordinarily low probability per cell generation. This very low rate of accumulated mutations ($\sim 10^{-9}$ per base pair per cell cycle) testifies to the high fidelity of DNA replication and to the efficiency of the DNA repair apparatus that subsequently erases any mistakes that are made during initial replication (both of which we will encounter in Chapter 12).

Stated differently, the strategy of entrusting anti-neoplastic defense mechanisms to highly stable DNA sequences would seem to reduce the likelihood of frequent, spontaneous breakdowns of these defenses and resulting neoplastic cell transformation. This explains why mutations seem to be required to liberate incipient cancer cells from the constraints imposed by these genome-based defense mechanisms. (In contrast, the breaching of anti-neoplastic barriers established by various *epigenetic* defense mechanisms would seem to occur far more often per cell cycle, given the phenotypic plasticity that many cells exhibit, as discussed below.) Taken together, this logic helps to explain why successful tumorigenesis in various adult human tissues generally requires, at a minimum, a significant number of somatic mutations and resulting mutant alleles (perhaps four to six), and why epigenetic changes, on their own, rarely succeed in creating robustly growing adult tumors.

This parallel between the histopathological progression of neoplastic tissues and genetic evolution was initially documented for human colorectal carcinomas (CRCs). Thus, in 1989 researchers at Johns Hopkins Medical School in Baltimore, Maryland recognized the existing evidence that mutant alleles of genes such as *ras* and *p53* can contribute to cell transformation under experimental conditions *in vitro*. They therefore sought to determine whether they could find *in vivo* correlates of this genetically driven transformation by examining the genomes of sizable groups of small colonic adenomas, mid-sized adenomas, large adenomas, and frank colorectal carcinomas. It was plausible that as colonic tissues advanced progressively from normalcy to high-grade malignancy, the epithelial cells in these various tissues would accumulate increasing numbers of somatic mutations in various cancer-causing genes.

This is just what these scientists discovered (**Figure 11.9**). The genes that they examined included the K-*ras* oncogene and a number of tumor suppressor genes (TSGs). In fact, the identities of the TSGs that participate in colon cancer pathogenesis were not known when they began their work, so they searched instead for chromosomal regions that suffered loss of heterozygosity (LOH) during tumor progression. Recall that a high rate of LOH in a particular chromosomal region

provides strong indication that this region harbors a TSG, and that developing cancer cells exploit the LOH mechanism as a means of shedding the still-functional (that is, actively expressed) wild-type alleles of such a TSG (see Section 7.4).



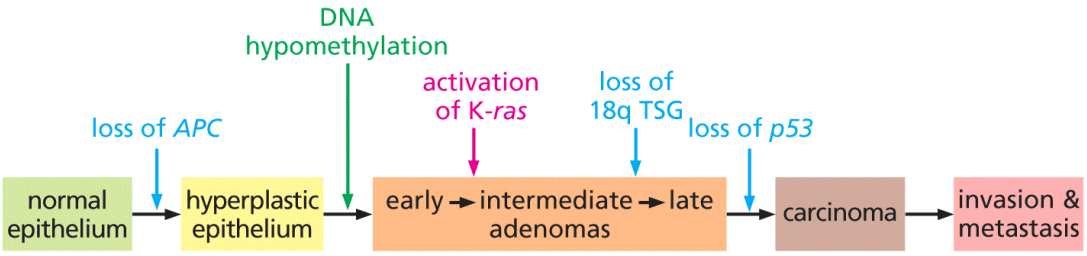
Events during colon tumor progression. Loss of heterozygosity in chromosome 5 q occurs during the transition from normal epithelium to hyperplastic epithelium. Activation of K-ras occurs during the transition from early adenoma to intermediate adenoma. Loss of heterozygosity in chromosome 18 q occurs during the transition from intermediate adenoma to late adenoma. Loss of heterozygosity in chromosome 17 p occurs during the transition from late adenoma to carcinoma. Invasion and metastasis follow.

Figure 11.9 Colon tumor progression and loss of heterozygosity in various chromosomal arms DNA from tissue samples representing various stages of colon cancer progression was analyzed for loss of heterozygosity (LOH) by examining the behavior of chromosomal markers present on the long and short arms of most chromosomes, as described in Figure 7.11B. In general, each chromosomal arm was represented by one or more genetic loci that existed in heterozygous form in the normal tissue of a patient. As tumor progression proceeded, the involved colonic epithelial cells exhibited increasing numbers of chromosomal arms that had lost heterozygosity. Certain chromosomal regions (*blue lettering*) suffered especially high rates of LOH, suggesting that they carried tumor suppressor genes that were being inactivated, in part, through the LOH mechanism. Analyses of K-*ras* oncogene activation (*pink lettering*) indicated additional changes in the genomes of evolving premalignant cells. (Adapted from B. Vogelstein et al., *Science* 244:207–211, 1989.)

This research demonstrated that early-stage adenomas often showed loss of heterozygosity in the long arm of Chromosome 5 (that is, 5q). Almost half of slightly larger adenomas carried, in addition, a mutant K-*ras* oncogene. Even larger adenomas also tended to have high rates of LOH on the long arm of Chromosome 18 (that is, 18q); about half of all carcinomas showed, in addition, an LOH on the short arm of Chromosome 17 (that is, 17p); (see also Figure 7.11B and Table 7.1).

These observations provided strong support for the idea that as epithelial cells acquire increasingly neoplastic phenotypes during the course of tumor progression, their genomes show a corresponding increase in the number of altered genetic loci. Equally important, these changes involve both the activation of a proto-oncogene into an oncogene (for example, K-*ras*) and the apparent inactivation of at least three distinct TSGs. This was the first suggestion of a phenomenon that is now recognized to be quite common: the number of inactivated TSGs present in a human cancer cell genome often greatly exceeds the number of activated oncogenes within this genome.

The identities of the genetic loci on Chromosomes 5 and 17 were revealed soon after this genetic progression was laid out (**Figure 11.10**). The Chromosome 5q21 gene that is often the target of LOH was found to be the *APC* (adenomatous polyposis coli) tumor suppressor gene (see Section 7.11), and the Chromosome 17p13 gene was identified as the *p53* tumor suppressor gene (see Chapter 9). The identity of the gene or genes on Chromosome 18q that are inactivated during colon carcinoma pathogenesis remains unclear to this day. Of additional importance, tumors that carry a mutant *ras* allele rarely acquire in addition a mutant *PI3K* allele. This suggests that an evolving premalignant cell will acquire an advantageous set of phenotypes from one of these mutations (for example, *ras*) and that descendants of this cell acquire no additional benefit from mutating a second gene conferring a redundant cell-biological function. This sequence of changes, as laid out in Figure 11.10, raises the question of whether these mutations are acquired in a specific or at least preferred sequence during the course of tumor pathogenesis (**Sidebar 11.4**). A more detailed accounting of these genetic changes and those occurring during pancreatic carcinoma development is given in **Supplementary Sidebar 11.3**.



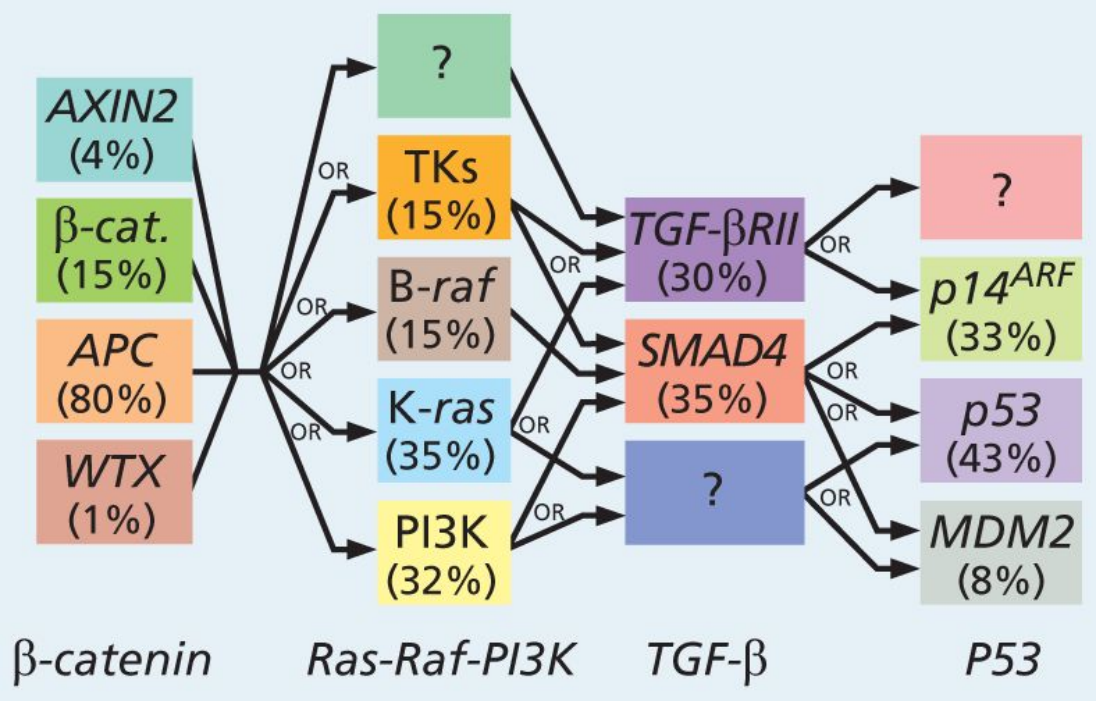
More events during colon tumor progression. Loss of A P C occurs during the transition from normal epithelium to hyperplastic epithelium. D N A hypomethylation occurs during the transition from hyperplastic epithelium to early adenoma. Activation of K-ras occurs during the transition from early adenoma to intermediate adenoma. Loss of the 18 q tumor suppressor gene occurs during the transition from intermediate adenoma to late adenoma. Loss of p53 occurs during the transition from late adenoma to carcinoma. Invasion and metastasis follow.

Figure 11.10 Tumor suppressor genes and colon carcinoma progression Each of the inactivated TSG(s) on Chromosome 18q remains unclear. About half of colon carcinomas also had mutant, activated alleles of the K-*ras* gene (*pink lettering*), and the genomes of most evolving, pre-neoplastic growths were found to suffer widespread hypomethylation (loss of methylated CpGs; *green lettering*). The precise contribution of DNA hypomethylation to tumor progression remains unclear; some evidence suggests that it creates chromosomal instability.

Sidebar 11.4 Is there a fixed order of somatic mutations during multi-step tumor progression?

The most obvious way to rationalize the steps in colon cancer development involves an ordered succession of genetic changes that strike the genomes of colonic epithelial cells as they evolve progressively toward malignancy, as illustrated in Figure 11.10. Indeed, the order of acquisition of mutant alleles affects in a major way the efficiency and speed with which tumors are formed. It turns out the most efficient route to primary carcinoma formation involves mutations of the *APC* gene, then in K-*ras*, then *Smad4*, and finally *p53*.

To be more precise, mutation of each of the genes indicates the deregulation of a specific signaling pathway. Hence, the order of disrupting these *pathways* is the ultimate determinant of the rapidity of tumor progression, and the nature of each pathway (rather than the specific identity of a specifically mutated gene) is the critical determinant of ultimate biological effects (**Figure 11.11**). Thus, mutations in the gene encoding β-catenin can substitute for mutant *Apc* alleles, whereas mutations of the *B-Raf* or the gene specifying PI3 kinase can replace a mutant *Ras* allele. Moreover, promoter methylation and shut down of the gene specifying the Type I TGF-β receptor can replace *Smad 4* mutant alleles, and so forth. This theme of preferred order is echoed in other tumor types as well.



A diagram showing many alternative paths during cancer progression. The diagram lists four pathways, left to right, and for each pathway lists several genes whose mutation would advance the progression. For the beta catenin pathway, the possible gene mutations and their frequencies are AXIN 2, 4 percent; beta catenin, 15 percent; A P C, 80 percent; and W T X, 1 percent. For the R a s R a f P I 3 K pathway, the possible gene mutations and their frequencies are T K s, 15 percent; B r a f, 15 percent; K r a s, 35 percent; P I 3 K, 32 percent; and an unknown fifth gene. Any of these may follow the beta catenin mutation. For the T G F beta pathway, the possible gene mutations and their frequencies are T G F beta R I I, 30 percent; S M A D 4, 35 percent; and an unknown third gene. Each of these may follow two or three of the R a s R a f P I 3 K mutations. Finally, for the P53 pathway, the possible gene mutations and their frequencies are p14 A R F, 33 percent; p53, 43 percent; M D M 2, 8 percent; and an unknown fourth gene. Each of known genes may follow two of the T G F beta mutations.

Figure 11.11 Alternative paths during cancer progression The genetic alterations shown in Figure 11.10 do not accurately represent an invariant program of genetic alterations acquired by pre-neoplastic cells during the progression of all colorectal carcinomas. In actual human tumors, both the *combination* of mutated genes and the *temporal order* in which the responsible mutations are acquired vary greatly. (Only the combinations of mutant genes are depicted in this figure.) Loss of APC function (or functionally equivalent alterations, *left column*) represents a starting point that is common to almost all human colon carcinomas, ostensibly because the resulting mutant cells are trapped in the colonic crypts rather than

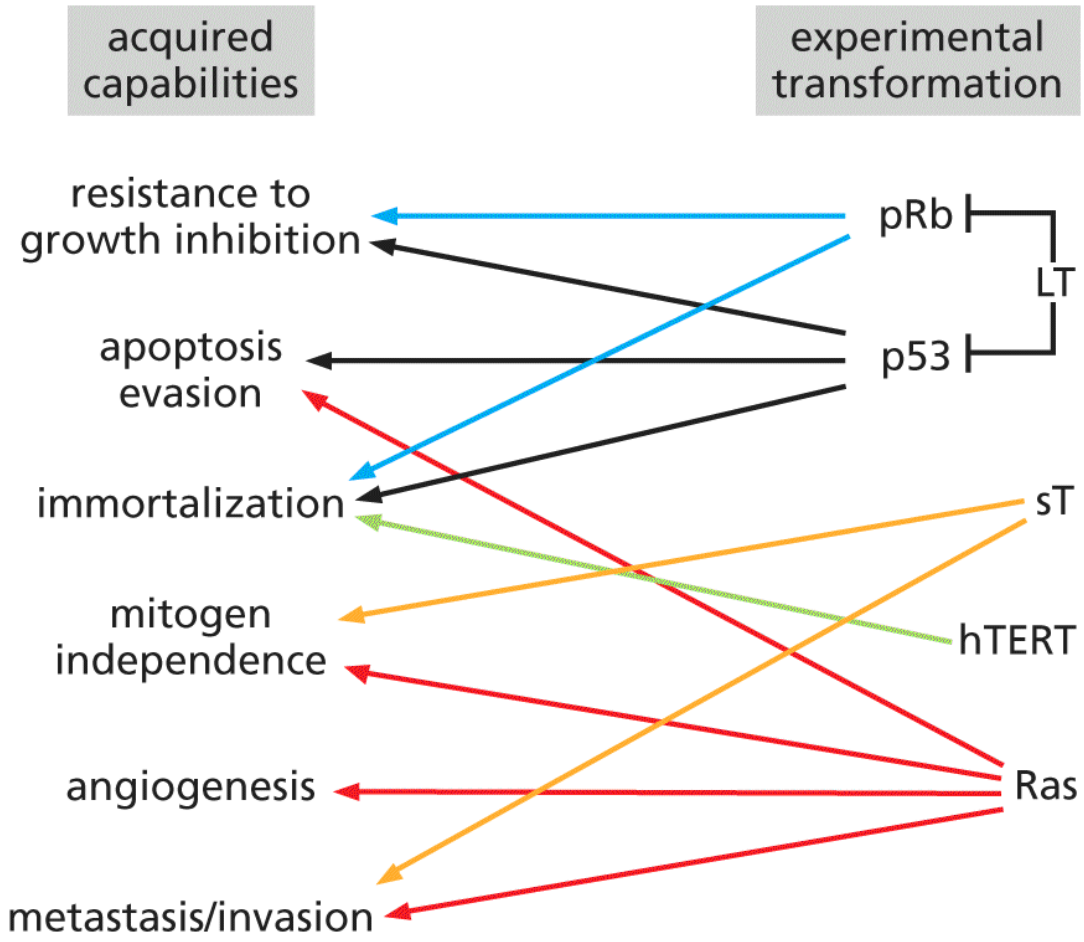
migrating up and out; all of these changes seem to potentiate β-catenin function and to generate the clusters of aberrant crypts (see Figures 7.20 and 11.24B) encountered in colonoscopy. However, the identities of the genes altered in subsequent steps are variable, as is the precise order of these changes. (For the sake of clarity, the gene names given here reflect the names of their respective protein products.) Alterations in the Ras–Raf–PI3K pathway is shown as the second step, as these changes are often found in adenomas prior to the formation of frank carcinomas. These changes have been grouped functionally (so that the *second column* shows the Ras pathway; the *third column*, the TGF-β pathway; and the *fourth column*, the p53 pathway). Mutations in the *p53* gene are usually seen in carcinomas but not adenomas, indicating that its loss represents a relatively late step. Importantly, the precise number of genetic steps and epigenetic steps (notably promoter methylation) occurring during human colon cancer pathogenesis is not known. Moreover, there is only indirect evidence that all four of these pathways must be altered in order for a human colorectal carcinoma to form. The percentages indicate the proportion of colorectal carcinomas that exhibit a change in the gene in question, including activating mutations in proto-oncogenes and inactivating changes in tumor suppressor genes. (Courtesy of Y. Niitsu.)

As an example, in mice bearing germ-line mutant alleles of the *p53* gene, mutations of *PTEN* are the favored initial somatic mutations during the pathogenesis of thymic lymphomas, followed later by amplification of the cyclin D1-encoding gene and then mutations in the *Ikaros* gene, which encodes a zinc finger transcription factor. The well-documented order of these acquired somatic mutations suggests that, in the case of each developing tumor, an earlier mutation sets the stage for the actions of the subsequently acquired mutant alleles. Further support for the essentiality of specific chronological orders of events comes from individuals who inherit mutant germ-line alleles of the *p53* gene and suffer from Li–Fraumeni syndrome (see Section 9.3). Although mutant *p53* alleles frequently occur as one of the later steps of colorectal carcinoma pathogenesis, these individuals rarely develop colorectal tumors and instead develop them elsewhere throughout the body, revealing the unique role of germ-line mutant *Apc* alleles in initiating multi-step colon cancer pathogenesis.

As discussed in the previous chapters and in this one, incipient cancer cells must undergo a set of fundamental cell-biological changes in order to progress to the state of cells found in high-grade malignancies. These changes in cell-biological behavior, that is, cancer cell phenotypes, have been enumerated and proposed to be shared in common by a wide range of malignant cells and are termed "Hallmarks of Cancer." As initially proposed, they include, minimally, the acquired traits of (1) autonomously driven proliferation, (2) resistance to the anti-proliferative effects of certain signals

received from the tissue microenvironment, (3) an elevated resistance to several forms of cell death, (4) an ability to induce the in-growth of new blood vessels (neo-angiogenesis), (5) an ability to proliferate indefinitely, that is, cell immortalization, (6) an ability in the case of solid tumors to disseminate and seed new tumor colonies, that is, the process of metastasis. Two more traits have subsequently been added to this list of traits shared by diverse types of cancer cells: (7) an ability to resist and evade elimination by the immune system and (8) a deregulation of cellular energy metabolism.

Having agreed, at least tentatively, upon a set of these widely exhibited cancer-associated cellular traits, we confront the observations that each of these traits can be acquired through multiple alternative genetic or biochemical solutions. As an example, signals that drive proliferation can be acquired by structural alteration of growth factor receptors, their overexpression, the acquired ability to produce and constitutively secrete the cognate ligand of a receptor (leading to autocrine signaling), or the structural alteration of signal-transducing proteins lying downstream of the receptors as components of the complex mitogenic signaling pathway. In addition, there is no one-to-one correspondence between the actions of most somatically mutated genes and acquisition of critical cell-biological phenotypes such as the Hallmarks of Cancer cited above (**Figure 11.12**).



A diagram listing acquired cell capabilities on the left and the corresponding experimental transformations on the right. Immortalization and resistance to growth inhibition can be elicited by using L T to inhibit p R b or p53. Using L T to inhibit p53 also elicits apotosis evasion. Immortalization can also be elicited by transforming h TERT. Transforming s T elicits mitogen independence and metastasis slash invasion. Transforming R a s elicits apotosis evasion, mitogen independence, angiogenesis, and metastasis slash invasion.

Figure 11.12 Cancer cell genotypes vs. phenotypes During the course of tumor progression, human cells acquire a number of distinct cancer-associated phenotypes, such as the Hallmarks of Cancer cited here. Independent of this, genetic analyses of human tumors and laboratory experiments reveal that a number of distinct genes must be acquired by or introduced into human cells in order to transform them to a tumorigenic state. How then, does each of these introduced genes contribute to the cell phenotypes associated with tumorigenicity? As indicated here, genes such as that encoding hTERT, the catalytic subunit of telomerase, affect only the phenotype of immortalization, whereas other genes, such as the one encoding SV40 large T (LT), used experimentally to neutralize

both p53 and pRb, disrupt two distinct cellular signaling pathways and affect multiple phenotypes. For example, by inactivating p53, LT elicits at least three changes in cell phenotype—resistance to growth inhibition, evasion of apoptosis, and immortalization; by neutralizing pRb, LT also affects two of these phenotypes. The most widely acting protein is likely to be Ras, which affects susceptibility to apoptosis, dependence on exogenous mitogens, angiogenesis, and invasiveness and metastatic ability. Hence, a one-to-one mapping between genes and cancer-associated phenotypes is not possible. (Because hTERT has been found to be physically associated with the β-catenin–TCF/LEF transcription factor complex, its actions may extend beyond cell immortalization.)

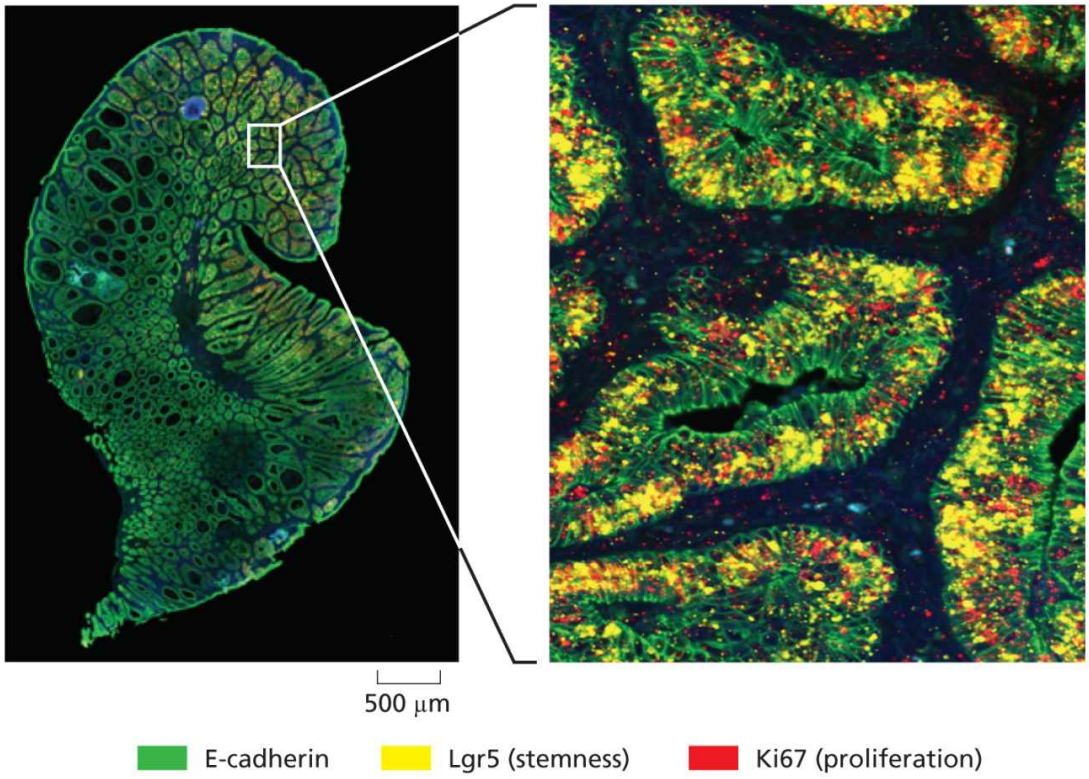
Finally, we should note that these various genetic and epigenetic changes do not represent an upper limit to the number of alterations that contribute in essential ways to colon cancer progression. For example, the type of genetic analysis used to identify this particular series of four chromosomal regions registered only those loss-of-heterozygosity (LOH) events in tumor suppressor genes that occurred at a significant frequency above the general background rate of LOH associated with all chromosomal arms in advanced tumor cells (see Figure 7.11B). Accordingly, LOH events that occur with a relatively low frequency (that is, those present in 20% or fewer of the tumors analyzed) would not be registered in such an analysis, even though these events might lead to the elimination from the genome of an incipient cancer cell of functionally important tumor suppressor genes. Similarly, changes in gene copy number, such as amplification of mutant oncogenes, were also not registered in this early work.

Epigenetic events, including the repression of certain genes through promoter methylation (see Section 7.7) and the de-repression of others through demethylation, may also contribute importantly to tumor progression. Recently, evidence has accumulated that hypomethylation (that is, demethylation of normally CpG methylated DNA sequences), such as that observed in early adenomas (see Figure 11.10), has a functional consequence that is independent of its possible effects on gene transcription: widespread chromosomal instability, which presumably favors tumor progression. How precisely it does so is unclear; a de-repression of usually-silent transposable elements in the cell genome may contribute to this genomic destabilization.

The publication of this “genetic biography” of colon cancer tumorigenesis, as depicted in Figure 11.10 (see also **Supplementary Sidebar 11.3**), should ideally have been followed by similar descriptions of a wide variety of other tumor types, with each of such biographies involving alterations of its own particular set of oncogenes and tumor suppressor genes as accompaniments of specific histopathological states. Unfortunately, only a handful of such descriptions have actually been reported in detail. At present, therefore, we cannot cite lists of genetic alterations in tumor cell

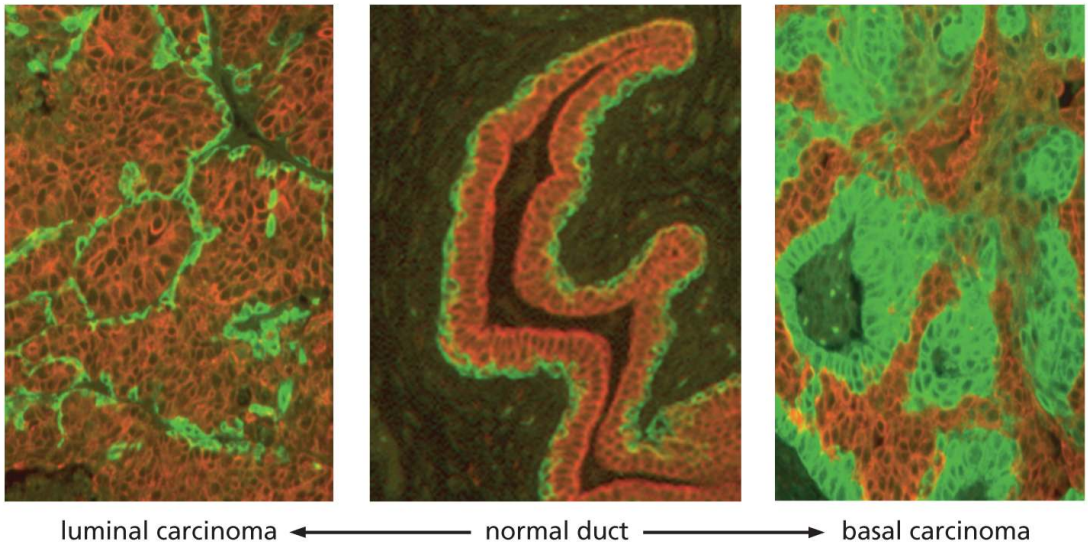
genomes to illustrate the molecular underpinnings of the multi-step nature of cancer progression in most organs. However, with the availability of large-scale, whole-genome sequencing technologies, these biographies will surely be described in the near-term future.

The accumulations of multiple genetic and epigenetic changes during tumor formation might suggest that the final cellular end-products of tumorigenesis bear little resemblance to their most recent, fully normal ancestors—the normal cells-of-origin. In fact, it seems increasingly likely that many of the differentiation programs of normal cells-of-origin persist in their neoplastic descendants years if not decades later (**Figure 11.13**). One indication of this at the molecular level is the extensive retention of sequence-specific CpG methylation sites present in the genomes of the normal cells-of-origin within the genomes of derived neoplastic cells; these methylated CpG play critical roles in the cell-heritable transmission of differentiation programs. Accordingly, even though certain oncogenic changes in tumor cell genomes (for example, loss of pRB function and gain of Myc function; see Section 8.9) tend to cause loss of differentiated characteristics, this loss is incomplete; that is, these genetic changes fail to eradicate all traces of the differentiation program that preexists in the normal tissue. Indeed, the retention of differentiated traits—distinctive morphologies and protein markers—in most (~95%) tumors allows pathologists to classify these growths into different subgroups with reasonable accuracy.



A carcinoma on the left, roughly 4 millimeters long, and on the right a small portion greatly magnified. The magnified portion contains a mixture of red and yellow across mostly geen cells

(A)



Three images, with a normal duct in the middle, having a narrow band of red and an even thinner border of green along it. On the left is a luminal carcinoma, appearing as a mass of red cells with veins of green running through it. On the right is a basal carcinoma, appearing as a mass of green and red cells, with green predominating.

(B)

Figure 11.13 Retention of differentiated characteristic in human tumors (A) The tumors arising in a transgenic mouse model of colorectal carcinoma pathogenesis (*left*) would seem to have little if any resemblance to the histology of the normal colon. At higher magnification (*right*), the cells are seen to form ductal structures with clear evidence of their epithelial origin (evidenced by E-cadherin expression, significant levels of cell proliferation, and stemness). (B) The ducts in the normal mammary gland (*middle*) are composed of two major types of epithelial cells: luminal cells that form the lining of ducts (*red-orange*) and underlying basal cells (*green*) that provide various types of physiological support to the luminal cells. These cell types can be distinguished by immunofluorescence staining using antibodies that are specific for the cytokeratin molecules that these cells express: cytokeratins 8 and 18 are expressed characteristically in luminal cells, whereas cytokeratin 5 is expressed in basal cells. These markers can be used to classify breast carcinomas into two major histological classes—luminal (*left*)

and basal (*right*)—and the resulting classifications hold strong implication for the prognosis of breast cancer patients. However, some evidence indicates that these classifications may not properly reveal the identities of the respective normal cells of origin, and suggests, for example, that certain basal breast carcinomas may actually originate from luminal progenitors. (A, L. Caplan and J. Roper, courtesy of The Broad Institute, Inc. B, from J.I. Herschkowitz et al., *Genome Biol.* 8:R76, 2007. With permission from Springer Nature.)

These findings, on their own, raise another issue that complicates our understanding of cancer biology and remains poorly resolved: Precisely how do the differentiation programs of normal cells-of-origin interact with and influence the phenotypes of derived cancer cells bearing various sets of somatically mutated cancer-forming genes?

OceanofPDF.com

Glossary

epigenetic
: (1) Referring to a process that affects phenotype without the involvement of heritable changes in the nucleotide sequence of the genome. (2) Referring to a mechanism enabling the transmission of a heritable trait from a cell or organism to its progeny that does not depend directly on changes of specific nucleotide sequences in its genome. (3) Referring to a mechanism that creates a cell-heritable trait, as in (2), and maintains expression of this trait in the absence of ongoing exposure to the stimulus that initially induced the expression of this trait. *See also* **epigenetics**, **genetic**.

epigenome
: The entire ensemble of modifications of a genome that do not affect its nucleotide sequences, such as methylation of CpG dinucleotides in the DNA and modifications of chromatin-associated proteins, notably histones. The epigenome is presumed to dictate the transcriptome of a cell, that is, the pattern of expression of a cell's repertoire of genes. *See also* **transcriptome**.

zinc finger
: A protein structural domain that binds and is stabilized by one or more zinc ions. Zinc fingers are employed by certain transcription factors to recognize and bind specific oligonucleotide sequences in DNA.

Hallmarks of Cancer
: A set of cell-biological traits that are shared in common by the neoplastic cells forming a wide range of distinct types of tumors, are required for expression of the neoplastic cell phenotype, and distinguish such cells from the traits of corresponding normal cells.

cell-of-origin
: The fully normal cell that serves as the ancestor of all the neoplastic cells within a tumor, i.e., their last common normal ancestor.

11.4 Cancer development seems to follow the rules of Darwinian evolution

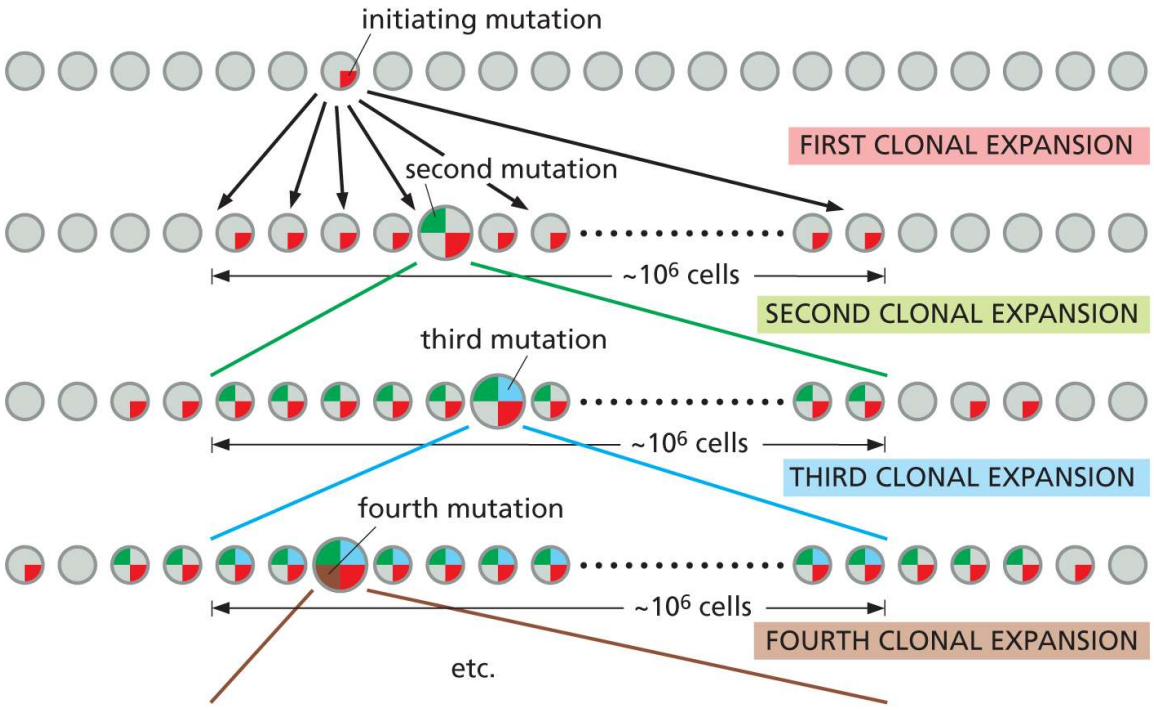
The observations about colorectal cancer made at Johns Hopkins University demonstrated that the histopathological changes occurring during tumor progression (see Figure 11.10) were *correlated* with genetic changes in cells of the colonic mucosa. More important, however, it became plausible that these genetic changes were actually *causing* the phenotypic progression of these cells and the tissues they form.

Years earlier, in the mid-1970s, researchers had speculated that tumor development could be understood in terms of a biological process that resembles Darwinian evolution. The results of the genetic analyses of human colorectal cancer progression could be mustered to provide further support for this model. (Although Darwin himself knew virtually nothing about genes and genetics, the "modern synthesis" of Darwinian theory introduces Mendelian and population genetics into the evolutionary processes that Darwin first postulated.)

In the case of cancer development, the evolving units are individual cells competing with one another in a population of cells, rather than individual organisms competing with one another within a species. Like the modern depiction of Darwinian evolution, random mutations are presumed to create genetic and thus phenotypic variability in a cell population. Once a genetically heterogeneous cell population has been generated through stochastic genetic and epigenetic events, the forces of selection may then favor the outgrowth of individual cells (and their lineal descendants) that happen to be endowed with mutant alleles and cell-heritable epigenetic alterations conferring advantageous traits, notably traits that favor proliferation and survival in the microenvironment of a living tissue. In the language of evolutionary biologists, such favored cells are said to exhibit increased fitness.

Combining Darwinian theory with the assumptions of multi-step tumor progression, researchers could now depict tumorigenesis as a succession of clonal expansions, (where the term "clonal" indicates a cell population all of whose members descend from a single, common ancestor) (**Figure 11.14**). The scheme

goes like this: a random mutation creates a cell having particularly advantageous proliferative or survival traits. This cell and its descendants then proliferate more effectively than their neighbors, eventually yielding a large clonal population of descendants that dominates the tissue and crowds out phenotypically less favored neighbors. Sooner or later, this particular cell clone will reach a large enough size (for example, 10^6 cells) that yet another advantageous mutation, which strikes randomly with a probability of about one per 10^6 cell generations, becomes mathematically possible, striking one or another cell within this now-expanded clonal population.



A sequence of clonal expansions. In the first clonal expansion, an initiating mutation in one of many cells is replicated into perhaps 1 million offspring cells. In the second clonal expansion, one of these offspring cells undergods a second mutation that is than passed on to a new set of 1 million offspring cells. This process is repeated in a third and a fourth clonal expansion, and so on.

Figure 11.14 Darwinian evolution and clonal successions Darwinian evolution involves the increase in number of organisms that are endowed with advantageous genotypes and thus phenotypes; a formally similar scheme seems to describe how tumor progression occurs. One cell amid a large cell population sustains an initiating mutation (*red sector, top*) that confers on it a

proliferative and/or survival advantage over the other cells. Eventually, the clonal descendants of this mutant cell dominate in a localized area by displacing the cells that lack this mutation, resulting in the first clonal expansion. When this clone expands to a large enough size (e.g., 10^6 cells), a second mutation—one that strikes with a frequency of $\sim 10^{-6}$ per cell generation—may occur (*green sector*), resulting in a doubly mutated cell that has even greater proliferative and/or survival advantage. The process of clonal expansion then repeats itself, and the newly mutated population displaces ("succeeds") the previously formed one, yielding a process that is termed *clonal succession*. This results once again in a large descendant population, in which a third mutation (*blue sector*) occurs, and so forth. Although classical Darwinian evolution is thought to depend on mutations in the genomes of organisms, it is highly likely that other heritable changes in cell populations, notably promoter methylation events (see Section 7.7), can play an equally prominent role in multi-step tumor progression. Importantly, this scheme does not take into account that clonal successions may require greatly different time intervals to reach completion. For example, later successions are likely to proceed far more rapidly than earlier ones because the participating cells, having acquired oncogenic mutations, may proliferate more rapidly and have more mutable genomes.

Importantly, this new, secondary mutation alters a gene and encoded protein so that it is functionally *complementary* to the actions of the earlier mutation in the ways that it affects tumor cell proliferation and survival. For example, in the case of colorectal cancer (CRC), if the first mutated gene is *APC,* the subsequently mutated allele, such as K-*ras,* will *collaborate* with one or more mutant *APC* alleles to favor cell outgrowth and survival rather than *duplicating* the actions of the existing mutant *APC* allele (see Figure 11.10). (In the discussion here, advantageous cell-heritable epigenetic alterations are, for the sake of this argument, included under the rubric of genetic mutations.)

Implicit in this scheme is a simple conclusion: in order to operate in a way that is functionally complementary to the actions of previously acquired mutant alleles, a newly acquired mutant allele must provide additional proliferative and/or survival advantage. Conversely, a newly generated allele that is functionally redundant with existing mutant alleles is unlikely to confer such additional advantage, and its retention in the descendants of this cells will accordingly not be favored by the forces of selection.

To be sure, a strict Darwinian model of cancer progression, which involves a series of clonal successions, is simplistic. For example, it must be amended to respond to the discoveries that cell-heritable epigenetic alterations of genes, such as promoter methylation and demethylation events (see Section 7.7 and Figure 11.10), play an important role in eliminating the activities of some genes (notably tumor suppressor genes as well as genes involved in the maintenance of the cell genome) and activating others. Here, we encounter a major discordance between tumor progression and Darwinian evolution because heritable epigenetic alterations, such as DNA methylation events, have not been shown to drive the evolution of species.

This scheme is simplistic in other respects as well. Thus, the number of distinct steps in tumor progression, each represented by a clonal expansion, may be underrepresented by counting the number of genetic loci that are altered during this process. As discussed in Chapter 7, the inactivation of a TSG is, almost always, a two-step process. First, one gene copy is mutated (or methylated) to inactivity. Thereafter, the surviving, still-intact gene copy is eliminated, usually through loss of heterozygosity (LOH). Knowing this and the fact that elimination of TSGs often represents the majority of the genomic changes occurring during tumor progression, we conclude that the number of distinct genetic alterations taking place during tumor progression may be almost twice as many as the number of loci that are involved.

In addition, the number of successive clonal expansions is difficult to quantify by studying the *dynamics* of multi-step tumor formation. Thus, certain genetic and epigenetic accidents may occur only infrequently, thereby creating rate-limiting events that slow down the progress of the entire process, whereas other events may happen very quickly, triggering clonal expansions that do not register as rate-limiting events when calculating the multiplicity of events as discussed in **Supplementary Sidebar 11.1**. Of equal importance, we know rather little about the time intervals between successive clonal expansions. The time elapsed between these expansions is actually critical to human health, as long intervals may effectively preclude the appearance of a tumor within a human life span, whereas short intervals may dictate the appearance of a tumor that requires attention in the oncology clinic, possibly even in mid-life.

Because an infrequently occurring genetic or epigenetic alteration (or a pair of alterations, in the case of TSGs) triggers each of these clonal expansions, the expansions are likely to be spaced far apart in time. During the development of sporadic colorectal cancers, a decade or more may separate one critical genetic

alteration from the next, and in many individuals, the process as a whole may stretch over a century. (For example, one of the key steps—the evolution from polyp to invasive cancer—has been estimated to take as long as 17 years, depending on the degree of dysplasia present in the precursor polyp.) Still, it is clear that some people develop sporadic colon carcinomas in far less time, and so this schedule must be compressed in the colons of these individuals. Moreover, there is no reason to think that each clonal expansion requires an interval of time that is comparable to the time required for other such expansions. As an example, for various molecular reasons, the formation of a mutant K-*ras* allele via point mutation may occur more slowly than the elimination of *APC* function through losses of both copies of this gene.

We know almost nothing about the physiological mechanisms that govern the lengths of the time intervals between successive clonal expansions. In the case of the disease of colon cancer, we know that the incidence of this disease varies by as much as twentyfold internationally and that environmental factors, specifically foodstuffs (rather than genetic susceptibility) are responsible for these dramatic differences. (As Figure 2.18 shows, a population migrating from one country to another exhibits a colon and prostate incidence rates typical of its new host country within a generation or two, ruling out genetics as the key determinant of cancer risk in the great majority of these cancer cases.) It is highly likely that certain constituents of diet greatly increase the rate at which clonal successions occur, that is, compress the time intervals between these successions. This might occur through two alternative mechanisms. Mutation rates may increase progressively during the course of multi-step tumorigenesis due to acquired defects in the genes tasked with maintaining genomic integrity, as described in the next chapter. In addition, non-genetic mechanisms, specifically the tumor promoters to be described in Section 11.11 may accelerate the rate of clonal expansions, acting exclusively through nongenetic mechanisms. Perhaps in individuals who consume certain foodstuffs, 5 or fewer years intervene between successive clonal expansions rather than the usual 10 or 20. As a consequence, a disease process that usually requires a century to reach completion may reach its neoplastic endpoint in 30 or 40 years — well within a human life span. Finally, individuals who bear mutations in DNA repair genes that are inherited through the germ line may experience increases in the rapidity of clonal expansions. In the context once again of the gut, such people may suffer from greatly accelerated rate of formation of premalignant and malignant growths in the colon—the syndrome of hereditary non-polyposis colon cancer (HNPCC).

In fact, there is another dimension of complexity that we have not yet confronted. Specifically, the tissue microenvironment (TME) in which normal and pre-neoplastic cells find themselves. There is clear evidence that this TME, which is represented by the stroma of normal and neoplastic epithelial cells, changes progressively with age, and that aged tissue microenvironments can be more hospitable to the inception and outgrowth of pre-neoplastic and frankly neoplastic cell clones. Hence, part of the increasing incidence of cancer with age may not derive exclusively from cell-autonomous processes (that is, those operating entirely within the precursors of carcinoma cells) that govern the dynamics of clonal expansion. Instead, tumors may occur more frequently in older people in part because the microenvironments within their aging tissues increasingly favor the eruption of tumors.

OceanofPDF.com

Glossary

fitness

(1) Term to reflect the likelihood that, during the course of evolution, an organism will leave more descendants within a species as a consequence of its increased adaptation to the environment in which it exists or elevated ability to compete successfully with other similar individual organisms within the species. (2) Similar dynamics applying to the ability of an individual cancer cell or group of cancer cells to outcompete other such cells within a tumor.

clonal succession

Process by which one clonal population of cells displaces and thus succeeds a preexisting clonal population of cells; by implication, the displacing cell population has acquired a more advantageous phenotype relative to that of the cell population that is being displaced. *See also* **clonal expansion**.

tumor promoter

(1) An agent that furthers the progression of multi-step tumorigenesis by nongenetic mechanisms, notably those involving inflammation and/or mitogenesis, sometimes termed promoting agent. Tumor promoters are presumed to work by accelerating the rate of clonal expansion of already-mutated cells. (2) The DNA sequence associated with a gene that controls its transcription. *See also* **promotion**.

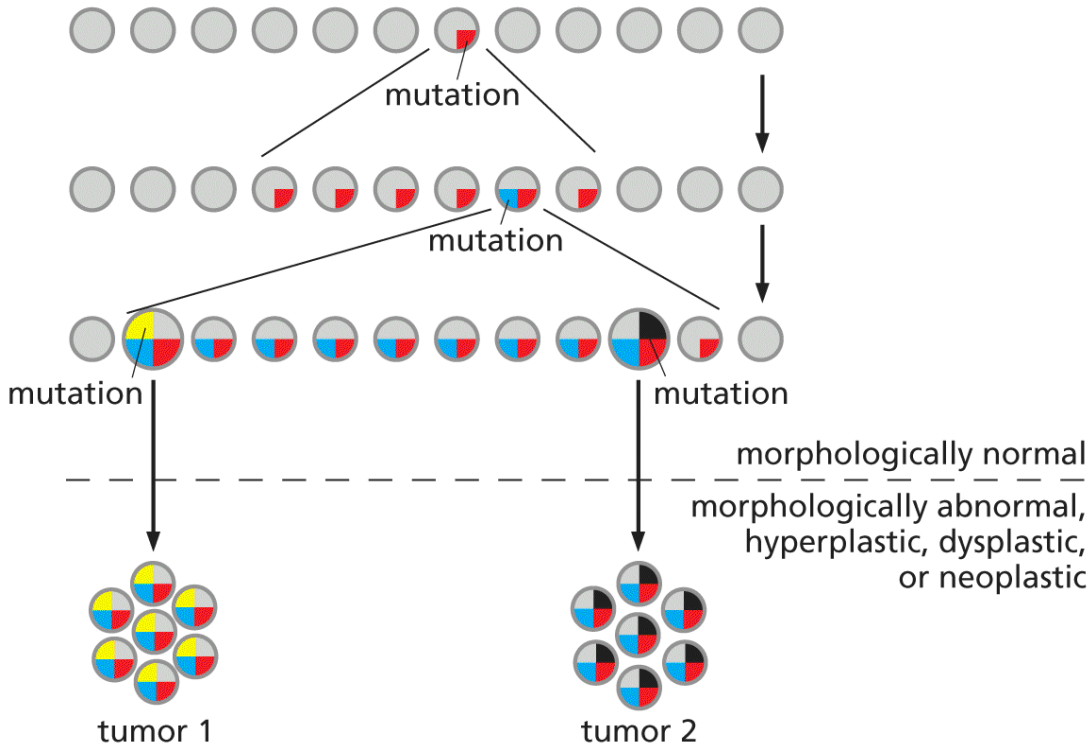
11.5 Multi-step tumor progression helps to explain familial polyposis and field cancerization

As described in the previous section, the first step in the development of the great majority of *sporadic* colon carcinomas (that is, those not driven by an inherited mutant gene) involves the inactivation of the *APC* gene—precisely the same gene that is inherited in mutant form by individuals suffering from the *familial* polyposis syndrome (Section 7.10). Now, in the context of multi-step tumorigenesis, we can understand why inheritance of a mutant *APC* allele results in polyposis and colon cancer: the first step in colon cancer progression, which involves the inactivation of an *APC* gene copy, has already occurred in all of the colonic epithelial cells of an individual suffering from familial polyposis. That is, each of their cells, including those in the colon, is $APC^{+/-}$ (rather than $APC^{+/+}$).

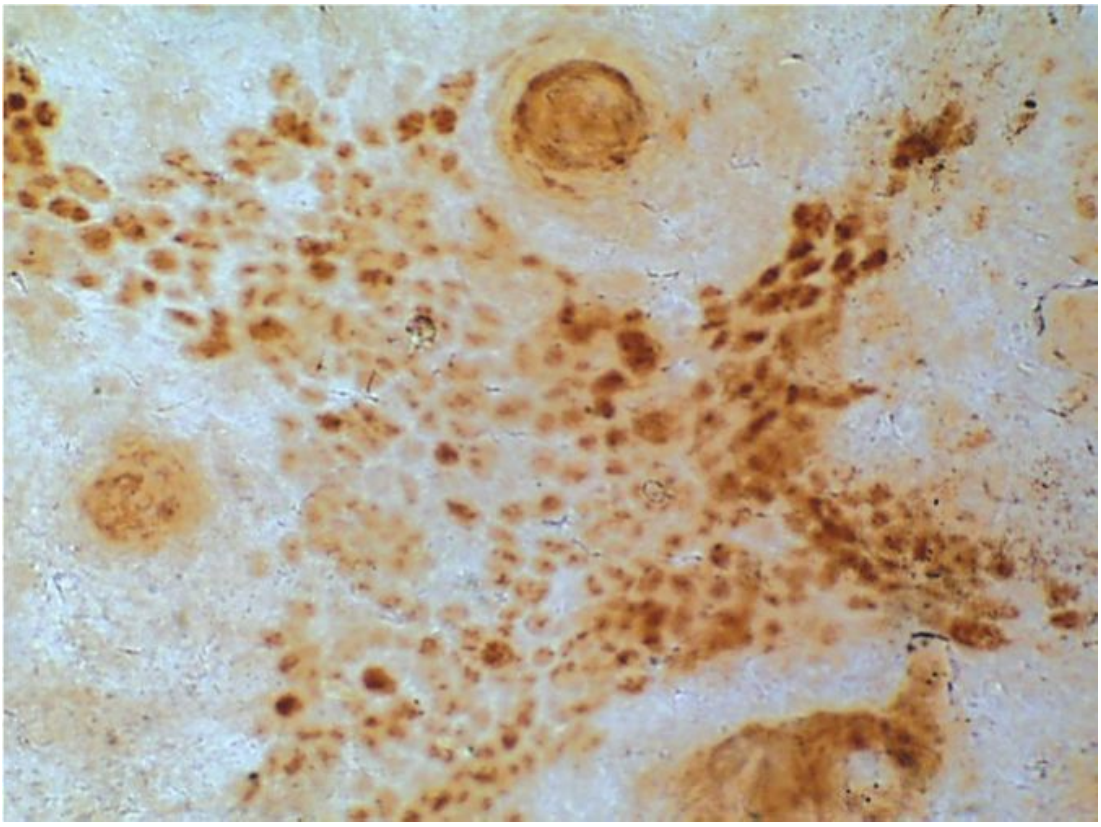
Consequently, a common mechanism of inborn susceptibility yielding familial cancers involves an acceleration of a critical rate-limiting step; in the case of the gut, this step involves elimination of the two copies of the *APC* gene in one or another cell. Thus, one of the two steps in this process no longer depends on infrequently occurring somatic mutations (because it has already occurred and affected the inherited germ-line genome and therefore all of the cells throughout the body of an afflicted individual).

This model of multiple clonal expansions also bears on another important issue in tumorigenesis: tissues affected by sporadic tumors occasionally sprout multiple tumors that arise at similar times in different sites in the tissue and seem to be formed independently of one another. This phenomenon is often called field cancerization. Thus, as an example, two or more premalignant or frankly malignant growths may erupt suddenly in an epithelial tissue, separated from one another by many centimeters of apparently normal epithelium. Because the appearance of any single sporadic (that is, nonfamilial) neoplasm is, on its own, a highly improbable event, the simultaneous appearance of two or more seemingly independent sporadic growths would seem to be extremely unlikely. Our understanding of multi-step tumorigenesis provides a key insight into the underlying processes at work here (**Figure 11.15**).



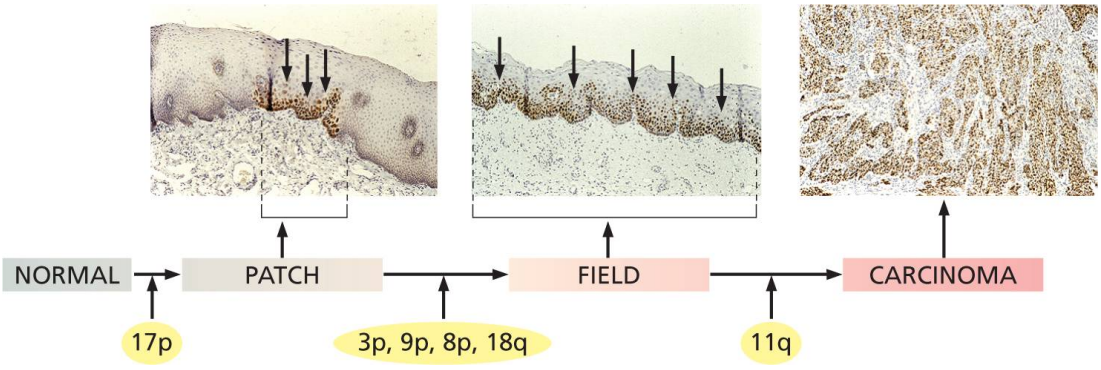
Two successive mutations produce a large number of cells that carry two mutations but remain morphologically normal. One of these then undergoes a third mutation to produce tumor 1, while another cell undergoes a different third mutation to produce tumor 2. Tumors 1 and 2 are both morphologically abnormal, hyperplastic, dysplastic, or neoplastic.

(A)



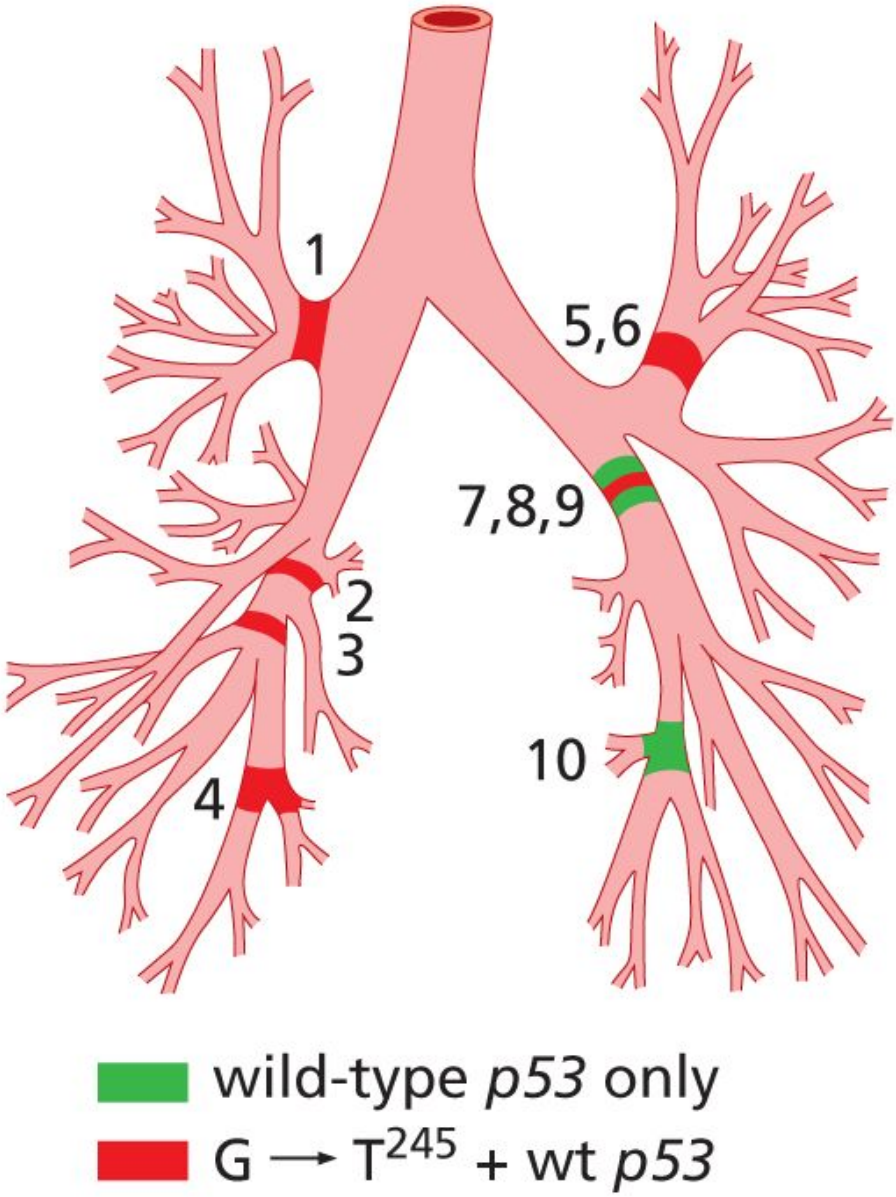
A histology image with many rust red nuclei and a few larger larger areas of similar color appearing against a pale background.

(B)



A cancerization progression. The progression from normal to patch, marked by a 17p mutation, is seen histologically as a small area of brown flecks in a layer of cells. Progression from patch to field is marked by 3p, 9p, 8p and 18q mutations, and is seen histologically as a larger area of brown flecks. Progression to carcinoma is marked by an 11q mutation.

(C)



A diagram of the bronchial tree of a deceased lung cancer patient. Four distinct sites in the patient's right lung and three sites in the patient's left lung contain a G T245 mutation plus wild type p53. Three sites in the right lung contain wild type p53 only.

(D)

Figure 11.15 Field cancerization A large area of histologically normal but genetically altered epithelium can sprout multiple, apparently independent foci of

neoplastic cells, all of which carry the one or more mutations common to this area as well as subsequently acquired mutants that are unique to each focus. (A) According to one model of field cancerization, one cell sustains an initiating mutation (*red sector, top middle*). Following extensive proliferation, some of its clonal descendants may subsequently acquire a second mutant allele (*blue sector*), and the doubly mutated "initiated" cells may then proliferate and eventually occupy a large patch of epithelium. Although these cells have already undergone several of the early steps of multi-step tumor progression, they continue to form an epithelium that is histologically normal. Subsequently, two cells located at different sites within this large patch of initiated cells may independently acquire additional mutations (*yellow sector left; black sector right*); both of these cells will now advance over the boundary (*dashed line*) to acquire a histologically abnormal appearance, spawning hyperplastic, dysplastic, even neoplastic growths. These two tumors will appear to have arisen independently even though they derive from the same clone of initiated cells. (B) Histologically normal patches of p53-mutant keratinocytes, detected here by immunostaining, can be found in sun-exposed human skin and may contain as many as 3000 cells. Such patches appear to represent fertile ground for the inception of basal cell carcinomas. (C) p53-positive (i.e., *p53*-mutant; see Section 9.9) cells, detected by immunostaining, are initially found in small, histologically normal patches of the oral epithelium early in the progression of squamous cell carcinomas in the oral cavity (*left image, brown spots*). As tumor progression proceeds, large fields of *p53*-mutant cells can be found that remain quite normal histologically, although they have often undergone loss of heterozygosity (LOH) of markers on the indicated chromosomal arms (*middle*). Eventually, after additional genetic changes, including LOH of the long arm of Chromosome 11, several of the cells in a field may progress independently to squamous cell carcinomas (*right*). (D) An extreme case of field cancerization can be seen here in lungs of a patient examined upon autopsy. Cells within widely scattered areas in both lobes of the lungs were found to share the same rare *p53* somatic mutation (present either in homozygous or heterozygous configuration, *red*), indicating their common genetic origin (see also Figure 11.8C). Although these areas did indeed exhibit mild squamous metaplasia, no carcinomas could be detected; hence, none of these widely dispersed fields had spawned a carcinoma by the time of the patient's death. (B, courtesy of D.E. Brash. C, from B.J.M. Braakhuis et al., *Cancer Res.* 63:1727–1730, 2003. With permission from American Association for Cancer Research. D, from W.A. Franklin et al., *J. Clin. Invest.* 100:2133–2137, 1997. With permission from American Society for Clinical Investigation.)

Imagine that a clone of cells undergoes some of the initial genetic alterations that launch these cells partway down the road toward full-fledged neoplasia; these

alterations confer a proliferative or survival advantage on these cells but have no outward effect on the histopathological appearance of the tissue in which these cells arise. In the eyes of a pathologist, this tissue will appear entirely normal. Nonetheless, these alterations poise these cells to progress further toward neoplasia.

After many years, this clone of mutant cells, because its constituent cells possess slightly elevated proliferative or survival potential, may have expanded to form a large patch of outwardly normal epithelium. Thereafter, two cells, located far from one another within this patch (that is, “field”) and sharing the same set of somatic mutations, may then suffer new oncogenic mutations independently of one another, and each of the resulting multiply-mutated cells may spawn a papilloma or carcinoma (see Figure 11.15A). Indeed, at the experimental level, genetic analyses of apparently normal bladder epithelium, oral mucosa, and skin, as well as of esophageal and lung epithelia, have revealed large patches of cells, some many centimeters wide, that are morphologically normal but already carry a mutant gene, often a mutant allele of *p53* (see Figure 11.15B); alternatively, widely dispersed patches of dysplastic tissue having a common genetic origin can be documented (Figure 11.15C and D).

Strikingly, similar processes operate in the hematopoietic system. Thus, as many individuals age, subpopulations of lymphoid cells in the circulation can be found that share common oncogenic mutations; such subpopulations occur in individuals in which there are no clinical signs of incipient cancers, that is, either lymphomas or leukemias. The common origin of the cells and their association with a specific clonal subpopulation of cells is indicated by the otherwise-rare, highly specific mutation(s) that the cells within one of these subpopulations share, indicating that each of these subpopulations represents a genetically homogeneous cell population descended from a common ancestor in which the mutation first arose. For this reason, the presence of such subpopulations is considered a manifestation of the process of clonal hematopoiesis. Of note, individuals harboring such clonal subpopulations in their blood or bone marrow exhibit an elevated risk of eventually developing a hematopoietic malignancy, once again indicating a field effect albeit in a liquid tumor. Hence, the development with increasing age of pre-neoplastic cell populations appears to occur in diverse tissues governed by very different types of regulatory mechanisms.

OceanofPDF.com

Glossary

field cancerization

Phenomenon in which an outwardly normal region of an organ or tissue produces multiple, ostensibly independently arising premalignant growths or frank neoplasms that actually share a common clonal origin and share a common set of abnormalities, including somatic mutations. Field cancerization is presumed to reflect the proliferative and survival advantage of somatic mutations (or heritable changes in the epigenome) that are not manifested in the outward behavior of the affected cells, but were already widely dispersed in this region prior to the appearance of these clearly preneoplastic or frankly neoplastic outgrowths. *See also* **clonal hematopoiesis**.

clonal hematopoiesis

Development in hematopoietic cell lineages of clonal populations of cells in which the constituent cells share a common somatic mutation or set of mutations that appears to favor their preferential clonal expansion in the hematopoietic system; such cells have nonetheless not developed a frankly neoplastic phenotype although they may be poised to do so.

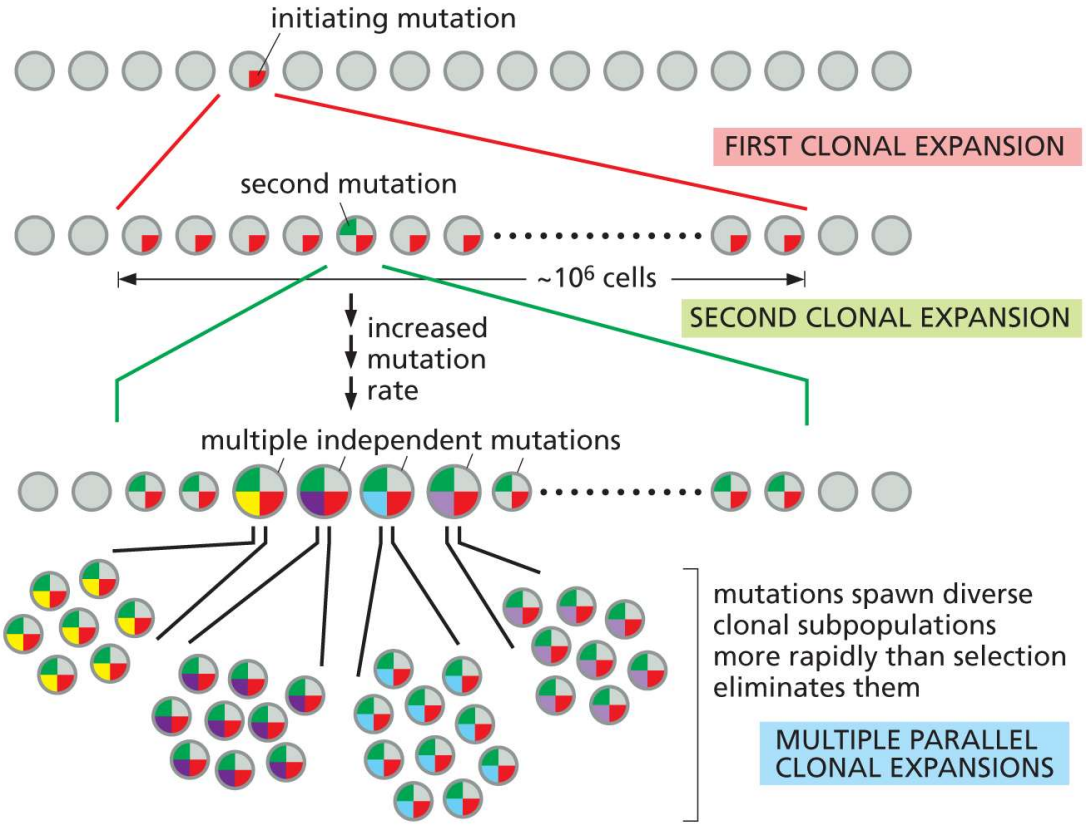
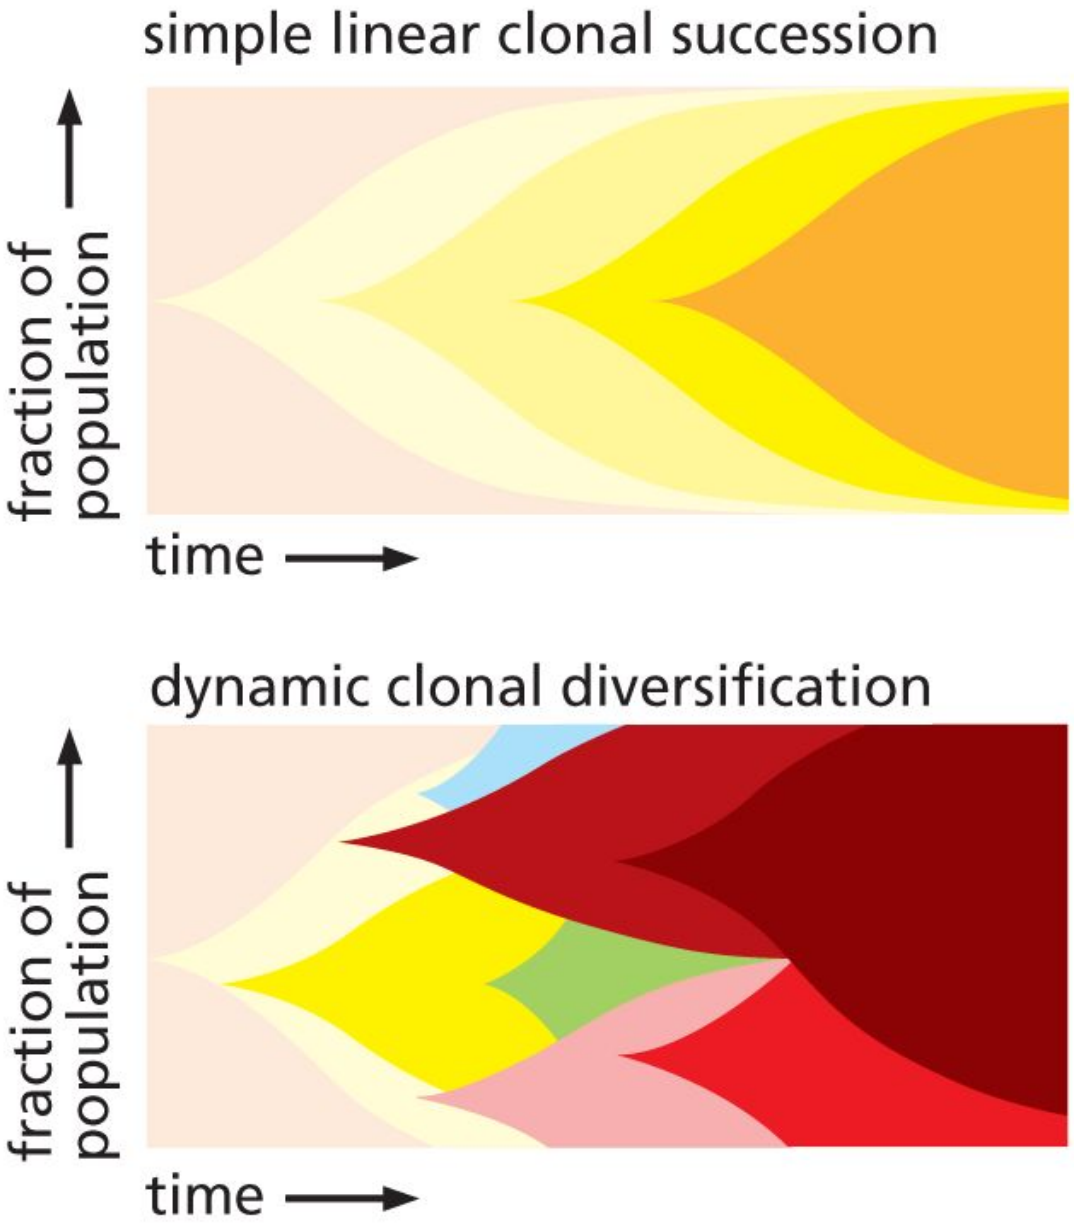
11.6 Intra-tumor diversification can outrun Darwinian selection

As multi-step tumor progression proceeds, the genomes and epigenomes of cancer cells become increasingly destabilized. Hence, the rates at which genetic and epigenetic changes accumulate increasingly *outpace* the rate at which Darwinian selection can eliminate less-fit variant subpopulations of cells. As a consequence, with each successive step, the populations of cells within a tumor become increasingly diverse at the genetic or epigenetic levels. This increased intra-tumoral heterogeneity can be best documented by isolating multiple single-cell-derived cell clones from a tumor. Such clonal populations originating from the same tumor often differ markedly in their rates of proliferation, susceptibility to apoptosis, tendency to invade and metastasize, and organization of intracellular metabolism (**Figure 11.16 A and B**).



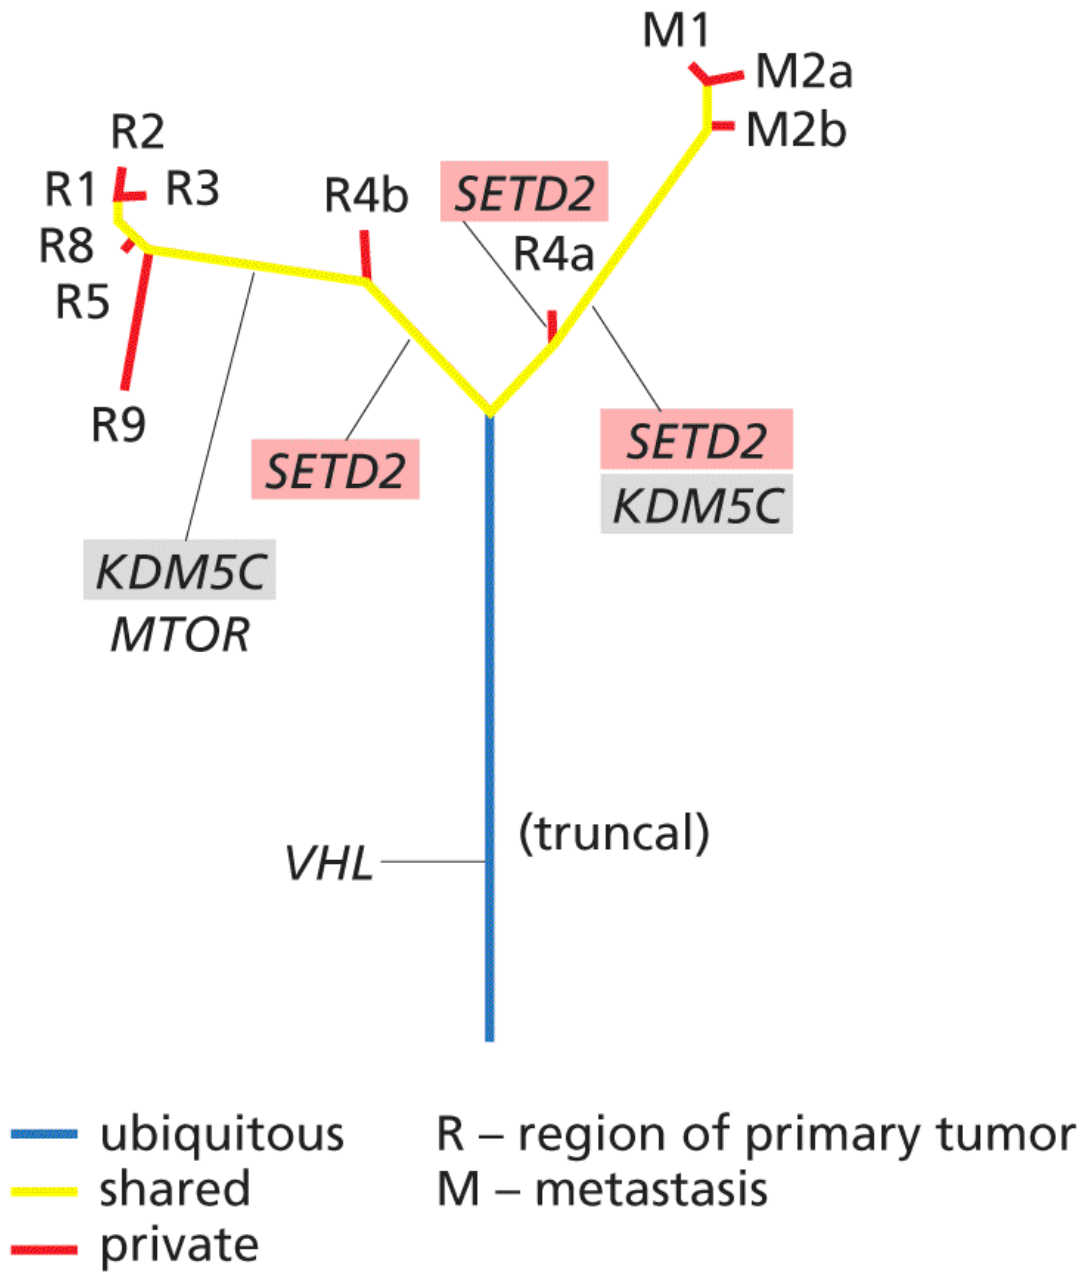
A succession of cycles of mutation and clonal expansion is followed by an increased mutation rate and multiple independent mutations with associated

clonal expansions occurring in parallel, as mutations spawn diverse clonal subpopulations more rapidly than selection eliminates them.
(A)



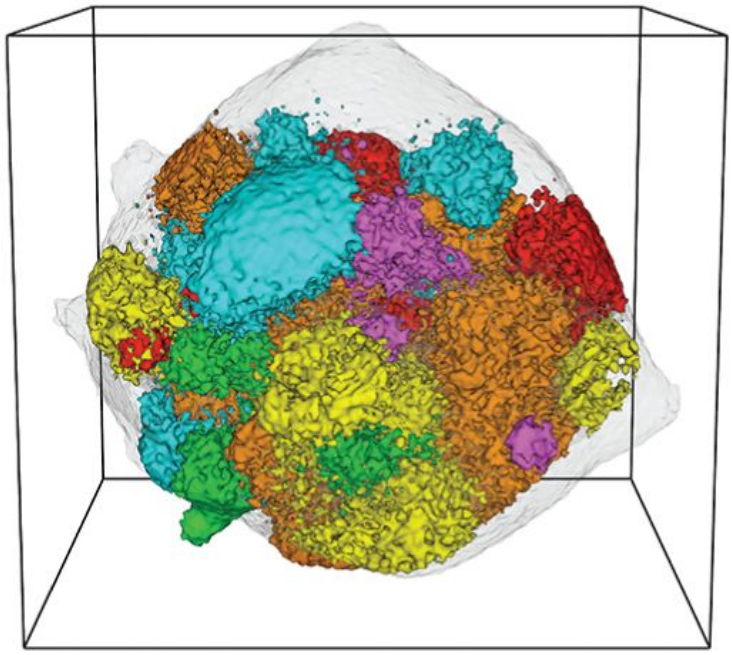
An illustration of the difference between simple linear clonal succession and dynamic clonal diversification. In simple linear clonal succession, one mutation at a time establishes itself and is on the way to taking over the entire population but then begins to give way to another mutation that does the same. In dynamic clonal diversification, mutations occur quickly enough that at any given time, multiple clonal populations coexist and none is on the way to dominance.

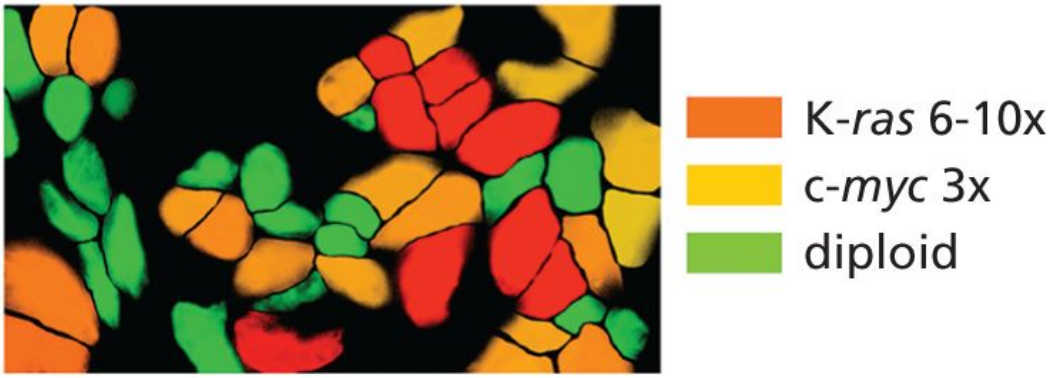
(B)



The results of a detailed sequencing analysis of a renal tumor. The first mutation, in the V H L gene, is shared by all cells in the tumor. This mutation is represented by the trunk of a tree diagram. Branches on the left and right then indicate mutations found only in some part or other of the tumor. The main branches are designated as shared, while the branch tips are designated as private. The left branches of the diagram correspond to various cell lines in

the primary tumor. The rightmost part of the right branch corresponds to metastatic tissue.
(C)





A comparison of the theoretical prediction of how clonal populations are distributed inside a tumor with the observed distribution. In theory, each clonal population should be concentrated in a different part of the tumor. A fluorescence microscopy image of a real tumor, however, shows that K-ras, c m y c, and diploid cells are heavily intermingled.

(D)

Figure 11.16 Clonal diversification caused by high mutation rates (A) As tumor progression proceeds, the genomes of tumor cells often become

increasingly unstable. As this occurs, the rate at which new mutant alleles are generated may exceed the rate at which Darwinian selection can eliminate phenotypically less-fit clones. Consequently, the tumor mass develops an increasing number of sectors, each dominated by a genetically distinct subclone of cells. (B) Recent surveys of both genetic and epigenetic (CpG methylation) heterogeneity within individual tumors have provided experimental support for the extensive diversification of distinct clonal populations within a tumor. Thus, the simple linear model of clonal succession (*above*) should be replaced, at least in late-stage tumors, by the dynamic changes depicted *below* in which multiple distinct subpopulations of cancer cells coexist within a tumor. (C) Detailed sequencing analyses of a primary human renal cell carcinoma and derived metastases provide some indication of the genetic diversification that occurs during tumor progression. As seen here, mutation of the *VHL* gene occurred early and was ultimately transmitted to all resulting neoplastic cells in this tumor; the shape of this tree reveals why this is termed a "truncal" mutation. Regions of the tumor (designated as R) indicate a diversification of an early population into two major branches, one of which spawned metastases (*right*), whereas the other did not (*left*). Multiple mutations of the *SETD2* and *KDM5C* genes occurred independently in distinct regions of the tumor, suggesting convergent evolution. Additional mutations were accumulated in derived metastases (*top right*). (D) Although the schemes of A and B imply the coexistence of distinct subclones within a tumor, they do not necessarily indicate the topological localization of these clones and their constituent cells. A computationally based model of how a tumor should develop predicts discrete sectors in which genetically (and epigenetically) distinct, individual subclones are localized in a tumor composed of 2 million cells. In contrast, use of fluorescence *in situ* hybridization (FISH) in a section of an actual tumor (*below*), such as the human breast cancer analyzed here, reveals the extensive physical intermingling of the individual cells deriving, in this case, from three major, genetically distinct subclones coexisting within this tumor. The three clones involve those with apparent diploid genomes, those with 3 copies of c-*myc*, and those with 6–10 copies of K-*ras* and a closely linked gene. (It is unclear which of these two topological patterns is more common in actual tumors.) (B, from A. Marusyk and K. Polyak, *Biochim. Biophys. Acta* 1805:105–117, 2010. With permission from Elsevier. C, from M. Gerlinger, A.J. Rowan, S. Horswell et al. *NEJM* 366:888-892, 2012. With permission from Massachusetts Medical Society. D, from A. Sottoriva et al., *PLoS Comput. Biol.* 7:e1001132, 2011, courtesy of A. Sottoriva; and N. Navin et al., *Genome Res.* 20:68–80, 2010. With permission from Cold Spring Harbor Laboratory Press.)

This heterogeneity present in highly progressed tumors contrasts starkly with the cellular products of selection that operated earlier during tumor progression at a time

when less-fit cells and subpopulations were successfully eliminated. Such efficient elimination is often termed purifying selection, in which only the most fit cells survive to yield homogeneous, clonal cell populations whose constituents are genetically and epigenetically identical to one another. As described later in Chapter 17, the intensive diversification of cells occurring within certain tumors and the resulting phenotypic heterogeneity of subpopulations of the cancer cells within such tumors greatly complicate anti-cancer therapies. Thus, some applied therapies may be highly effective in eliminating certain subpopulations of neoplastic cells within a tumor, while other co-existing subpopulations that happen to be resistant to therapy can emerge and create clinical relapses.

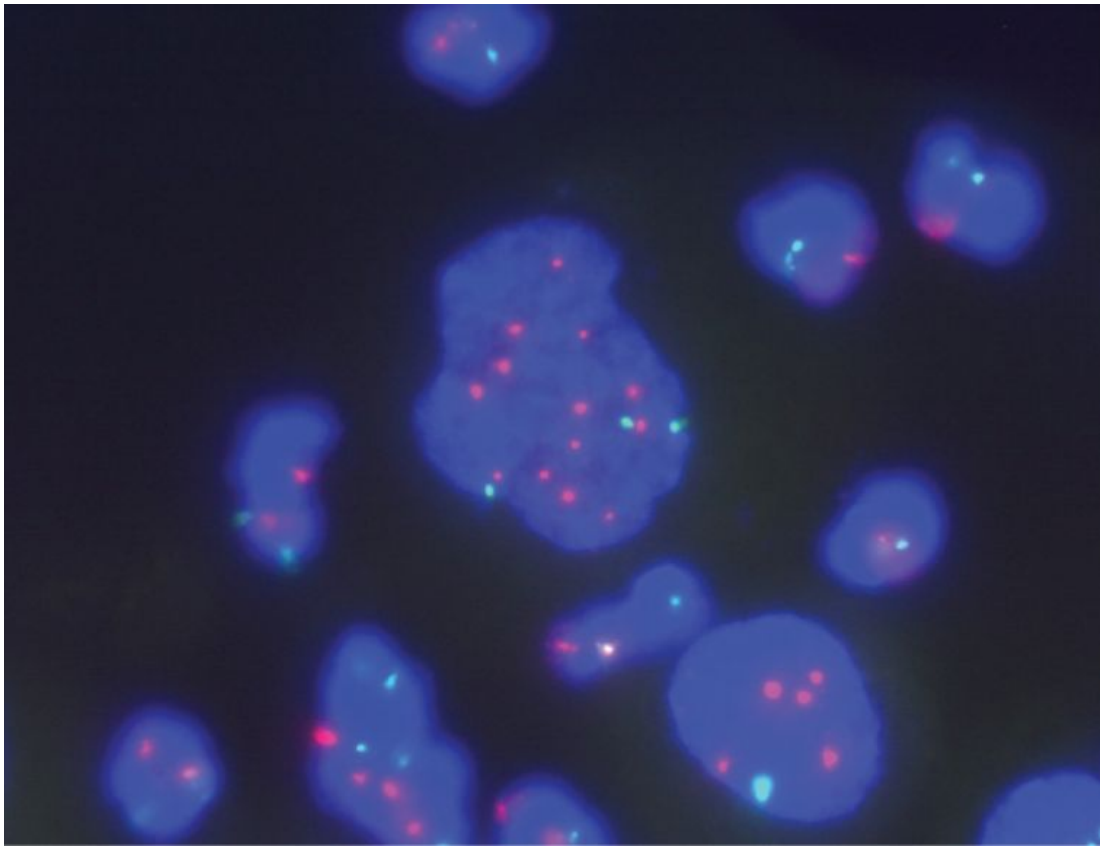
As a consequence, rather than looking like a linear series of clonal successions, actual tumor progression in many tumor masses is likely to resemble the highly branched scheme shown in Figure 11.16C, in which multiple genetically distinct subclones of cells coexist within a single tumor mass. Indeed, the dynamic nature of the expansion of some clonal subpopulations and the obliteration of others is suggested by Figure 11.16B.

Demonstrations of the genetic diversification of cells within a tumor cell population can be obtained by tracking the state of individual genes of interest within various cells of a primary tumor and derived metastases. For example, in a human pancreatic carcinoma, detailed genome sequence analysis of different sectors of the tumor revealed genetically distinct subclones, each of which was estimated to comprise at least 100 million cells. Interestingly, several of these subclones each spawned its own set of genetically related metastases found at distant sites in the body of the cancer patient—a topic that we will pursue in greater depth in Chapter 14. An illustration of these processes operating during the formation of a renal cell carcinoma is provided by Figure 11.16C, in which an initial, commonly shared mutation (often termed truncal) is inherited by derived clonal subpopulations and metastases.

Of note, in Figure 11.16C, the relative *lengths* of the branches were gauged by the number of neutral mutations accumulated throughout the genomes of the cells under analysis. Such functionally silent neutral mutations are often termed passenger mutations because they are carried along with driver mutations, the latter affecting genes whose alteration is assumed to be functionally important and capable of conferring selective advantage on the cells bearing them. Almost invariably, the passenger mutations are far more numerous than driver mutations and are reflective of widespread genetic instability within tumor cells. The genes affected by driver mutations, as discussed in the next chapter, are often identified because they are repeatedly found in mutant form in the genomes of multiple independently arising tumors, suggesting that mutant alleles of these genes confer a strong phenotypic advantage on those cells that happen to acquire them.

The precise localization of individual subclones and associated cells within a tumor is itself unclear. A computer-based modeling of how such subclones arise (distinguished from one another by heritable differences in DNA sequence or CpG methylation) predicts large sectors occupied by individual subclones, which may indeed represent the configuration of many tumors. However, analysis of individual carcinoma cells within a tumor may well reveal a more complex situation, in which the cells of various subclonal populations become intermingled (Figure 11.16D).

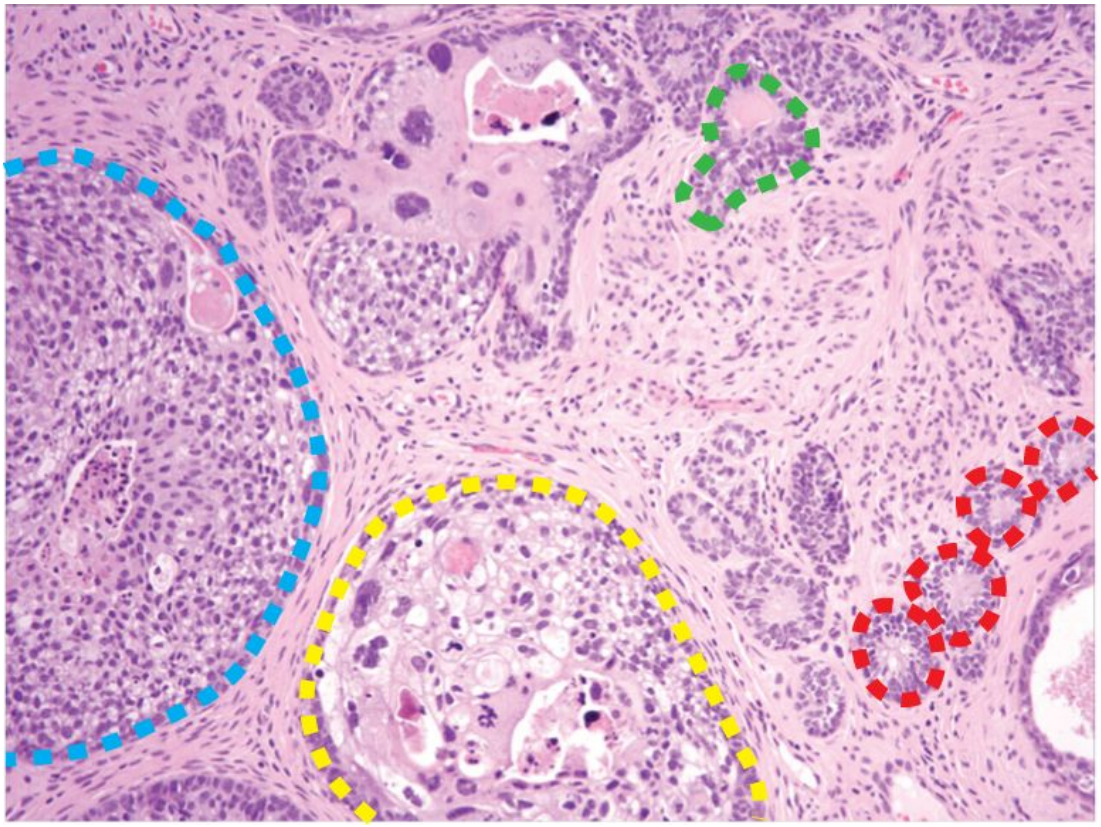
A vivid example of genetic instability and resulting genetic diversification is shown in **Figure 11.17**, in which the FISH (fluorescence *in situ* hybridization) technique was used to determine the copy number of Chromosomes 11 and 17 in individual cells deriving from a human lung carcinoma. As is apparent, the copy number of Chromosome 17 (which carries the gene specifying cyclin D1) varies enormously from one cell to another, whereas the copy number of Chromosome 11 is relatively stable. Such variability indicates that the tumor cell genomes being analyzed here are quite plastic, possibly changing each time the cells pass through a cycle of growth and division. These fluctuations seem to occur almost randomly and at a rate that vastly exceeds the ability of (Darwinian) selection to eliminate less-fit variants.



A fluorescence microscopy image. Multiple dark blue nuclei are visible, unusually variable in size and shape. All contain both red and green dots, typically far more

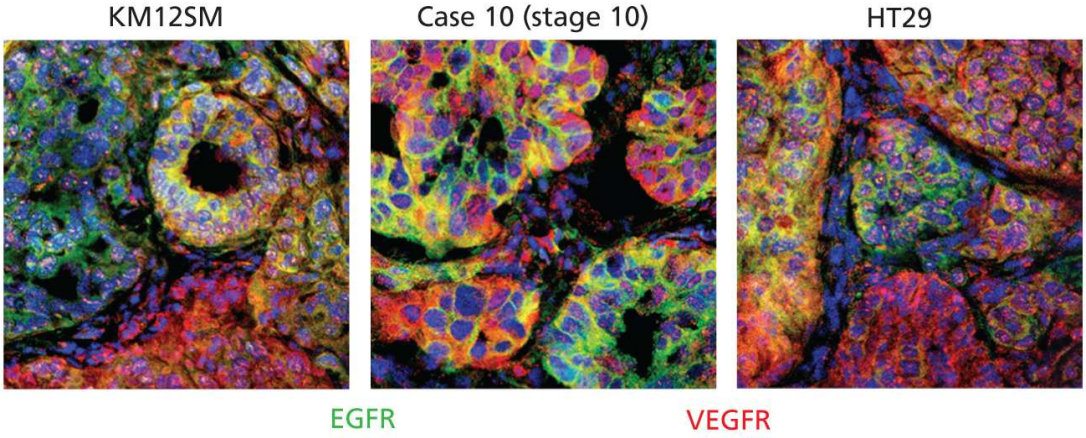
of the red ones, but the large nuclei contain far more dots than the small ones.
Figure 11.17 Frequent variations in chromosome number in tumors In high-grade tumors, the numbers of chromosomes often fluctuate wildly from one cell to another, indicative of great cell-to-cell genetic heterogeneity. In this image, the use of FISH revealed the copy numbers of Chromosomes 11 (*green*) and 17 (*pink*) in cells from a *pleural effusion* in a non-small-cell lung carcinoma patient. In addition to fluctuations in chromosome number, highly polyploid giant nuclei are apparent. (From M. Fiegl et al., *J. Clin. Oncol.* 22:474–483, 2004. With permission from American Society of Clinical Oncology.)

Yet another source of diversification has not even been addressed here: epigenetic mechanisms may profoundly shift the transcriptomes and thus the phenotypes of cancer cells without any underlying changes in the cancer cell genomes (**Supplementary Sidebar 11.4**); such epigenetic plasticity would not be registered in the genetic analyses described in Figure 11.16. The resulting phenotypic diversification may be apparent at the histopathological level (**Figure 11.18A**). Alternatively, surveys of protein expression in tumor sections using immunofluorescence provide dramatic testimony to the diversification of small, discrete subpopulations of cancer cells within a tumor (Figure 11.18B). In principle, the variability in the expression of the EGF and VEGF receptors shown in this figure might well result from genetic diversification. Far more likely, however, are epigenetic mechanisms—localized, frequent fluctuations in cell-to-cell signaling in the tumor microenvironment yielding phenotypic diversity that does not directly reflect underlying, slowly occurring genetic diversification. Finally, reversible shifts in cell phenotype make it almost impossible to map with precision the developmental histories of individual tumors (**Sidebar 11.5**).



A histology image in the usual pink and purple colors but with regions outline in dashed colored lines. On right are four small red circles in a row. In the lower center is a large region outlined in yellow. Above is a small, irregular region outlined in green. To the left is a large area with more densely packed nuclei outlined in blue.

(A)



Three immunofluorescence images of cancer cells glowing green, red and yellow. Left to right, the images are labeled K M12S M, Case 10 (stage 10), and H T29. Below the images, the letters E G F R appear in green, and the letters V E G F R appear in red.

(B)

Figure 11.18 Phenotypic diversification within a tumor cell population
Independent of the genetic diversification of subpopulations of cells within a tumor (see Figure 11.16) is the ability of tumor cells to enter into new phenotypic states by activating epigenetic programs associated with alternative states of differentiation. (A) An adenoid basal carcinoma (ABC) of the cervix from a 94-year-old woman demonstrates heterogeneous cytologic features. To the far right, a row of small basaloid islands infiltrates the cervical stroma (*red circles*). Above them (*top right*) is an area of columnar cell differentiation within such a nest of basaloid cells (*green circle*). In the center and left are two large nests of neoplastic squamoid cells (*yellow, blue*) exhibiting various degrees of *atypia*. In both cases, the large nests are surrounded by rims of basal cell layers, findings characteristic of ABC. ABC is typically associated with a conventional high-grade squamous intraepithelial lesion (*not shown*) and HPV infection; this case was positive for HPV type 16. The high frequency of these variant morphologies in this particular subtype of carcinoma strongly suggests that these islands of cells represent distinct differentiation programs activated by the various carcinoma cells rather than genetic diversification. (B) Use of immunofluorescence with antibodies that react with the EGF (*green*) and VEGF (*red*) receptors reveals great phenotypic diversity even within small sectors of these tumor xenografts; cells co-expressing both receptors are seen as *yellow*. Tumors analyzed in the *left* and *right* panels derive from cancer cell lines, and the tumor in the *center* panel derives from a surgical specimen. (A, courtesy of M. Hirsch and M. Loda. B, from T. Kuwai et al., *Am. J. Pathol.* 172:358–366, 2008. With permission from American Society for Investigative Pathology.)

Sidebar 11.5 Transient shifts in phenotype complicate the biographies of individual tumors

Almost all of the cell-intrinsic changes in cancer cell phenotype described here—whether genetic or epigenetic—are by definition cell-heritable and thus impose stable markings on the clones of evolving premalignant cells and their direct descendants. There are, however, certain changes in cells that may be critically important in influencing or directing the trajectory of an evolving cell population but are not memorialized by permanent, cell-heritable marks, simply because this class of changes

are reversible and thus may be present only transiently during one period of the developmental history of a given tumor and lost thereafter. Examples of these might be periods of genomic stress (described in Chapter 12), oxidative stress, and activation of EMT programs (described in Chapter 14). The transient involvement of these stressors and cell-biological programs in tumor pathogenesis reminds us that the cell-heritable features of highly progressed tumor cells represent an incomplete record of the biological events that shaped their development, often being experienced by cells only during a brief window of time *en route* to the formation of full-fledged aggressive tumors.

OceanofPDF.com

Glossary

purifying selection
: Process occurring during Darwinian evolution in which negative selection eliminates less-fit variants, leaving behind a population of cells or organisms that is most fit.

truncal
: Referring to a genetic alteration that is present in the genomes of all of the otherwise-heterogeneous neoplastic cells within a tumor and is indicative of their shared descent from a common ancestral cell; such mutations are associated with the trunk of a branched tree drawn to depict graphically the evolutionary history of these cells from their common ancestor.

passenger mutation
: Mutation that confers no selective advantage on a cell carrying it but whose presence in a population of cells is increased because it resides in the same genome as other mutant alleles that do indeed confer advantage; sometimes termed bystander mutation. *Compare* **driver mutation**.

driver mutation
: Mutation creating an allele of a gene that is advantageous for the cell that sustains it and results in clonal expansion of the progeny bearing mutant alleles of this gene. *See also* **driver gene**, **passenger gene**.

11.7 Tumor stem cells further complicate the Darwinian model of clonal succession and tumor progression

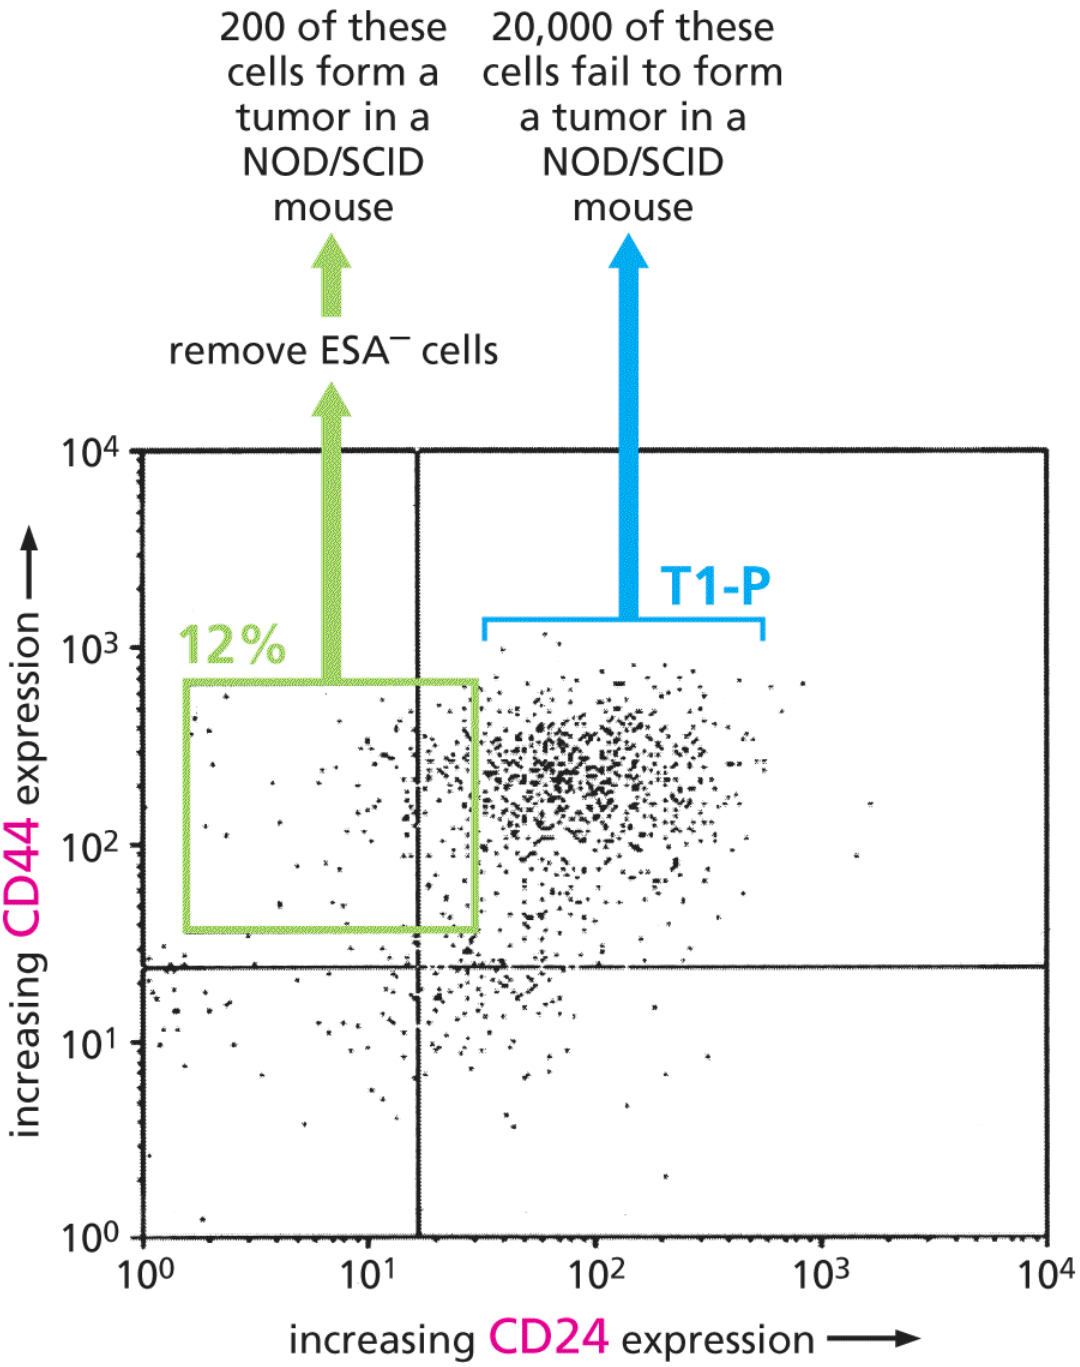
As depicted above, the clonal succession model proposes that a mutant cell spawns a large flock of descendants and that among these numerous descendants, a new mutational event (or heritable epigenetic alteration) will confer a novel, advantageous phenotype and thereby trigger yet another wave of clonal expansion. (For the sake of simplicity, we return for the moment to the model of Figure 11.14, which dictates that each clonal expansion generates a genetically homogeneous cell population.) In fact, many experiments have forced a revision of the notion that all of the cells within a genetically homogeneous cell clone are biologically equivalent to one another and therefore equally capable of becoming ancestors of new, more-progressed, successor populations of cells.

These insights came from attempts to resolve and fractionate tumor cell populations that were ostensibly genetically homogeneous into subpopulations that might, in spite of their common genetic identity, differ from one another phenotypically. In initial experiments, the cancer cells within a specific human tumor were separated into distinct subclasses. These separations took advantage of distinct sets of cell-surface proteins displayed by the different subpopulations. In particular, the technique of fluorescence-activated cell sorting (FACS) was used to fractionate living cancer cells after labeling them (via their cell-surface proteins) with monoclonal antibodies linked to fluorescent dyes (**Supplementary Sidebar 11.5**). Importantly, cells separated by this procedure can be recovered in viable form and used thereafter in biological experiments, including tests of their ability to seed tumors following injection into host mice.

Use of the FACS technique initially enabled researchers to segregate populations of acute myelogenous leukemia (AML) cells into majority and minority populations; in one such experiment, the latter represented less than 1% of the neoplastic cells in the overall leukemia cell population. As few as 5000 cells in the minority subpopulation were able to produce new tumors upon injection into host mice and were therefore deemed to be “tumorigenic”; in contrast, as many as 500,000 AML cells from the majority subpopulation were unable to seed a tumor. In fact, the leukemia cells in this majority subpopulation exhibited many of the attributes of differentiated granulocytes

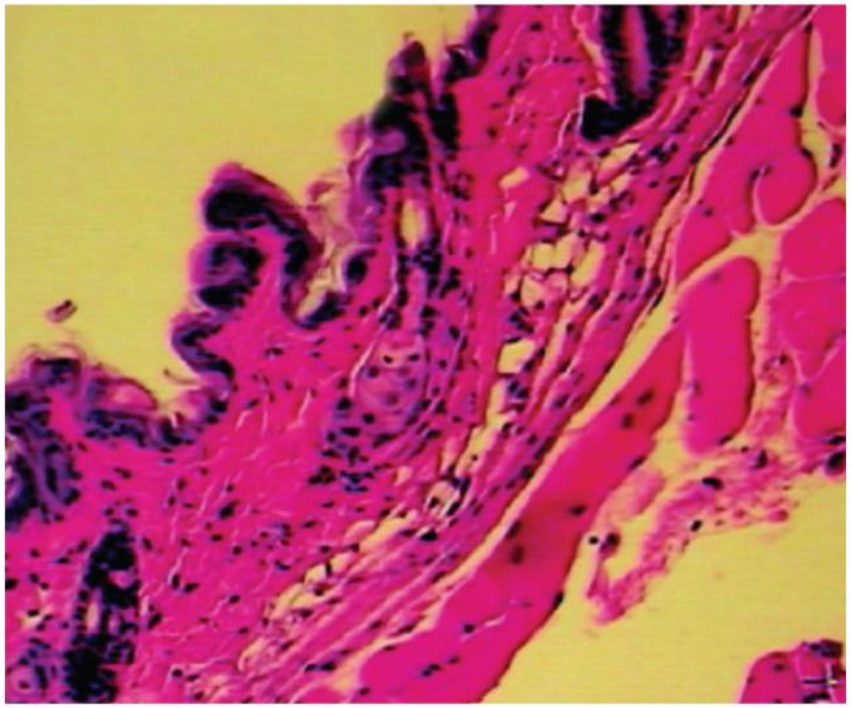
or monocytes, and these cells had limited ability to proliferate. These observations provided compelling evidence that the AML tumors were composed of small populations of self-renewing, tumorigenic cells and large populations of more differentiated cells that had little, if any, ability to serve as founders of new cell populations and thus new leukemias.

Subsequent experiments extended these results to human breast cancer cells prepared by culturing cells extracted directly from tumors. In these later experiments, the minority tumorigenic cell population within a tumor represented only about 2% of the overall neoplastic cell population. When implanted in a host mouse, 200 of these minority cells could seed a new tumor, but as many as 20,000 cells from the majority cell population failed to do so (**Figure 11.19**). Of note, the majority and minority breast cancer cell subpopulations both contained comparable proportions of cells in the active growth-and-division cycle, and both subpopulations were purified away from contaminating nonmalignant cells (such as stromal cells) that were present in the original tumor masses. Also, later genomic analyses confirmed that these two cell populations did not differ from one another genetically.

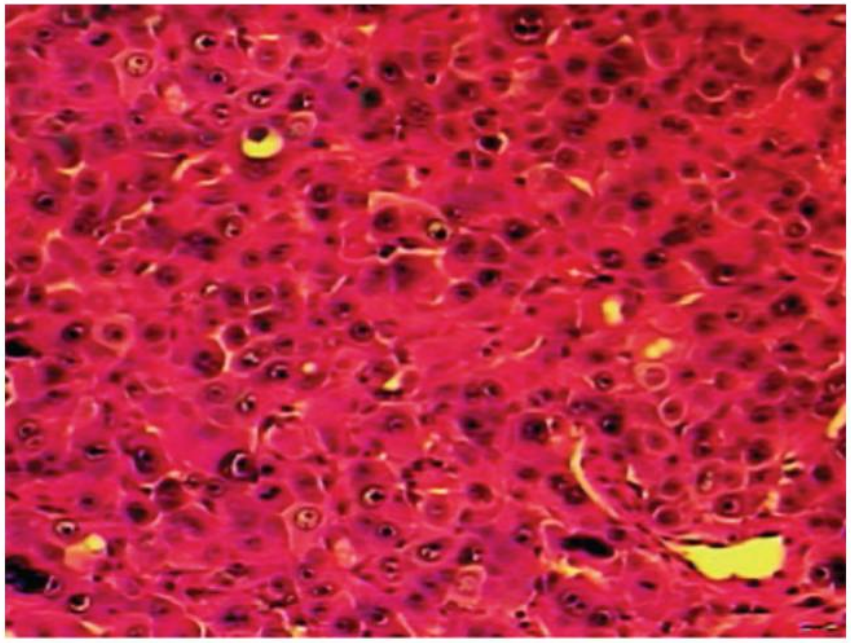


A scatter plot with increasing C D 24 expression on the horizontal axis and increasing C D 44 expression on the vertical axis. Each dot represents a single cell. A square of cells with low C D 24 expression and high C D 44 expressior is noted has having had cells removed that did not express E S A. 200 of the remaining cells formed a tumor in a N O D slash S C I D mouse. By contrast, 20,000 cells with high C D 24 expression and high C D 44 expression formed no such tumor.

(A)



implanted CD24 high cells



implanted CD24 low cells

Two color micrographs. The upper one, from a site where C D 24 high cells were implanted, shows normal skin and muscle tissue. The lower image, from

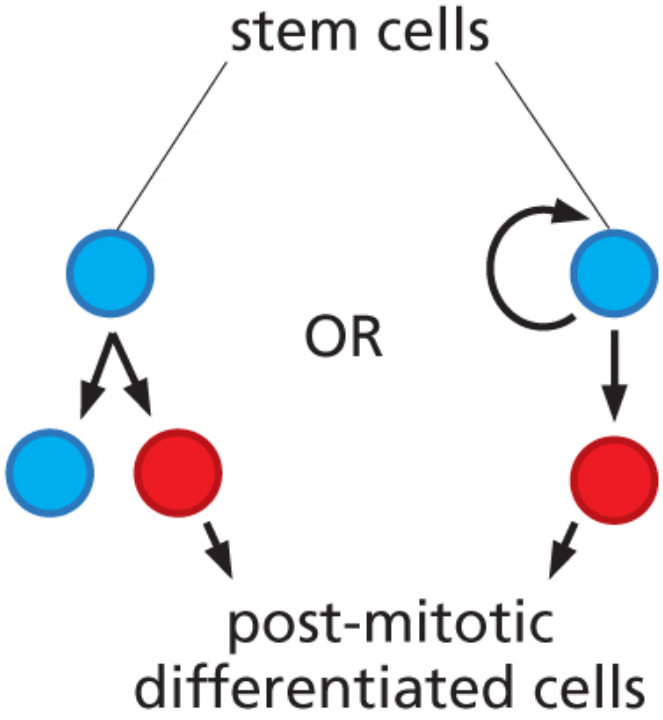
a site where C D 24 low cells were implanted, shows cancerous tissue. (B)

Figure 11.19 Enrichment of breast cancer stem cells (A) Metastatic human breast carcinoma cells were freed of contaminating noncancerous (stromal) cells and separated from one another (using FACS; see **Supplementary Sidebar 11.5**). The expression of two distinct cell surface antigens—CD24 and CD44—was gauged simultaneously, each being detected with a specific monoclonal antibody linked to a distinct fluorescent dye. The intensity of staining is plotted logarithmically on each axis. Each black dot in the graph represents the detection of a single cell. In this experiment, a 12% subpopulation of cells that expressed low CD24 and high CD44 antigen staining (*green box*) was separated from cells (T1-P) that showed high CD24 expression and high CD44 expression (*blue bracket*). (B) The cells in the 12% minority population were further enriched by sorting for those that expressed epithelial surface antigen (ESA), which resulted in the elimination of contaminating stromal cells that did not express this antigen. Following injection into a NOD/SCID immunocompromised mouse, 200 of the $CD24^{low}$ $CD44^{high}$ ESA^{+} cells were able to form a tumor, whereas 20,000 of the $CD24^{high}$ $CD44^{high}$ cells failed to do so. The *upper* micrograph shows a section through the subcutaneous site of implantation of $CD24^{high}$ cells, in which only relatively normal skin and underlying muscle wall can be seen (*above left*); the *lower* micrograph shows a section through the tumor that formed following injection of the $CD24^{low}$ cells. (From M. Al-Hajj et al., *Proc. Natl. Acad. Sci. USA* 100:3983–3988, 2003. With permission from National Academy of Sciences, U.S.A.)

The tumors that eventually arose from the implanted minority cells were once again composed of minority and majority cell populations that showed, as before, vast differences in their ability to seed a new group of tumors, that is, in their relative tumorigenicity. In subsequent years, subpopulations of tumor-initiating cells (TICs) have been demonstrated in a wide spectrum of other solid tumors, such as neuroectodermal, pancreatic, colorectal, and hepatocellular carcinomas, as well as certain hematopoietic malignancies.

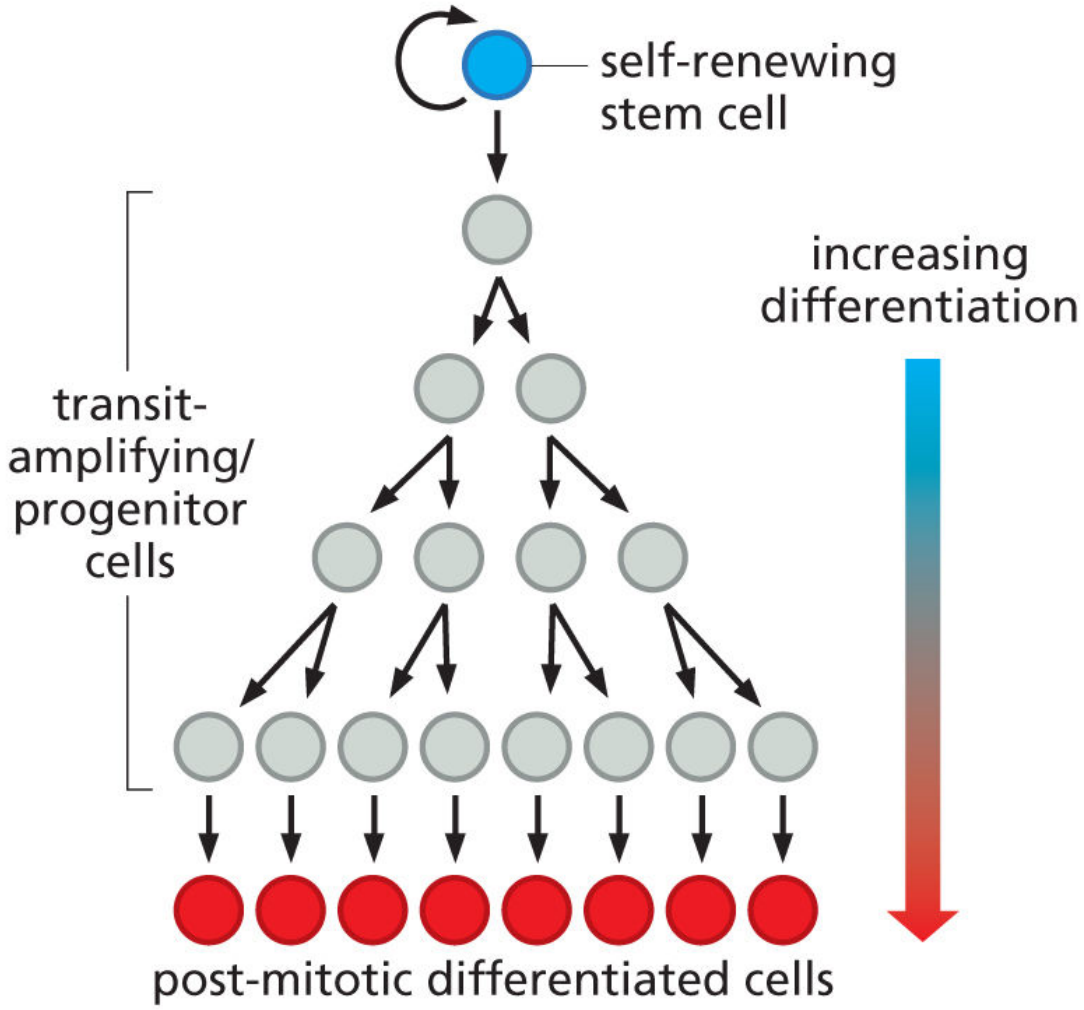
Taken together, these experiments indicate that the neoplastic cell populations originating in a variety of tissues are organized much like most normal epithelial tissues (**Figure 11.20**), in which relatively small pools of self-renewing stem cells are able to spawn large majority populations of descendant cells that have only a limited proliferative potential *in vivo*. In each of the experiments shown here, the tumorigenic minority cells expressed a set of antigenic markers on their surfaces that were distinct from those exhibited by cells in the majority populations. These experiments provided

further indication that two cancer cell subpopulations can coexist within the same tumor in alternative phenotypic states even though they are genetically identical (**Sidebar 11.6**).



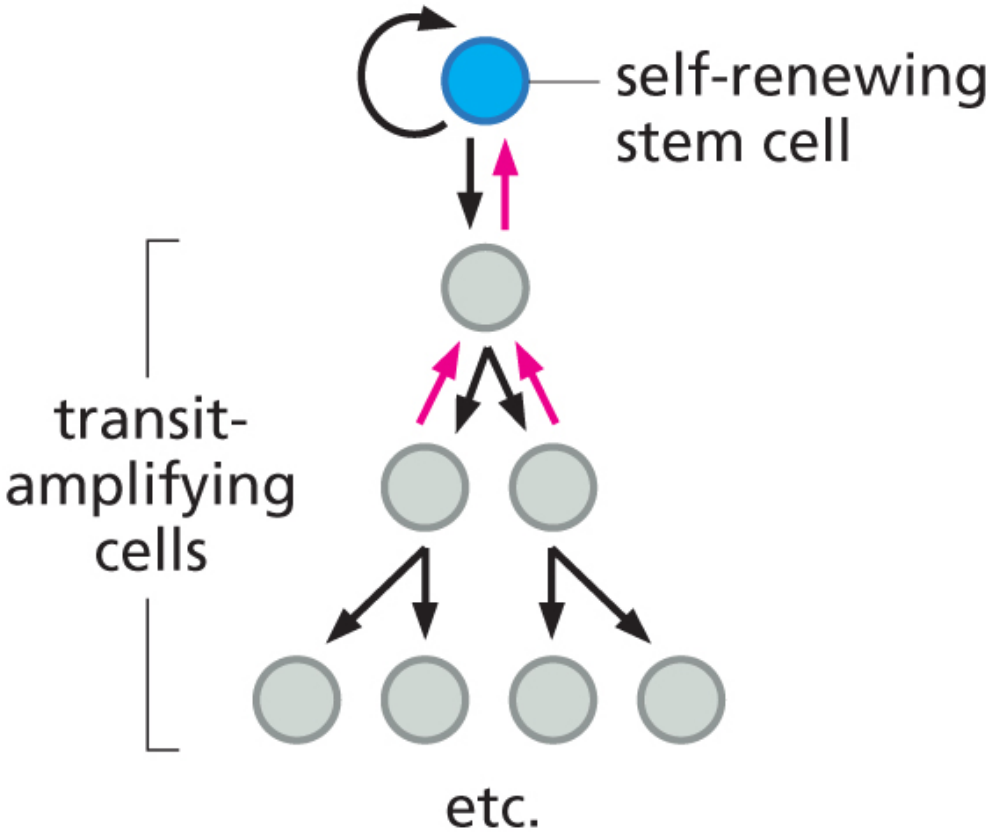
Two ways of graphically representing mitosis of a stem cell that produces one stem cell and one differentiated cell. One convention looks like normal cell reproduction with a parent cell and two daughter cells. The other convention shows just one parent and one daughter but with an additional arrow circling from the parent back to itself. Either way, the end result is post-mitotic differentiated cells.

(A)



A self-replicating stem cell produces one transit-amplifying progenitor cell, which produces two transit-amplifying progenitor cells, which each produce two transit-amplifying progenitor cells, and so on in a process of increasing differentiation that eventually produces post-mitotic differentiated cells.

(B)



A self-replicating stem cell produces one transit-amplifying progenitor cell, which produces two such cells, which each produce two cells, etc., but the process is reversible: cells can de-differentiate.

(C)

Figure 11.20 Stem cells and their progeny (A) The simplest organization of stem cell behavior involves an asymmetric cell division of a stem cell (*blue*), in which one of the daughter cells becomes a stem cell like its mother, whereas the other daughter (*red*) exits the stem cell state and may initiate a program of differentiation. This can be depicted in two graphic conventions, both of which are shown here. (B) In many tissues, a more complex scheme appears to operate. As in panel A, one of the daughters of a dividing stem cell becomes a stem cell. However, the other becomes a “transit-amplifying cell” (sometimes termed a “progenitor cell”; *gray*), which is committed to enter a differentiation pathway but does not yet participate in end-stage differentiation. Instead, this cell and its progeny undergo a series of symmetric cell divisions before its descendants eventually enter into a fully differentiated, post-mitotic state (*red*). Because a single stem cell can spawn dozens if not hundreds of differentiated descendants that carry out the work of a tissue, this cell does not need to proliferate frequently.

Moreover, if the differentiated cells within a tissue cease dividing (and become *post-mitotic*), the great bulk of the cell proliferation within such a tissue is associated with transit-amplifying/progenitor cells. (C) A variation on the scheme shown in panel B recognizes that diverse lines of evidence indicate the reversibility of the processes leading toward increased differentiation (*red arrows*). Such evidence indicates the possibility of dedifferentiation both in normal and neoplastic tissues.

Sidebar 11.6 Organization of stem cell hierarchies

In normal tissues, the cells are organized in a hierarchy, such as that depicted in Figure 11.20B. At the apex of the hierarchy is a stem cell, one of whose daughters remains a stem cell, while the other daughter exits the stem cell state and initiates a program of differentiation. (Because this particular cell division yields two phenotypically distinct daughters, it is often termed *asymmetrical*, in contrast to most cell divisions, which generate two phenotypically identical daughters and are therefore termed *symmetrical*.) The daughter cell that is formed directly by division of the stem cell and has exited the stem cell state is often termed a transit-amplifying cell, also termed a progenitor cell (see Figure 11.20B). Such cells are present in many normal tissues and represent intermediates between stem cells and their fully differentiated descendants. In addition, in certain tissues, transit-amplifying/progenitor cells may pass through a large succession of symmetrical cell divisions before their descendants eventually become fully differentiated. Hence, the initially formed transit-amplifying/progenitor cell can spawn dozens if not hundreds of differentiated progeny, which means that (1) the stem cell needs to divide only once in order to generate a large flock of fully differentiated descendants; (2) the stem cell may therefore divide only periodically rather than continually, even in a tissue in which differentiated cells are continually being lost and replenished; and (3) the great majority of ongoing cell divisions within a tissue are associated with the mitotically active transit-amplifying cells and not the stem cells.

This scheme of normal tissue organization has been appropriated by researchers attempting to understand the organization of the neoplastic cells within a tumor. Thus, the tumor-initiating cell (TIC, that is, one capable of seeding the outgrowth of a tumor), often termed a cancer stem cell (CSC), is self-renewing and has the ability to generate the countless neoplastic progeny that together constitute a tumor. Although the CSC and its progeny are genetically identical, the progeny cells have also lost tumor-initiating ability during the course of their initial differentiation. Indeed, as the details of the cellular programs that govern the CSC state are elucidated, it becomes increasingly apparent that these CSC programs are organized in a fashion that is similar to those operating in the corresponding normal tissues, that is, tumors do not

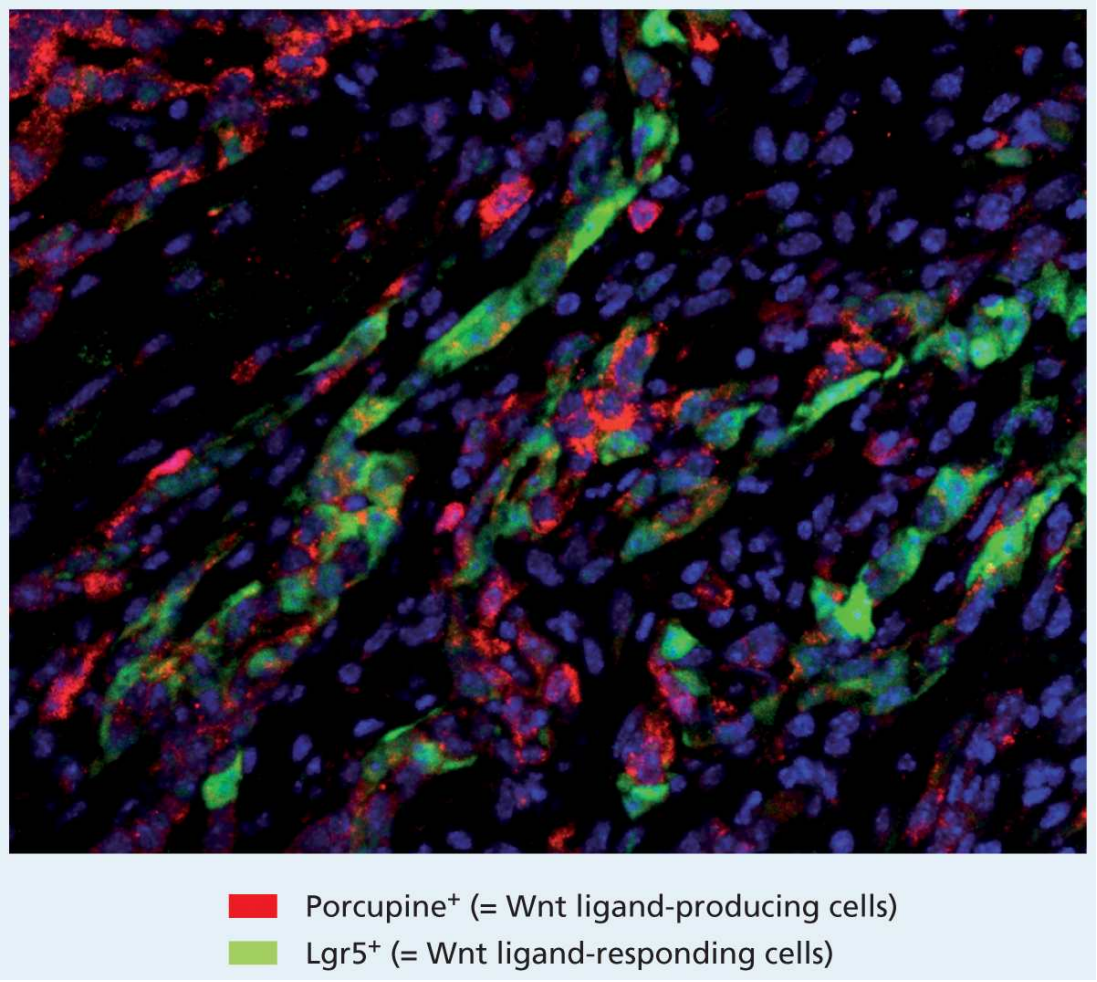
invent new stem cell programs but simply appropriate or modify ones operating in their corresponding normal tissues-of-origin.

The hierarchical scheme depicted in Figure 11.20B must surely be amended to reflect what is known and not known about the cell types that co-exist within individual tumors. For example, the existence of transit-amplifying/progenitor populations within populations of neoplastic cells is not documented. Similarly, the entrance of more differentiated neoplastic progeny into post-mitotic states remains a matter of speculation. Finally, there is evidence that the SC program operating in normal epithelial tissues is modified in derived carcinomas into a SC program that is operative in such tissues during the course of wound repair (**Sidebar 11.7**).

Sidebar 11.7 Conditions required for stem cell maintenance

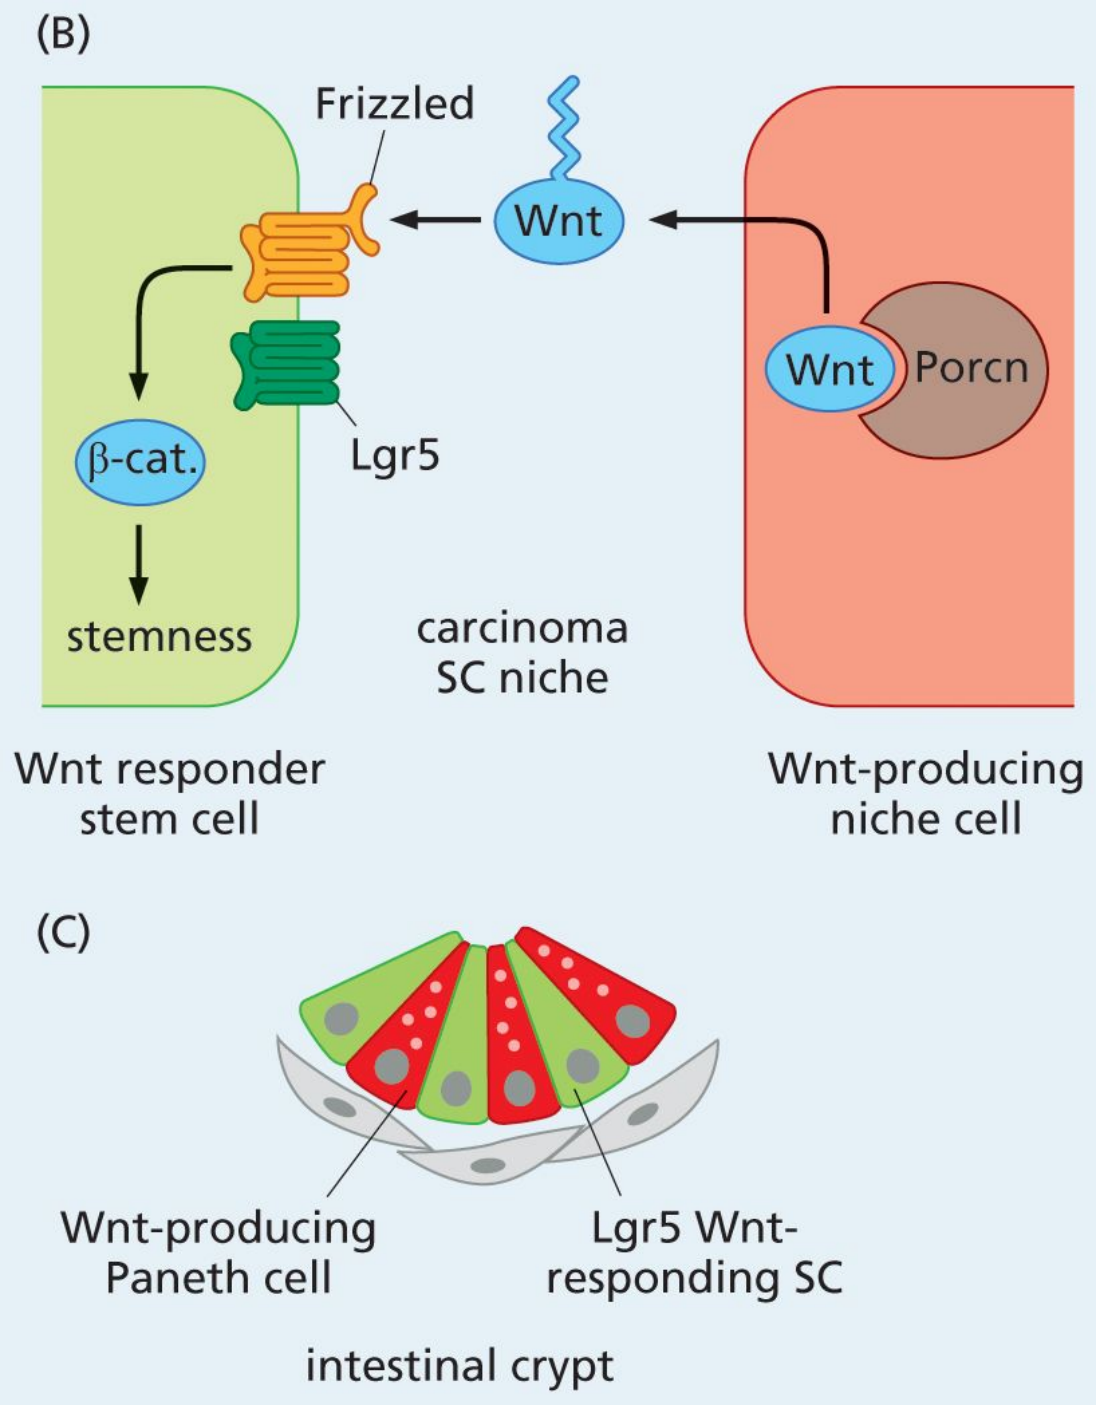
The continued residence of normal stem cells in the SC state generally depends on their continued localization in specialized tissue microcompartments, termed stem cell niches, in which the niche-forming cells, acting together with specialized extracellular matrix (ECM), provide paracrine signals to support and sustain the SCs in the SC state; such niche-forming cells represent cell types that are distinct from those of the SCs. In the context of the normal intestinal crypts, as an example (see Figure 7.20B), the SCs reside side by side with Paneth cells, which provide them with some of the paracrine signals required for continued residence in the SC state. Most important among these are Wnt3 ligands (see Figure 5.18).

It is less clear how the neoplastic CSCs maintain their residence in the SC state; one possible mechanism derives from the actions of autocrine signaling of the sort first illustrated in Figure 5.8C. Such signaling affords the continuous maintenance of a phenotypic state through the actions of self-sustaining, positive-feedback loops. An alternative scenario has become even more likely in light of work completed in recent years studying a mouse model of lung adenocarcinoma. In these tumors, it is clear that progenitor carcinoma cells can assume two distinct functional states. One cell type displays the cell-surface Frizzled (Fzd) proteins that operate as receptors for canonical Wnt ligands, which have long been known to be critical for SC function (see Figure 5.18). These Fzd receptors operate together with LRP5/6 co-receptor proteins and the ancillary Lgr5 cell-surface protein that amplifies Wnt binding signaling; indeed, display of Lgr5 seems closely tied to the SC state and serves as a specific marker of various types of epithelial SCs. A second type of carcinoma cell displays intracellular Porcupine protein, which functions to attach lipid tails post-translationally to recently synthesized Wnt proteins, thereby preparing them for secretion into the extracellular space. These two cell types (displaying either the Lgr5 or Porcupine marker) reside in close juxtaposition in the lung adenocarcinomas (**Figure 11.21A**).



A fluorescence microscopy image. It shows many dark blue nuclei but also several bands of bright red and green running at an angle through the image.

(A)



A diagram of a W n t responder stem cell and a nearby W n t producing niche cell. Within the niche cell, a W n t detaches from Porcupine and makes its way out of the cell, sprouts a zigzaggy extension, and then binds to a Frizzled receptor on the stem cell in the presence of L g r 5. The activated receptor promotes beta catenin, which promotes continued stemness.

The bottom of an intestinal crypt, where w n t producing paneth cells and L g 5 responding stem cells alternate in an upside down fan pattern.

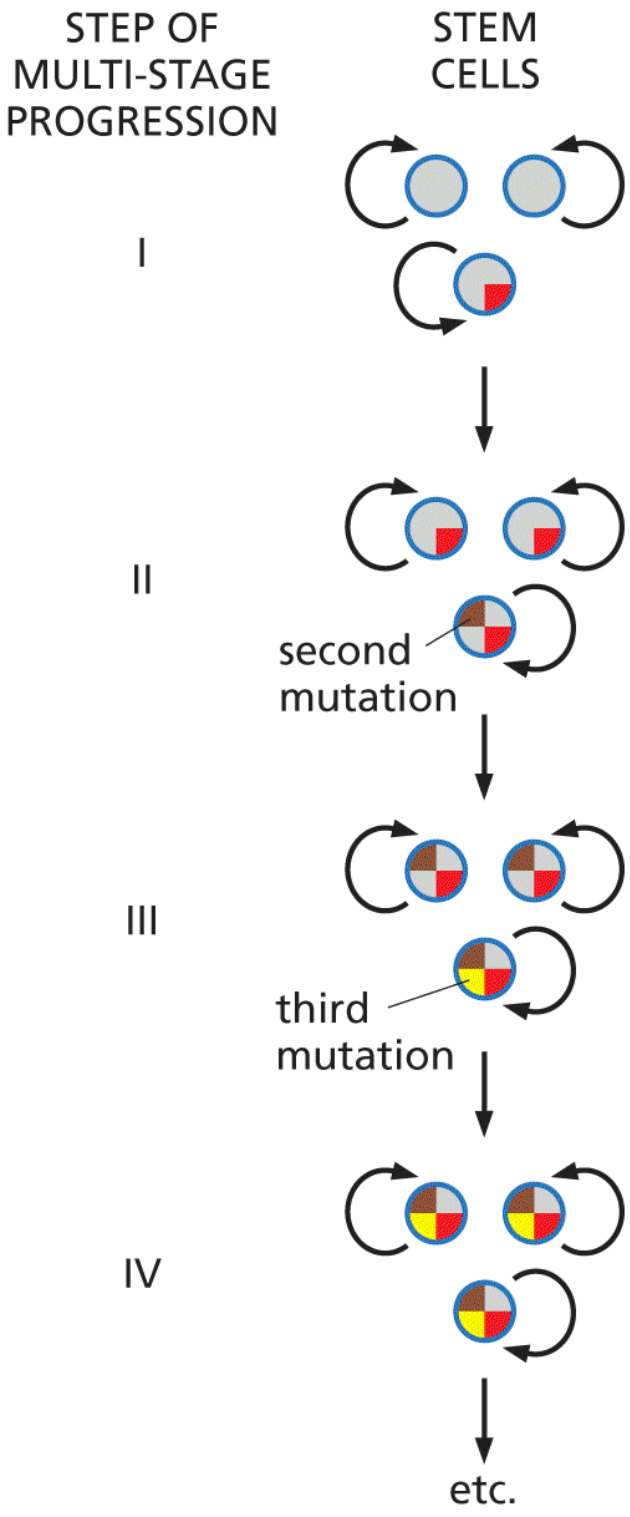
Figure 11.21Tumors may deploy niche-forming cells to sustain the cancer stem cells (A) The carcinoma cells formed in a transgenic mouse model of lung adenocarcinoma were analyzed for their expression of the Lgr5 epithelial stem-cell marker (*green*) or, alternatively, for expression of the Porcupine enzyme (*red*), which indicates the presence of cells synthesizing and releasing Wnt proteins. Because normal stem cells reside in a niche that is created, in part, by cells secreting canonical Wnt proteins and such stem cells depend on Wnt proteins to sustain their residence in the stem-cell state, such a niche-stem cell interaction is presumed to operate as well in the adenocarcinomas being analyzed here and illustrated in panel B. (C) The close juxtaposition of normal stem cells and niche-forming cells operates as well in the intestinal crypts (see Figure 6.19C). In the latter case, the Wnt-secreting niche-forming cells are Paneth cells, which exert other functions as well in these crypts. β cat.—β-catenin; Porcn— porcupine. (A and B, adapted from T. Tammela, F.J. Sanchez-Rivera, N.M. Cetinbas et al. *Nature* 545:355–359, 2017. With permission from Nature.)

To summarize, Porcupine serves as a good marker for niche-forming, Wnt-secreting cells, whereas Lgr5 functions as a good marker of the SCs that depend on the secreted Wnt protein for their stemness. Moreover, it is clear that oligopotent progenitor cells in these tumors differentiate to generate both the SC niche-forming cells as well as the CSCs that reside in these niches (Figure 11.21B). This is strikingly reminiscent of the situation operating in the normal intestinal crypt (Figure 11.21C) where a common progenitor cell generates both the Paneth cells that operate as niche-forming cells as well as the SCs that depend on residing in the Paneth-generated niches (see Figure 7.20B).

An additional dimension of complexity derives from observations made in both normal and neoplastic epithelial cells that the hierarchy depicted in Figure 11.20B does not operate in a rigid fashion. Thus, there is clear evidence in both normal epithelial tissues and in their neoplastic derivatives that non-SCs, such as transit-amplifying cells, can *dedifferentiate* backward into SCs under certain conditions (see Figure 11.20C, *red arrows*). This holds implications for the identities of cellular genomes that are objects of mutation during multi-step tumor development (**Supplementary Sidebar 11.6**). In normal tissues, this dedifferentiation may be triggered by the depletion of cells from the normal SC compartment, resulting in the upward pointing arrow in this figure and the replenishment of missing SCs. Precisely how such dedifferentiation processes are regulated is poorly understood. These phenomena suggest an additional notion that is yet to be documented: that epithelial cell populations, independent of their state of neoplastic transformation, spontaneously

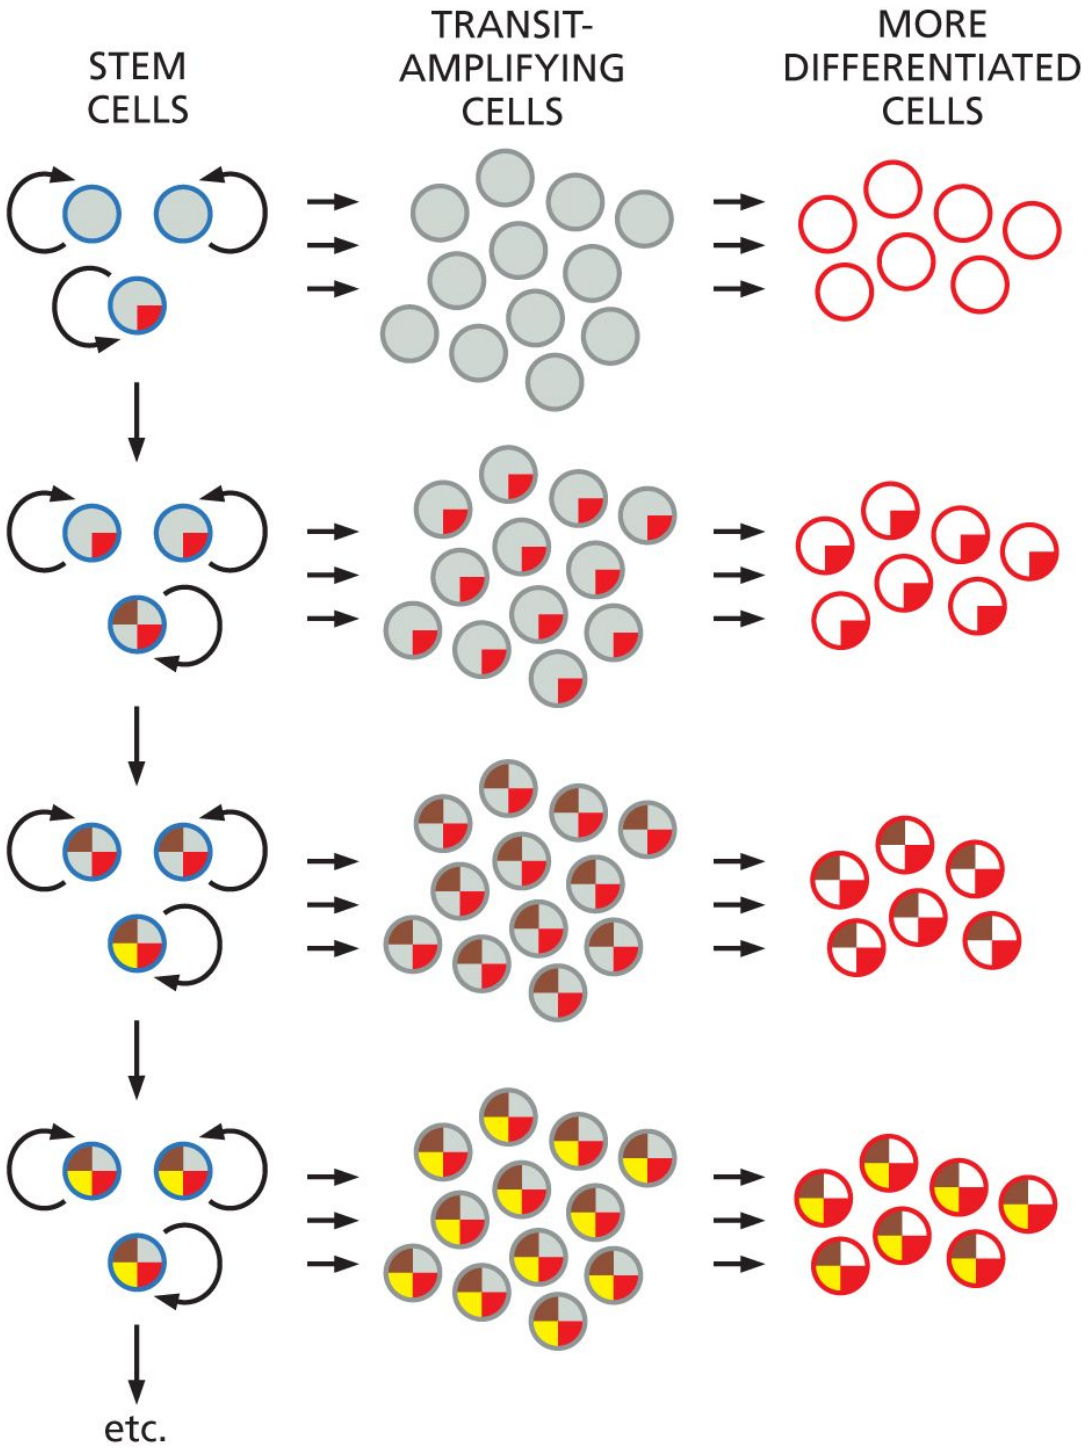
organize themselves into hierarchies of the sort depicted in Figure 11.20B and that phenotypic plasticity (that is, an ability to transition between alternative phenotypic states) is essential to create and maintain such hierarchies.

The existence of these hierarchies creates a new dimension of complexity within individual tumors. If virtually all epithelial cell populations organize themselves in this fashion, as speculated here (see Sidebar 11.7), it becomes likely that stem cell hierarchies are established within each of the cell populations that are formed during each of the multiple phases of multi-step tumor progression. Previously, we drew a linear, one-dimensional progression from a normal cell to a tumor cell (**Figure 11.22A**). Now, with this newer information in hand, it seems more appropriate to describe multi-step tumor progression in the form of a two-dimensional map, with the SCs formed at each stage of tumor progression spawning multiple distinct subpopulations of more and less differentiated cells (Figure 11.22B).



Four numbered steps in the multi-stage progression of a tumor. In step 1, a single mutation arises during stem cell reproduction. In step 2, a second mutation arises in one of several cells that all carry the first mutation. In step

3, a third mutation arises in one of several cells that all carry the first two mutations. In step 4, many stem cells now carry all three mutations.
(A)



The same four steps as in Part A, but additionally at each step many transit-amplifying cells are created, carrying no mutations, one mutation, two mutations, or all three mutations. Each group of transit-amplifying cells produces more differentiated cells carrying the corresponding number of mutations.

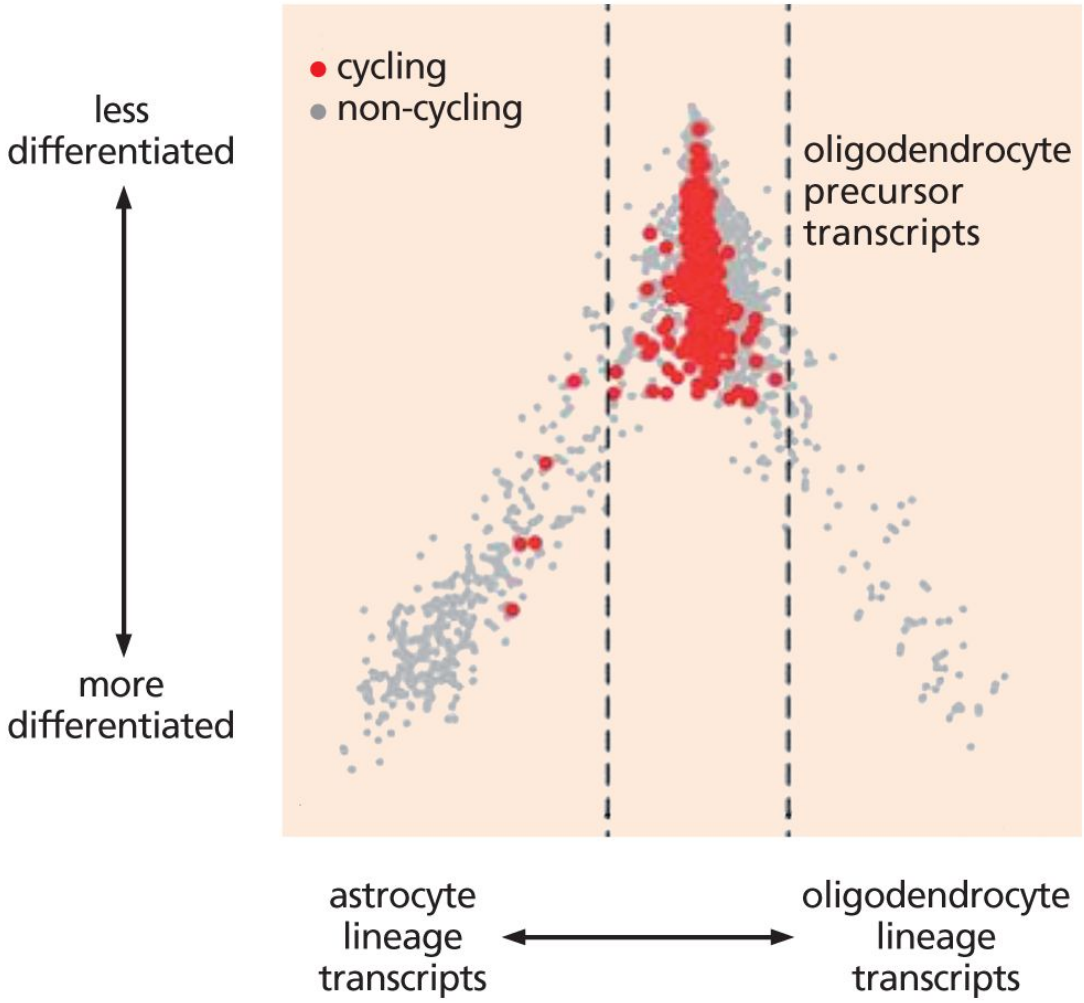
(B)

Figure 11.22 Multiple alternative phenotypic states at different stages of tumor progression (A) The scheme of multi-step evolution operating during tumor progression depicted in Figure 11.14 can be simplified graphically to indicate a linear succession of cell populations that succeed one another during this progression. Each of these states is defined by a distinct set of genetic and cell-heritable epigenetic alterations. (B) However, if epithelial cell populations (in the case of carcinomas) tend to spontaneously organize in a hierarchical fashion, as illustrated in Figure 11.20B, then the cell populations constituting *each stage* of tumor progression are also likely to self-organize into a similar hierarchical fashion. (This notion is further supported by the fact that fully normal and fully neoplastic epithelial cell populations both have stem cell subpopulations, providing strong indication that all of the intermediate cell populations formed during multi-step tumor progression will also contain subpopulations of stem cells.)

The existence of cancer stem cells is of more than academic interest. Because they may reside in a more mesenchymal phenotypic state, they are often more resistant to conventional chemo- and radiotherapies, as described in Chapter 17, and to more recently developed checkpoint immunotherapies, as described in Chapters 15 and 16. As a consequence, these cells may survive initial treatment, persist, and ultimately generate the new tumors whose appearance signals clinical relapse. In addition, there is clear evidence indicating that the cells that seed metastases at distant sites in the body must also possess tumor-initiating function, that is, they must operate as cancer stem cells (described in Chapter 14).

In fact, the involvement of CSCs in tumor pathogenesis suggests yet another dimension of complexity that we have not yet mentioned, even in passing: like normal SCs, CSCs may exhibit an ability to launch cells into multiple distinct differentiation lineages, that is, they may function like oligopotent stem cells. Such phenotypic diversification, if it occurs, should operate entirely independently of the genetic diversification that accompanies high-grade tumor progression and illustrated in Figure 11.16.

Recent observations using single-cell RNA sequencing techniques have indeed demonstrated that CSCs within individual tumors can indeed reside in hierarchies that lead, via phenotypic branching to generate multiple, phenotypically distinct subpopulations of cancer cells (**Figure 11.23**). As seen in this image, cells within a pediatric glioma could be resolved using single-cell RNA sequencing (scRNAseq) into three populations—a highly proliferative stem-like cell subpopulation and two distinct subpopulations that were generated by the stem cells and contained cells expressing transcriptomes typical of one or another differentiated normal cell lineage of the central nervous system; these more differentiated cells were nonproliferative and ostensibly post-mitotic. Such depictions of CSC differentiation have been extended by compelling demonstrations of the role of SCs in the formation and growth of skin papillomas (**Supplementary Sidebar 11.7**).



An image somewhat like a scatter plot. In the vertical direction, cells are more differentiated at the bottom and less differentiated at the top. The horizontal direction represents a continuum with astrocyte lineage transcripts on the left and

oligodendrocyte lineage transcripts on the right. In the middle is a zone characterized by oligodendrocyte precursor transcripts. The dots form an inverted vee pattern, with gray dots predominating at the left and right ends, representing non-cycling cells, and red dots predominating in the central peak, representing cycling cells.

Figure 11.23 Glioma stem-like cells spawn cells that enter into distinct differentiation states The transcripts present in the cells of a subtype of glioma that are formed in the central nervous systems of young children have been analyzed by single-cell RNA sequencing (scRNAseq). These cells fell into three distinct subpopulations based on their expression of a series of cell-specific transcripts. These included stem-like cells that exhibited transcripts characteristic of oligodendrocyte precursors, as well subpopulations that expressed, to differing extents, transcriptomes that were typical of differentiated cells of either the astrocyte or the oligodendrocyte lineage. Increased expression of these lineage-specific transcriptomes is plotted as increasing horizontal distances, *rightward or leftward*, from the less-differentiated precursors. Cells with less-differentiated transcriptomes are localized between the two dashed lines. Actively proliferating cells are indicated as *red dots*, whereas nonproliferating cells are indicated as *gray dots*. (From M.G. Filbin, I. Tirosh, V. Hovestadt et al., *Science* 360:331–335, 2018. With permission from AAAS.)

Moreover, as discussed in great detail in Chapters 13 and 14, the cell-biological program termed the epithelial-mesenchymal transition (EMT) operates epigenetically to drive carcinoma cells into a mixture of cell states that can be arrayed along a spectrum that ranges from highly epithelial to highly mesenchymal phenotypes. Here, once again, we see an example of a nongenetic program that profoundly affects the behavior of cancer cells but is not reflected in the "genetic biographies" discussed in Section 11.3. When taken together, these various considerations tell us that truly accurate depictions of multi-stage tumor pathogenesis will need to be mapped in a multi-dimensional space encompassing both genetically and epigenetically governed traits. In addition, as discussed in **Supplementary Sidebar 11.8**, the Darwinian model, on which many of the arguments in this section are based, remains unproven in many of its aspects.

A final complication has not even been explored here: recently acquired experimental evidence indicates clearly that within an individual tumor, different clonal subpopulations of tumor cells actively *collaborate* with one another rather than *compete*. Such collaboration flies in the face of the traditional model of Darwinian evolution, which is firmly grounded on mechanisms of competition between individual members of a species which allow more fit subpopulations to outgrow and eventually eliminate closely related, less-fit subpopulations. At present it remains unclear how

often such interclonal competition dictates the growth and lethality of various types of human tumors.

OceanofPDF.com

Glossary

tumorigenic
: (1) Referring to the ability of cells to form tumors when introduced into appropriate animal hosts. (2) Less commonly, pertaining to an agent such as a tumor virus that imparts this ability to cells.

tumorigenicity
: The ability of cells to serve as founders of new tumors, often gauged experimentally by transplanting cells into appropriate hosts.

transit-amplifying cell
: A relatively undifferentiated cell that is initially generated by division of a stem cell and is capable of exponential proliferation for a limited number of successive cell generations before spawning highly differentiated progeny, which in many tissues become post-mitotic. *See also* **progenitor**.

progenitor cell
: A cell derived from a stem cell whose descendants undergo a limited number of proliferative divisions before undergoing end-stage differentiation. *Also termed* **transit-amplifying cell**.

cancer stem cell
: A neoplastic cell that resides within a tumor, is able to both self-renew and generate non-stem-cell progeny, and can be defined experimentally by its ability to seed a tumor when implanted in a suitable host such as a mouse. *Also termed* **tumor-initiating cell**.

niche
: A functional locale that supports the survival and proliferation of specialized cells. Specific niches support the proliferation and survival of stem cells in normal tissues and, quite possibly, cancer stem cells in tumors.

Paneth cell
: Secretory cells that reside in the bottom of intestinal crypts and also help to create a stem-cell niche for adjacent intestinal stem cells. *See also* **niche**.

oligopotent
: Referring to the ability of a less differentiated cell, such as a stem cell, to differentiate into two more distinct progeny.

plasticity

Describing an ability to readily transit between alternative states, such as distinct phenotypic states.

11.8 Multiple lines of evidence reveal that normal cells are resistant to transformation by a single mutated gene

The description of multi-step tumorigenesis presented in Figure 11.10 is satisfying because it seems to provide a clear and definitive rationale of how multi-step tumor pathogenesis proceeds. In truth, however, it fails in at least two important ways. First, it describes genetic alterations as *correlates* of histopathological changes without proving *causality*; that is, it fails to demonstrate that the accumulated mutant alleles are actually responsible driving tumorigenesis forward. And second, it provides no explanation of why so many mutant genes are required for tumorigenesis to reach completion.

In the end, these shortcomings could only be addressed by intervening experimentally in the process of tumorigenesis, more specifically, by reconstructing it in detail in the laboratory. To begin, the introduction of well-defined genetic alterations into previously fully normal cells offered the prospect of revealing with precision how specific changes in cell genotype function to create the neoplastic cell phenotype.

In fact, certain early experiments (described in Chapter 4) seemed to indicate that the genetic rules governing the transformation of normal mammalian cells into tumorigenic cells are actually extremely simple. Recall, for example, the experiment in which a mutant, activated H-*ras* oncogene from a human bladder carcinoma was introduced via transfection into previously normal NIH 3T3 mouse fibroblasts (see Section 4.1 and Figure 4.1). Having acquired the mutant *ras* oncogene, these cells became fully transformed, to the point that they were capable of seeding tumors in appropriate host mice.

This behavior of the *ras*-transformed NIH 3T3 cells indicated that the requirements for transforming these cells were quite minimal. A single genetic alteration of these cells —the acquisition of a *ras* oncogene—sufficed to convert them to a transformed, tumorigenic state. Moreover, the mutation that originally created the *ras* oncogene was itself a simple point mutation. Taken together, these findings suggested that a point mutation affecting one of the NIH 3T3 cells' own native H-*ras* proto-oncogenes would yield the identical outcome—full transformation to a neoplastic state. In one stroke, a point mutation should transform a normal cell into a tumor cell.

We know from our earlier discussions of human tumor cell genetics that this conclusion—at least in the case of human cells—cannot be correct. We can verify this conclusion with a simple calculation. Given the rate at which specific point mutations occur randomly in the human genome, the number of point mutations accumulated per cell division, and the number of cell divisions occurring each day in the body ($\sim 3 \times 10^{11}$), some have estimated that several thousand new, point-mutated *ras* oncogenes are created accidentally every day throughout the human body and that the total body burden of cells carrying *ras* oncogenes must number in the millions. Clearly, human beings are not afflicted with a comparable number of new tumors each day.

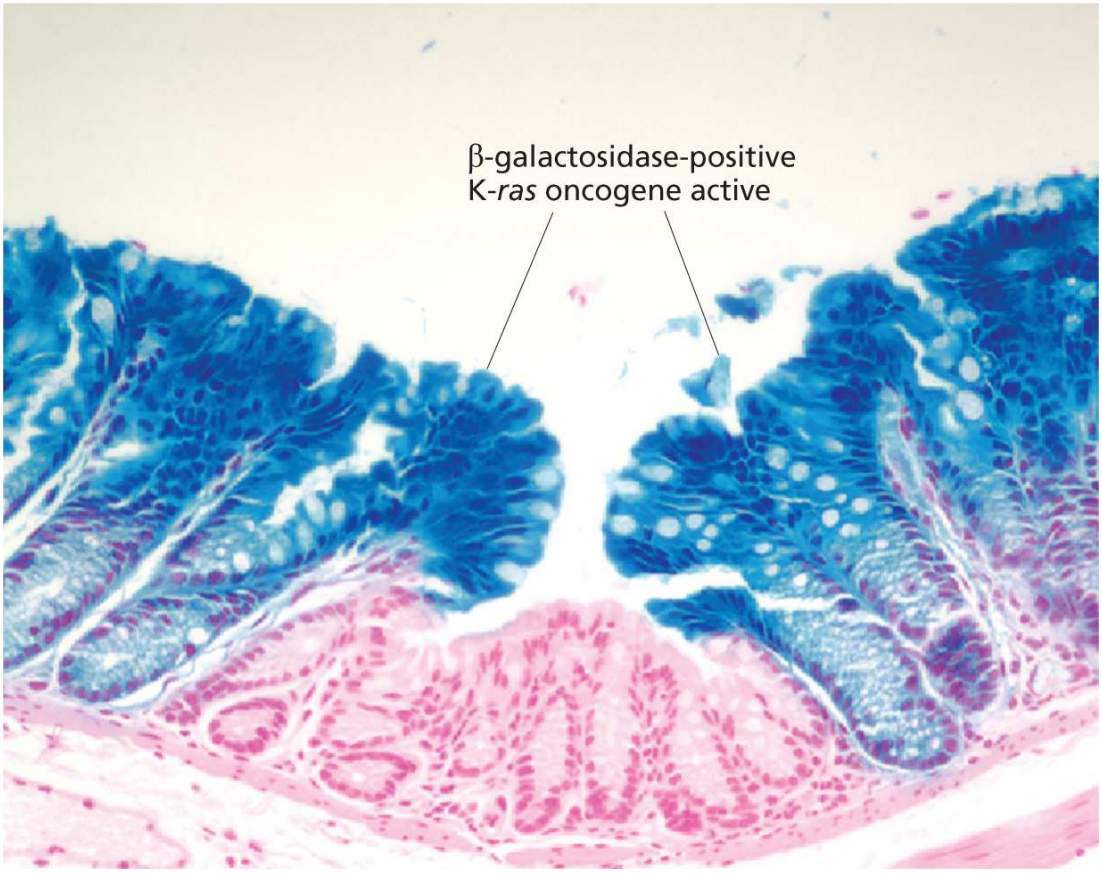
Something is terribly wrong here, either in these calculations or in the transfection experiments that were relied upon to gauge the genetic complexity of the transformation process. In the end, the flaw in in these calculations could be found in the design of the particular experiments, specifically in the "normal" cells that were used in the transformation assay. The NIH 3T3 cells, as it turns out, are not truly normal, because they constitute a cell line—a population of cells that has been adapted to grow in culture and can be propagated indefinitely (see Section 10.1). This history implies that these cells at some point underwent one or more genetic or epigenetic alterations that enabled them to grow in culture and to proliferate in an immortalized fashion (see Chapter 10).

As a consequence, investigators began in the early 1980s to examine the consequences of introducing a *ras* oncogene into truly normal cells—those from rat, mouse, or hamster embryos that had been recently explanted from living tissues and propagated *in vitro* for only a short period of time before being used in gene transfer experiments. Such cells—sometimes termed primary cells—were unlikely to have undergone the alterations that seem to have affected NIH 3T3 cells during their many-months-long adaptation to tissue culture and attendant immortalization.

The results obtained with primary rat and hamster cells differed from those observed previously with NIH 3T3 cells: These primary cells were not susceptible to *ras*-induced transformation. Control experiments left no doubt that these cells had indeed acquired the transfected oncogene and were able to express the encoded Ras oncoprotein, but somehow they did not respond by undergoing transformation and forming foci in the Petri dish. These observations provided the first evidence that the act of adapting rodent cells to culture conditions and selecting for those that have undergone immortalization yields cells that, in a fully unanticipated fashion, also become responsive to transformation by a single introduced gene, in this case an introduced *ras* oncogene.

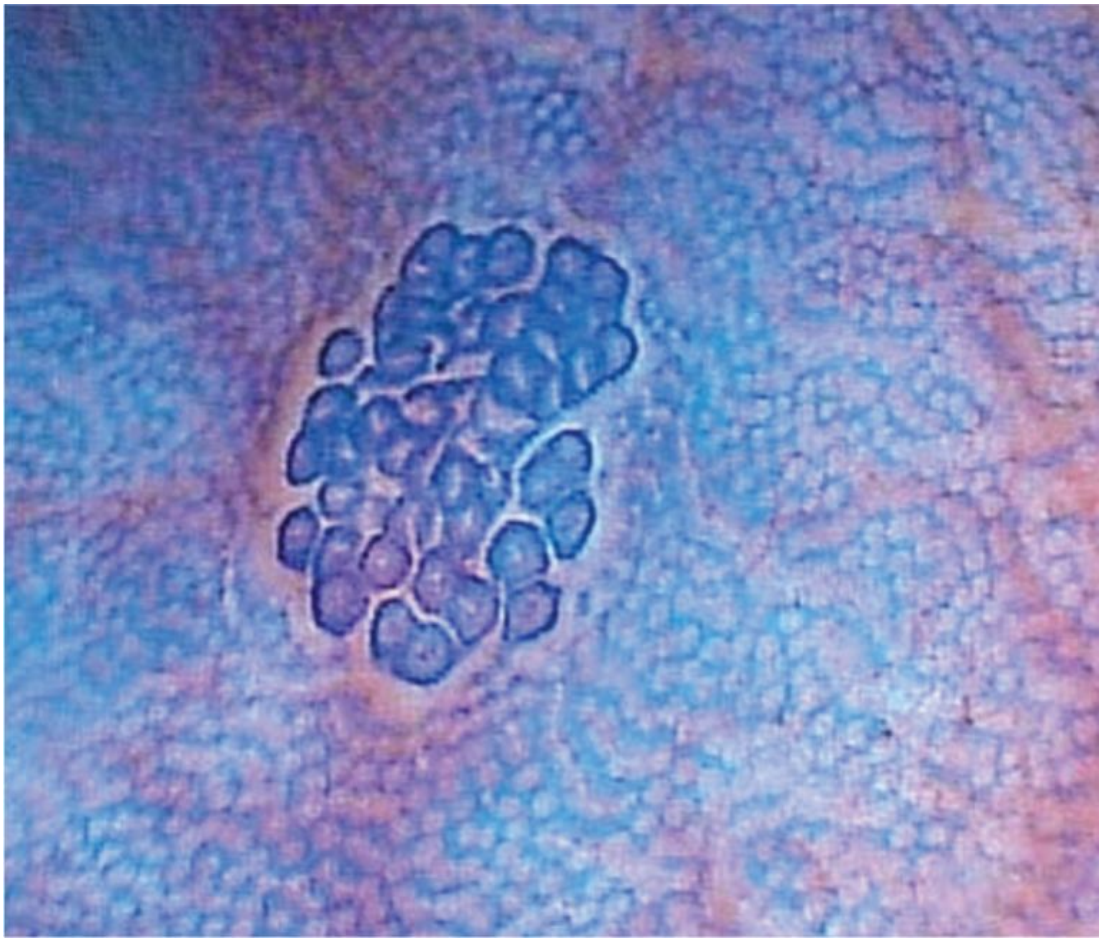
These *in vitro* experiments with primary cells have been extended by introducing activated *ras* oncogenes into the colonic epithelial cells of mice. The resulting *ras* oncogene–expressing cells create nothing more than hyperplastic epithelia, that is,

cells that are present in excessive numbers but are, in other respects, essentially normal (**Figure 11.24A**). Moreover, in a mouse model of skin carcinogenesis described later in Section 11.11, treatment with a mutagenic carcinogen can create H-*ras* oncogene–bearing cells that are detectable within a week, yet the skin remains morphologically normal for another year. In the human colon, clusters of cells bearing both the *ras* oncogene and inactivated copies of the *Apc* tumor suppressor gene form hyperplasias that are, in spite of these two alterations, incapable of forming adenomatous crypts (Figure 11.24B and **Sidebar 11.8**).



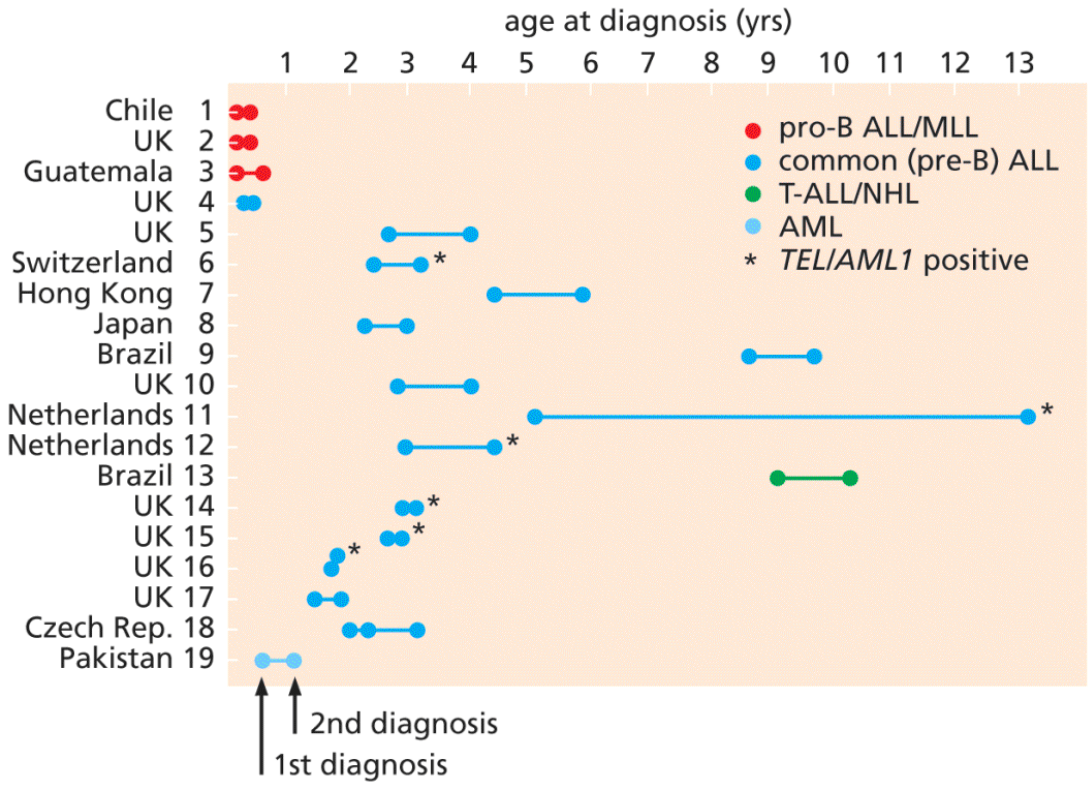
A histology image of colonic epithelial cells stained blue and pink. The blue ones are much larger, especially at the tops, but retain their normal orderly structure and arrangement.

(A)



An image of colon crypts seen from above, stained mostly blue with veins of pink. A cluster of three dozen or so crypts appear darker, with dark outlines.

(B)



A summary of data from 19 sets of twins in the U K and nine other nations who were both diagnosed with leukemia. Dots indicate the ages at which the each of the twins were diagnosed. In three twin pairs with a pro B, A L L slash M L L mutation, both diagnoses always came before age 1. In the 15 pairs with a common, pre B A L L mutation, age at first diagnosis was highly variable and the time between the first and second twin's diagnosis was variable but generally less than 2 years. Also shown are one pair sharing a T A L L slash N H L mutation, both diagnosed between ages 9 and 11, and one pair sharing an A M L mutation, both diagnosed around age 1, a few months apart. Six of the pairs have a twin that is TEL slash A M L 1 positive.

(C)

Figure 11.24 One or two oncogenic lesions do not suffice to generate full-blown tumors (A) A mouse germ line was re-engineered to create colonic epithelial cells in which both a mutant K-*ras* oncogene and the β-galactosidase gene could be activated in scattered cells by an infecting adenovirus. As indicated here, colonic epithelial cells in which both β-galactosidase (*blue*) and the K-*ras* oncogene (*not visible*) have become expressed create localized regions of hyperplasia in which the epithelial cells are otherwise normal, indicating that the *ras* oncogene on its own does not suffice to transform these cells into a tumorigenic state. (B) A cluster of aberrant crypt foci (ACFs) in the human colon

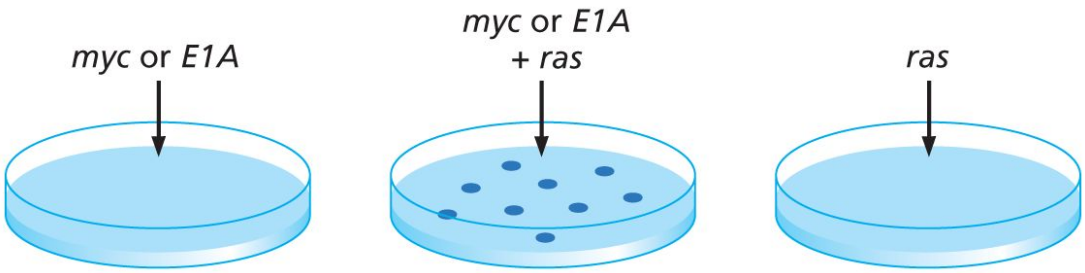
are clearly revealed by colonoscopy. ACFs like this one frequently carry an inactivated *APC* tumor suppressor gene together with an activated K-*ras* oncogene; they may eventually progress into adenomatous polyps, which themselves are still not full-fledged colon carcinomas. Hence, even two oncogenic genetic lesions, acting together, generate human cells that are still several steps short of being fully transformed. (C) Monozygotic (identical) twin pairs have been documented throughout the world in which both twins develop the same type of leukemia. The leukemias invariably share a common chromosomal marker or mutation, indicating that they derive from the same clone of initiated cells that somehow became shared between the twins. Although many of these leukemias are diagnosed at quite different postnatal ages (*dots*), these initiating somatic mutations, which occurred *in utero*, were not, on their own, sufficient to trigger the formation of a clinically apparent leukemia. The labels (*top right*) and the associated colors denote different subtypes of leukemia identified by distinctive gene markers. (A, courtesy of K.M. Haigis and T. Jacks. B, courtesy of Y. Niitsu. C, from M.G. Greaves et al., *Blood* 102:2321–2333, 2003. With permission from American Society of Hematology.)

Sidebar 11.8 Inborn oncogenes may predispose to cancer but do not suffice to create it

Certain “experiments of nature” also support the notion that single mutations in human cells are not sufficient for the development of cancers. For example, some individuals are born carrying a germ-line mutation of the gene encoding the Kit growth factor receptor; such mutations create a constitutively active, ligand-independent Kit receptor, which functions as a potent oncoprotein. These individuals are at high risk for developing gastrointestinal stromal tumors (GISTs), but these tumors only become apparent several decades after birth, even though a constitutively active Kit oncoprotein has been functioning in many of their cells since birth (see also Sidebar 5.6). Similarly, some individuals have been documented who carry mutant H-*ras* alleles in their germ lines yet usually develop tumors only after several decades. Early childhood leukemias in monozygotic (that is, identical) twins provide equally dramatic examples of the inability of single mutations, acting on their own, to create clinically apparent tumors (Figure 11.24C).

The resistance of fully normal, primary rodent cells to *ras*-induced transformation led to an interesting question: Were there yet other oncogenes that could render these cells susceptible to transformation by *ras?* In fact, a line of human promyelocytic leukemia cells had been reported to carry both an activated N-*ras* and an activated *myc* oncogene. This finding suggested the possibility that these two cellular oncogenes were cooperating with one another to create the malignant phenotype of the leukemia

cells. Indeed, when a *myc* oncogene was introduced together with an H-*ras* oncogene into primary rat embryo fibroblasts (REFs), the cells responded by becoming morphologically transformed (**Figure 11.25**) and, more important, tumorigenic; neither of these oncogenes, on its own, could create such transformed cells. An adenovirus *E1A* oncogene could be used in place of *myc* in these transformation assays.



Three petri dishes. The left one, labeled m y c or E1A, is empty. So is the right one, labeled r a s. The middle one, labeled m y c or E1A plus r a s, has generated nine foci.

Figure 11.25 Oncogene collaboration in rodent cells *in vitro* Cultures of early-passage rat embryo fibroblasts or baby hamster kidney cells were exposed to cloned DNAs via the calcium phosphate gene transfection procedure (see Figure 4.1). Introduction of a *myc* or adenovirus *E1A* oncogene into these cells (*left*), on its own, did not yield foci of transformants, although the introduced oncogenes did facilitate the establishment of these early-passage cells in long-term culture. Introduction of an H-*ras* oncogene via transfection (*right*) also did not yield foci of transformed cells, although it did allow significant numbers of these cells to form anchorage-independent colonies when they were introduced into a semi-solid medium such as dilute agar. However, the simultaneous introduction of *ras*+*myc* or, alternatively, *ras*+*E1A* did generate foci of transformed cells that were able to form tumors when injected into syngeneic or immunocompromised hosts.

This result yielded several interesting conclusions. These two cellular oncogenes clearly affected the phenotype of rodent cells in quite different ways, because they were able to complement one another in eliciting cell transformation. Each seemed to be specialized to evoke a subset of the cellular phenotypes associated with the transformed state. For example, *ras* was able to elicit anchorage independence, a rounded, refractile appearance in the phase microscope, and loss of contact inhibition, whereas *myc* helped the cells to become immortalized and reduced somewhat their dependence on growth factors. In subsequent years it became apparent that there were yet other complementary functions of the two. Thus, the Ras oncoprotein could supplant mitogenic signals normally supplied by growth factors, re-program cell

metabolism, and suppress apoptosis. Myc, for its part, could cooperate in driving cell proliferation, and promote various phenotypes only apparent *in vivo*, notably angiogenesis, invasiveness and metastasis (described in Chapters 13 and 14).

These oncogene collaboration experiments could be extended by demonstrating other pairs of collaborating oncogenes, some of which operated *in vivo* (**Table 11.1**). Together, such observations suggested a rationale for the complex genetic steps that accompany and cause tumor formation: each of the genetic changes provides the nascent tumor cell with one or more of the cell-biological traits needed in order to become tumorigenic (**Table 11.2**). These unique contributions seem to derive from the ability of each of these oncogenes to perturb a specific regulatory circuit or set of regulatory circuits within a cell. (Adenovirus E1A oncoprotein could supplant a Myc oncoprotein of entirely different structure and biochemical function, suggesting that these two proteins impinged on a common intracellular signaling circuit rather than on a common target protein within a cell; see Section 8.9.) Moreover, these experiments provided indication that cell proliferation and cell survival are governed by two or more distinct intracellular regulatory circuits, all of which must be perturbed before the cell will become tumorigenic. In the decade that followed, other pairs of collaborating oncogenes became apparent through research in a variety of experimental models (see Table 11.1).

Table 11.1 Examples of collaborating oncogenes *in vitro* and in *vivo*

"*ras*-like" oncogene[a]	**"*myc*-like" oncogene**[a]	**Target cell or organ**
***In vitro* transformation**		
Ras	*myc*	transfected rat embryo fibroblasts (REFs)
Ras	*E1A*	transfected rat kidney cells
Ras	SV40 *large T*	transfected REFs
Notch-1	*E1A*	transfected rat kidney cells

"*ras*-like" oncogene[a]	**"*myc*-like" oncogene**[a]	**Target cell or organ**
***In vivo* tumorigenesis**		
middle T	*large T*	polyomavirus-induced murine tumors
mil (=*raf*)	*myc*	MH2 avian leukemia virus chicken tumors
erbB	*erbA*	avian erythroblastosis virus chicken tumors
pim1	*myc*	mouse leukemia virus tumors
abl	*myc*	mouse leukemia virus tumors
Notch-1/2	*myc*	thymomas in transgenic mice
bcl-2	*myc*	follicular lymphomas in transgenic mice

Table 11.2 Physiological mechanisms of oncogene collaboration[a]

Oncogene pair	**Cell type**	**Mechanisms of action**
ras + SV40 *large T*	rat Schwann cells	*ras*: proliferation + proliferation arrest

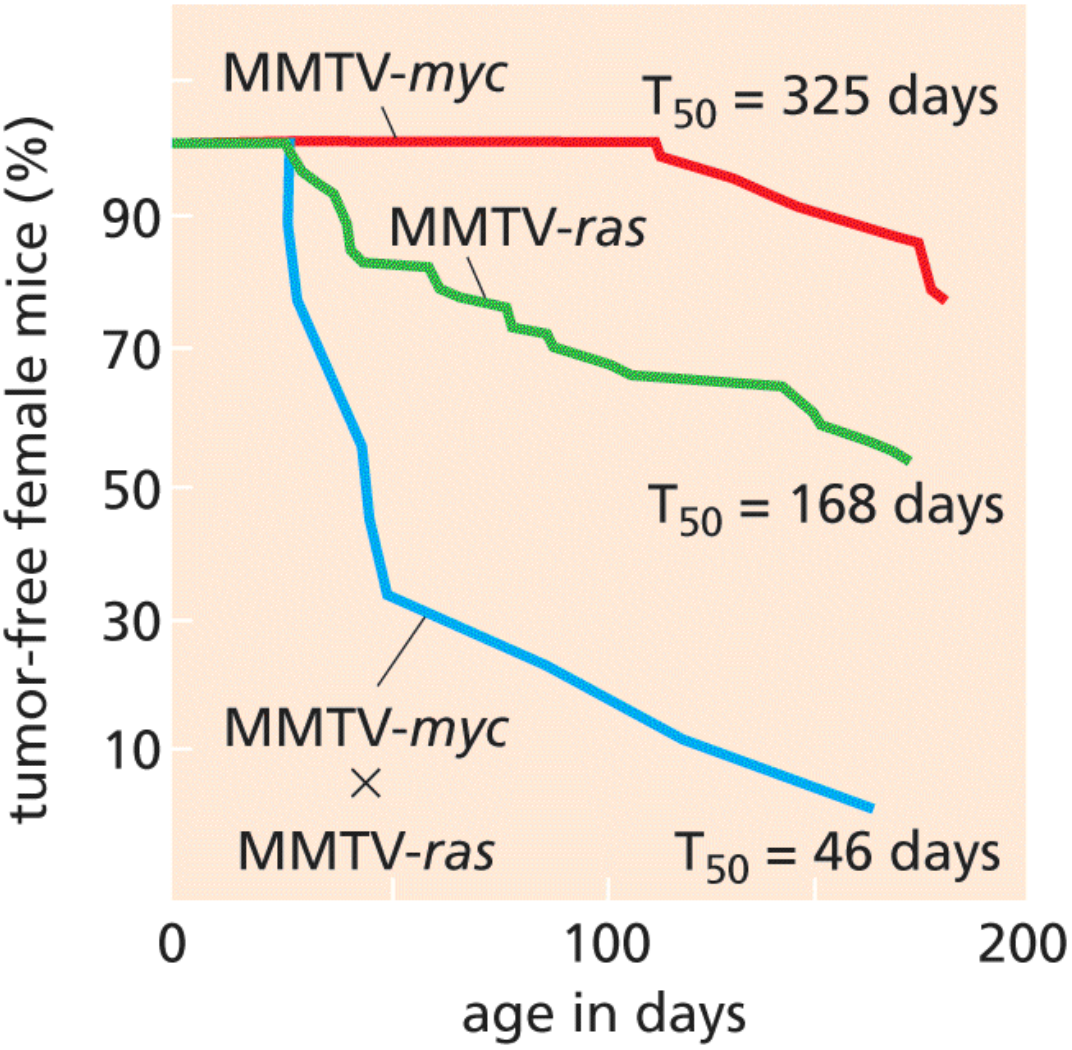
Oncogene pair	**Cell type**	**Mechanisms of action**
		large T: prevents proliferation arrest and reduces mitogen requirement
ras + *E1A*	mouse embryo fibroblasts	*ras*: proliferation and senescence
		E1A: prevents senescence
erbB + *erbA*	chicken erythroblasts	*erbB*: induces GF-independent proliferation
		erbA: blocks differentiation
TGF-α + *myc*	mouse mammary epithelial cells	*TGF*-α: induces proliferation and blocks apoptosis
		myc: induces proliferation and apoptosis
v-*sea* + v-*ski*	avian erythroblasts	v-*sea*: induces proliferation
		v-*ski*: blocks differentiation
bcl-2 + *myc*	rat fibroblasts	*bcl-2*: blocks apoptosis
		myc: induces proliferation and apoptosis

Oncogene pair	**Cell type**	**Mechanisms of action**
ras + *myc*	rat fibroblasts	*ras*: induces anchorage independence
		myc: induces immortalization
raf + *myc*	chicken macrophages	*raf*: induces growth factor secretion
		myc: stimulates proliferation
src + *myc*	rat adrenocortical cells	*src*: induces anchorage and serum independence
		myc: prolongs proliferation

These demonstrations of oncogene collaboration *in vitro* required extension and confirmation through *in vivo* studies involving mouse models of cancer pathogenesis. In many rodent models of cancer pathogenesis, tumors can be triggered by exposure of an animal to a mutagenic carcinogen, which acts in a random (sometimes termed stochastic) fashion to generate the mutant cellular alleles leading to cancer (as an example, see Section 11.11). An alternative to such experimental protocols can be achieved through the insertion of an already-mutant, activated oncogene into the germ line of a laboratory mouse, thereby guaranteeing expression of this transgene in some of its tissues. In practice, the expression of this oncogenic allele must be confined to a small subset of tissues in the mouse, using a tissue-specific transcriptional promoter to drive transgene expression. (If its expression were allowed, alternatively, in all tissues, including those of the developing embryo, it is likely that embryogenesis would be so profoundly disrupted that the developing fetus would die long before the end of gestation.)

An early version of this strategy for creating cancer-prone, transgenic mice (see, for example, Section 9.13) involved the insertion of oncogenic alleles of the *ras* and the

myc genes into the mouse germ line (**Figure 11.26**). In one influential set of experiments, expression of a *ras* oncogene and a *myc* oncogene were each placed under the control of the transcriptional promoter of mouse mammary tumor virus (MMTV), a retrovirus that specifically targets mammary tissues. Such hybrid genes could then be inserted into the mouse germ line, each becoming a transgene whose MMTV promoter ensured expression at significant levels only in mammary glands.



A line graph with percent of female mice that are tumor-free on the vertical axis and time on the horizontal axis. Three mutant mice strains are shown. All three remain 100 percent tumor free for about 30 days. After that, the percentage of tumor free M M T V m y c cross M M T V r a s mice plummets, to 50 percent in just 46 days. After that the curve continues to decline, but less steeply. The percentage of tumor free M M T V r a s mice falls less rapidly, reaching the 50 percent mark at 168 days. M M T V m y c mice remain tumor free much longer

than the other two strains, out past 100 days. After that, the curve drops but does not hit 50 percent until 325 days.

Figure 11.26 Oncogene collaboration in transgenic, cancer-prone mice The ability to create transgenic mice (see Figure 9.20A) made it possible to determine whether the *myc* and *ras* oncogenes are able to collaborate *in vivo* as well as *in vitro* (see Figure 11.25). Use of the MMTV (mouse mammary tumor virus) transcriptional promoter to drive expression of each oncogene ensured expression of both transgenes largely in the mammary glands. Transgenic mice carrying the MMTV-*myc* and the MMTV-*ras* transgene were bred to create double-transgenic mice carrying both transgenes. The incidence of mammary carcinomas in the three strains of mice—those carrying the MMTV-*myc* transgene only (*red curve*), the MMTV-*ras* transgene only (*green curve*), or both transgenes (*blue curve*)—was tracked over many months. The percentage of tumor-free mice (*ordinate*) is plotted vs. the age of the various strains of mice. "T_{50}" indicates the number of days required for one-half of the mice of a particular genotype to develop detectable mammary carcinomas. (From E. Sinn et al., *Cell* 49:465–475, 1987. With permission from Elsevier.)

As anticipated, the presence of either one of these oncogenic transgenes in the mouse germ line predisposed mice to eventual development of breast cancer. However, in spite of the expression of either a *ras* or a *myc* oncogene in most if not all of the mammary epithelial cells of these mice, their mammary glands showed either minimal morphologic changes (in the case of the *myc* transgene) or at most hyperplasia (in the case of the *ras* transgene). Moreover, breast tumors were observed only beginning at 4 weeks of age (for the MMTV-*ras* mice) and 12 weeks (for the MMTV-*myc* mice)—significantly long latency periods (see Figure 11.26). This confirmed that the presence of a single oncogene within a normal cell in living tissue was not, on its own, sufficient to transform this cell into a tumor cell. Instead, the kinetics of breast cancer formation in these mice pointed to the necessary involvement of one or more additional stochastic events before either the *ras* or *myc* oncogene–bearing mammary cells could progress to a tumorigenic state.

Double-transgenic mice that carried both MMTV-*ras* and MMTV-*myc* transgenes were created through mating between the two transgenic strains described above. These double-transgenic mice contracted tumors at a greatly accelerated rate and at high frequency compared with mice inheriting only one of these transgenes (see Figure 11.26). Therefore, the two oncogenic transgenes could collaborate *in vivo* to generate tumors, paralleling and corroborating the conclusions of the *in vitro* experiments described above.

Interestingly, even with two mutant oncogenes expressed in the great majority of mammary cells from early in development, tumors did not appear in these double-transgenic mice soon after birth but instead were seen with significant delay. Hence, the concomitant expression of two powerful oncogenes was still not sufficient to fully transform mouse mammary epithelial cells (MECs); instead, these cells clearly required at least one additional stochastic event, ostensibly a somatic mutation, before they would proliferate like full-blown cancer cells. (A hint about the identity of this third, stochastic event has come from careful analysis of rat cells that have been transformed *in vitro* by the *ras* + *myc* protocol; sooner or later, such cells usually acquire a mutation or a promoter methylation that leads to inactivation of the p53 tumor suppressor pathway; see Chapter 9.)

Note that the collaborative actions of transgenic oncogenes were already mentioned earlier, when we read of the synergistic actions of *myc* and *bcl-2* transgenic oncogenes in promoting lymphomagenesis (see Figure 9.20). In this case, the benefit of *bcl-2* (and its *bcl-*x_L cousin) derives largely from its anti-apoptotic effects. This work illustrates that oncogenes can collaborate through a variety of cell-physiological mechanisms to promote tumor formation, the point made in Table 11.2.

OceanofPDF.com

Glossary

primary cells
: (1) Literally, cells that have been recently explanted from living tissue into culture vessels and have not been propagated thereafter in culture. (2) More commonly, cells that have been explanted from living tissue into culture dishes and have been subjected to a relatively small number of successive *in vitro* passages thereafter.

stochastic
: Referring to an event that occurs randomly with a certain probability rather than in a precisely predetermined fashion.

transgene
: (1) A cloned gene that has been inserted experimentally into the germ line of an animal, often that of a laboratory mouse. (2) Less commonly, any experimentally altered gene in the germ line.

transgenic
: (1) Referring to an animal or breed of animal whose germ line has been experimentally altered, usually through the insertion of a cloned gene. (2) Less commonly, referring to an animal or breed of animal whose germ line has been altered through any of a variety of genetic manipulations, including the addition of a cloned gene or the alteration of a resident gene through homologous recombination or other procedure.

transgene
: (1) A cloned gene that has been inserted experimentally into the germ line of an animal, often that of a laboratory mouse. (2) Less commonly, any experimentally altered gene in the germ line.

latency
: The time period that defines the delay before a process reaches completion and becomes manifest or apparent.

11.9 Human cells are constructed to be highly resistant to immortalization and transformation

The biological lessons derived from studying mice and rats are usually directly transferable to understanding various aspects of human biology. Even though 80 million years may separate us from the most recent common ancestor we share with rodents, the great majority of biological and biochemical attributes of these distant cousins are present in very similar, if not identical, form in humans. The genomes of humans and rodents also seem very similar: essentially all of the roughly 20,000 protein-encoding genes discovered in the human genome have been found to have mouse orthologs. It stands to reason that the cell-biological processes of immortalization and neoplastic transformation should also be essentially identical in rodent and human cells.

The biological reality is, however, quite different. It is easy to immortalize rodent cells simply by propagating them through a relatively small number of passages *in vitro*. Spontaneously immortalized cells arise frequently and become the progenitors of cell lines, such as the NIH 3T3 cells discussed earlier (see Section 11.8). In contrast, human cells rarely, if ever, become immortalized following extended serial passaging in culture (see Chapter 10). Eventually, cultured human cells stop growing and become senescent, and spontaneously immortalized cell clones do not emerge. Moreover, attempts over a period of 15 years to experimentally transform human cells via transfected oncogenes consistently failed. These failures led to the notion that human cells were impregnable, that is, they simply could not be transformed experimentally. In fact, any human cells emerging from such failed transfection experiments were not even immortalized and therefore senesced sooner or later.

These repeated failures at experimental transformation of human cells prevented researchers from addressing a simple yet fundamental problem in cancer biology: How many intracellular regulatory circuits need to be perturbed in order to transform a normal human cell into a cancer cell? In the end, a solution to these failures was inspired by experience with cultured rodent cells, which indicated that once cells were immortalized in culture, they became responsive to transformation by a *ras* oncogene. The stark differences in the telomere biology of rodent and human cells (see Section 10.9) seemed to explain at least part of the difficulty of immortalizing human cells and thus their very different responses to introduced oncogenes. Recall that the cells of laboratory mice usually carry extremely long telomeric DNA (as long as 40 kb),

whereas normal human cells have far shorter telomeres. In addition, telomerase activity seems to be regulated differently in cells of the two species, that is, it is constitutively high in murine cells and almost absent in corresponding human cells. Accordingly, the immortalization problem related to human cells might be solved by adding the *hTERT* gene (encoding the catalytic subunit of the human telomerase holoenzyme) to other immortalizing oncogenes introduced into these cells.

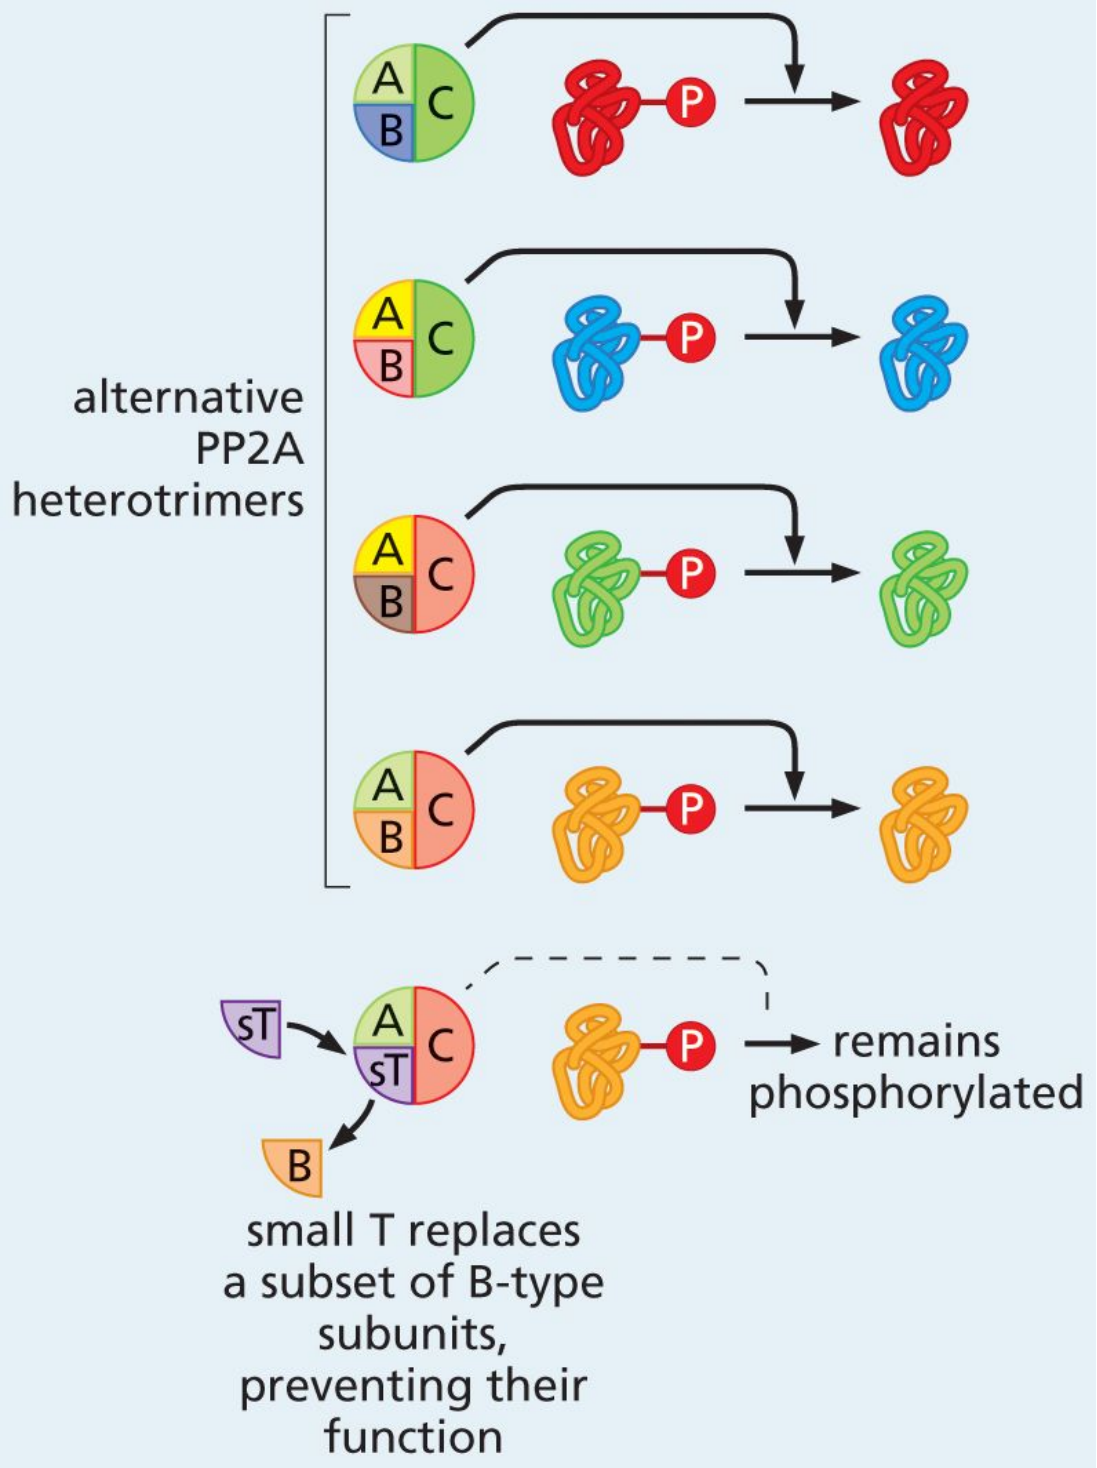
As it turned out, introduction of an *hTERT* gene in addition to the SV40 *large T* oncogene (whose product inactivates both pRb and p53 tumor suppressor proteins) did indeed yield immortalized human cells. (Alternative means of inactivating both pRb and p53, such as introduction of human papillomavirus *E6* and *E7* oncogenes, succeeded as well.) And once immortalization was achieved through these multiple changes, the resulting human cells, so the logic went, could then be transformed morphologically in the culture dish by introduction of an activated *ras* oncogene.

However, these morphologically transformed human cells were still not fully transformed, as indicated by their inability to form tumors when implanted in immunocompromised mouse hosts. (Recall that the faulty immune systems of such mice ensure that tissues of foreign origin, such as human tumors, are not eliminated by immunological attack.) In fact, these cells still required one more alteration, this one achieved by introduction of the gene encoding the SV40 small t oncoprotein. Small t perturbs a subset of the functions of the abundant cellular enzyme termed protein phosphatase 2A, notably PP2A enzyme complexes containing the B56γ subunit (PP2A; **Sidebar 11.9**).

Sidebar 11.9 The elusive fifth signaling pathway

It remains unresolved whether, in addition to the deregulation of the four signaling pathways described here, the fifth alteration—deregulation of the actions of PP2A—commonly occurs during the formation of most human cancers. PP2A is a phosphoserine/phosphothreonine phosphatase composed of multiple alternative regulatory subunits, a scaffolding subunit, and a catalytic subunit; altogether as many as 30 heterotrimeric forms of PP2A are thought to exist, each being defined by its complement of regulatory subunits, which in turn has been implicated in substrate recognition by the heterotrimeric holoenzyme complexes (**Figure 11.27**). In a number of cancers, the PR65α regulatory subunit of PP2A has been found in mutant form. And two cellular proteins, termed CIP2A and SET, are over-expressed in many human cancers and operate like the SV40 small T oncoprotein to protect the Myc protein from dephosphorylation by PP2A; the resulting preservation of phosphorylated Myc saves it from degradation. At the same time, CIP2A and SET protect kinases of the Ras–Raf–MEK–ERK pathway (see Section 6.5) from dephosphorylation, which would shut down the activation of this key mitogenic pathway achieved by actively signaling Ras

oncoproteins and as well as upstream mitogenic signaling proteins such as growth factor receptors. Yet other endogenous cellular inhibitors of PP2A have also been uncovered. Among the effects in transformation mediated by various combinations of PP2A subunits, the most important may well be the dephosphorylation of Myc, because a nonphosphorylatable mutant of Myc can replace SV40 small t oncoprotein in *in vitro* human cell transformation assays.



A diagram shows four different P P 2 A heterotrimers, each containing a small A unit, a small B unit, and a large C unit. Two A units are green, the other two yellow. The B units are four different colors. The C units are green or red. Each heterotrimer de-phosphorylates a particular cellular phosphoprotein. However,

when a small T subunit replaces a B subunit in an A B C complex, the corresponding protein remains phosphorylated.

Figure 11.27 Protein phosphatase 2A The PP2A holoenzyme is composed of A, B, and C subunits. There are 2 types of both A and C subunits, and 18 types of B subunit. The C subunits carry the catalytic activity of the holoenzyme and the B subunits direct the holoenzyme to specific substrates; the A subunits act as scaffolding to assemble B and C subunits into holoenzyme complexes. The various holoenzymes are responsible for dephosphorylating cellular phosphoproteins bearing either phosphoserine or phosphothreonine residues. The small T (sT) oncoprotein of SV40 can associate with the A and C subunits (*bottom*) and thereby prevent the association of certain B-type subunits with A + C. In so doing, sT prevents PP2A from dephosphorylating a subset of its normal constituency of substrates. This action contributes in an incompletely understood fashion to the experimental transformation of human cells. (Adapted from S. Colella et al., *Int. J. Cancer* 93:798–804, 2001.)

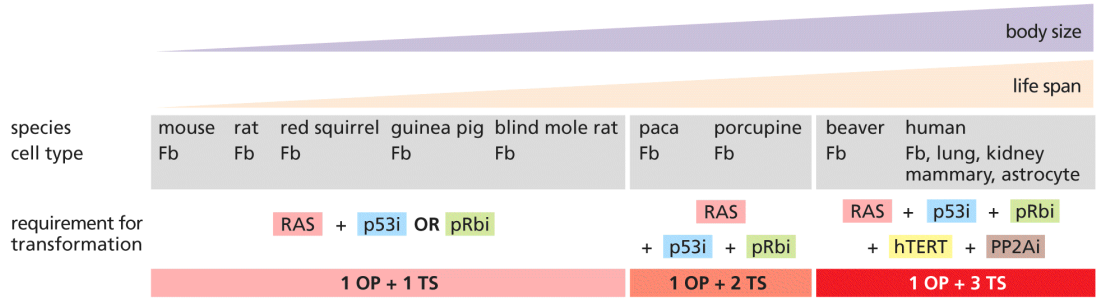
Taken together, these experiments demonstrated that *five* distinct cellular regulatory circuits needed to be altered experimentally before human cells can grow as tumor cells in immunocompromised mice (**Figure 11.28A**). These changes involve: (1) the mitogenic signaling pathway controlled by Ras (see Chapter 6); (2) the cell cycle checkpoint controlled by pRb (see Chapter 8); (3) the alarm pathway controlled by p53 (see Chapter 9); (4) the telomere maintenance pathway controlled by hTERT (see Chapter 10); and (5) the signaling pathways controlled by protein phosphatase 2A (PP2A); the latter include effects modulating the activity of a wide spectrum of ser/thr-phosphorylated proteins, among them those controlling the Ras, mTOR, Myc, β-catenin, and PKB/Akt signaling proteins (see Sidebar 11.9). (It remains possible that perturbation of alternative cellular signaling pathways quite distinct from the five listed here might also permit the experimental transformation of human cells.)

human cell transformation

pathway	Ras	pRb	p53	telomeres	PP2A
alternative genes/ molecules used to deregulate pathway	***ras***, *MEK+ Akt/PKB*, *MEK+IKBKε*, *PAK1+ Akt/PKB*	**SV40 *LT***, *CDK4 + D1*, HPV *E7*, *Rb shRNA*	**SV40 *LT***, DN *p53*, HPV *E6*, *p53 shRNA*	***hTERT***, *myc* + SV40 *LT*	**SV40 *sT*** in some cells: *myc* *Akt/PKB+Rac1*, *PI3K*, *B56 shRNA*

A table listing different pathways and the alternative genes or molecules to deregulate each pathway. The R a s pathway can be deregulated by r a s, M E K plus A k t slash P K B, M E K plus l K B K epsilon, or P A K 1 plus A k t slash P K B. The p R b pathway can be deregulated by S V 40 L T, C D K 4

plus D1, H P V E7, or R b s h R N A. The p53 pathway can be deregulated by S V 40 L T, D N p53, H P V E6, or p53 s h R N A. The P P 2 A pathway can be deregulated by S V 49 s T and in some cells by m y c, A k t slash P K B plus R a c 1, P I 3 K, or B56 s h R N A.
(A)



A listing of different mammalian species in order of increasing body size and lifespan: mouse, rat, red squirrel, guinea pig, blind mole rat, paca, porcupine, beaver, and human. Also listed are cell types: Fibroblasts for every species, and for humans additionally lung, kidney, mammary, and astrocyte. Across the bottom are listed gene and protein requirements for transformation. For the smallest species, up through blind mole rat, the requirement is 1 oncoprotein plus 1 tumor suppressor gene, or more specifically R A S plus p53i or p R b i. For the paca and porcupine, the requirement is 1 oncoprotein plus 2 tumor suppressor genes, or more specifically R A S plus p53i plus p R b i. For the beaver and human, the requirement is 1 oncoprotein plus 3 tumor suppressor genes, or more specifically R A S plus p53i plus p R b i plus h TERT plus P P 2 A i.

(B)

Figure 11.28 Intracellular pathways involved in mammalian cell transformation (A) The experimental transformation of human cells has been achieved through the insertion of various combinations of cloned genes into cells. Initially, a combination of three genes encoding the SV40 early region [which specifies both the large T (LT) and small T (sT) oncoproteins], the hTERT telomerase enzyme, and a *ras* oncogene was found to suffice for the transformation of a variety of normal human cell types to a tumorigenic state (*bolded*). These introduced genes were found to deregulate five distinct regulatory pathways involving (1) Ras mitogenic signaling, (2) pRb-mediated G_1 cell cycle control, (3) p53, (4) telomere maintenance, and (5) protein phosphatase 2A (PP2A). Subsequent work has found that other combinations of cloned genes suffice as well. For example, activation of the Ras signaling pathway can be mimicked by introducing a combination of constitutively active alleles of *MEK*

(*MEK*^{DD}) and *Akt/PKB.* Further dissection of these pathways has also revealed that a combination of *MEK*^{DD} with *IKBK*ε or *PAK1* with *Akt/PKB* also suffices to replace *ras* as an oncogenic activator. The disruption of pRb function can be achieved by a combination of ectopically expressed, CDK inhibitor–resistant CDK4 + cyclin D1 or a short hairpin construct (shRNA) directed against the *Rb* gene; p53 can be disrupted by an introduced dominant-negative *p53* allele or an shRNA directed against the *p53* gene; telomeres can be maintained by activating endogenous *hTERT* expression through a combination of introduced SV40 *LT+myc*; and PP2A function can be disrupted by an shRNA that inhibits the synthesis of the B56 subunit of PP2A. It is unknown whether these five pathways are required for the experimental transformation of all human cell types and whether deregulation of all of these five pathways occurs in all spontaneously arising human tumors. A comma in figure indicates "or." (B) The requirements for cell transformation differ in terms of the number of introduced genes needed to have full transformation. Indicated here are the cultured cells of a number of mammalian species (mostly rodents) that have been examined experimentally by introducing oncoproteins targeting or supplying the indicated cellular proteins. The indicated human cell types include fibroblasts, three epithelial cell types and astrocytes. Fb—fibroblast; i—inhibitor; OP — oncoprotein; TS —product of tumor suppressor gene; Rb—pRb. (B, courtesy of J. Westermarck.)

Experiments like these indicate why adult human cells are highly resistant to transformation. At the same time, it remains unclear whether the steps required to experimentally transform human cells *in vitro* accurately reflect the changes that normal cells must undergo within human tissues in order to acquire the attributes of cancer cells. In fact, four of these changes (involving Ras and hTERT activation, and pRb and p53 inactivation) are commonly seen in the cells of human tumors. For example, in a recent genetic survey of glioblastomas, 74% carried changes in the three critical pathways involving the pRb, p53, and Ras–MAPK proteins, and virtually all of these tumors exhibited elevated expression of hTERT as well. Of additional interest, a series of studies involving large-scale sequencing of 2658 cancer cell genomes derived from 38 distinct types of human cancer reported that, on average, these tumors carried four to five driver gene mutations per genome.

Extensions of such work, reported in 2014 and 2015, demonstrated that the targeted alteration of four genes (encoding the Apr, p53, K-ras, and Smad4 proteins) in the genomes of human Lgr5+ colonic crypt stem cells yielded tumorigenic cells with the features of invasive colorectal carcinomas; because these experiments employed cells that developed into colonic organoids in three-dimensional culture, they approached far more closely the conditions operating in human tissues *in vivo* (**Supplementary Sidebar 11.9**). In these experiments, each of the mutations introduced into the

genomes of the Lgr5+ stem cells replaced one of four protein factors (Wnt, R-spondin, EGF, Noggin) that was usually present in the culture medium and required to generate proper crypt morphogenesis *in vitro*. This work showed several things: It provided an independent accounting of how many genes needed to undergo mutation in order to create tumorigenic cells, that is, four instead of the five enumerated in Figure 11.28A. In addition, it showed that each of the requisite mutations rendered these colorectal cells independent of one or another specific extracellular signal.

These various lines of investigation seem to be converging on a number, possibly half a dozen, of the critical rate-limiting events involved in the formation of many human solid tumors. Nevertheless, it is likely that some normal human cells require a greater or lesser number of changes in order to undergo neoplastic transformation and the number of required changes differ between species (Figure 11.28B). Each of these requisite changes seems to reflect the need to deregulate or perturb a distinct signaling circuit operating within human cells (see Figure 11.28).

11.10 Mammalian evolution contributed to the complexity of human cell transformation

At this stage, we need to revisit the profound interspecies differences in the behavior of mouse versus human cells with respect to transformation. In particular, these differences require some type of biological rationale. We could begin here with noting that, in principle, the risk of tumor development in an organism is likely to be proportional to the cumulative number of cell divisions experienced by that organism during its lifetime; such cell divisions encompass both those needed to build up tissue mass during development as well as those involved in replacing cells that have been lost through physiologically programmed cell turnover. The complexity of the mammalian cell cycle, as laid out in Chapter 8, offers many opportunities for genetic disaster during the course of DNA replication and mitosis and thus during each of the myriad cell cycles occurring in a human body during a lifetime.

Changes wrought by evolution would seem to be essential to compensate, wherever possible, for the increased risk that, for example, large bodied, long-lived organisms like ourselves confront during an average life span. Thus, the cells in a mouse's body may pass through about 10^{11} mitoses in a mouse lifetime, whereas those in a human body pass through about 10^{16} cell cycles in a human lifetime. These numbers derive from the relative masses of the two organisms (which reflects cell number) times the average organismic life span. Such calculations are in one sense simplistic, because they do not account for other critical parameters, such as differing metabolic rates (which can affect mutation rates, as described in Chapter 12) as well as DNA repair capacity. (It remains to be seen how bowhead whales, which may weigh in at 100 tons and live up to 200 years, cope with the challenge of cancer development, which would seem to be 10,000 times higher than our own lifetime risks of cancer development. Provocatively, a

2021 genomics analysis provided clear evidence of accelerated evolution among whale species of genes involved in holding back cancer development including a number of tumor suppressor genes!)

These numbers, on their own, reveal the enormously increased risk of cancer development that is intrinsic to our biology relative to that of the mouse. Yet a human is not more prone to developing cancer than a mouse, creating a puzzle that is known as Peto's paradox. This logic suggests, in turn, that in response to the extreme peril created by our large bodies and long life spans, our bodies and tissues developed compensatory anti-neoplastic mechanisms. In principle, these heightened defenses—progressively erected as our mammalian ancestors evolved to increasingly larger sizes and longer life spans—depended on changes in our systemic physiology, such as defenses mounted by the immune system (as described in Chapters 15 and 16). In practice, however, many of these defenses were hardwired into our individual cells, rendering them far more resistant to transformation.

In the transformation experiments studies described here, these hardwired defenses might be reflected in the number of barriers placed to impede neoplastic cell transformation, each of these barriers being manifested by an additional requirement for transformation, that is, the need for an additional gene mutation. This logic, on its own, provides one rationale for why our cells have been evolved to be far more resistant to neoplastic transformation than have those of mice. Additional support for this thinking comes from the data presented in Figure 11.28B, which shows the positive correlation between the size/life span of mammalian species and number of introduced oncogenes required to transform their cells. Even more dramatic correlations come from measurements of constitutive TERT (telomerase) expression levels in normal somatic cells as they relate to the size of various rodents (**Supplementary Sidebar 11.10**). In this case the correlations are made entirely within one mammalian order and show inverse correlation—reflecting an apparent strategy of limiting telomerase activity as a way of constraining the outgrowth of neoplastic cells.

The measurement of telomerase levels reveals an anti-neoplastic mechanism that operates quite differently from those depending on

requirements for multiple genetic mutations as illustrated in Figure 11.28. In fact, there are likely to be dozens of other still-undiscovered anti-neoplastic mechanisms, whose existence can be deduced directly from the history of mammalian evolution: at least 10 mammalian orders, all descended from a ~25 gram common ancestor, independently invented large body sizes over the past 100 million years. Each of these developments must have required the compensatory co-evolution of highly effective defenses against cancer pathogenesis, many reflected in the hard-wiring of individual cells. This historical zoology yields insights that are of more than passing interest to experimental cancer researchers, simply because they dictate that attempts to develop many animal models of human cancer pathogenesis will often be hobbled because the cells of other mammals are organized differently from our own, at least in the molecular circuitry governing cell proliferation and survival.

Actually, independent of the intrinsic limitations of the cells of other mammalian species, there are cells of many humans that seem to break all of the rules of transformation that were described in Section 11.9. More specifically, the cells of human embryos and fetuses seem to be organized much differently from those present in adult tissues. Thus, a variety of pediatric cancers occur so early in life—some even arising prenatally—that it is difficult to imagine how the cells in these tumors could have had sufficient time to accumulate the cohort of mutations (and epigenetic changes) that seem to be required for the formation of adult malignancies.

This notion, really a speculation, is corroborated by genomic sequencing the genomes of a variety of pediatric tumors. As an example, a report in 2012 described the discovery of dozens to hundreds of mutations in the genomes of individual adult tumors, while the same research team had difficulty finding more than a single recurring mutation in early childhood rhabdoid tumors, similar to the unusually simple mutational spectrum present in the genomes of another important pediatric tumor type—retinoblastoma (see Chapter 8). This suggests the possibility that some pediatric cancers arise directly from certain embryonic cell types, and that such embryonic cells may be more readily transformed (that is, through far fewer alterations) than the cells that serve in various adult tissues as the

precursors of adult tumors. In fact, it is hard to imagine how or why this could not be the case.

The extreme case of this simplified genetic route to transformation derives from study of embryonic stem (ES) cells, which can be extracted from very early embryos. ES cells are, by all measurement, genetically wild type, yet are tumorigenic (yielding teratomas) when implanted in syngeneic hosts. They seem to be the only example of genetically wild-type cells that are tumorigenic. This suggests that, in order to become tumorigenic, certain cells within later embryos require a number of genetic changes that are *intermediate* between the number needed by ES cells (zero) and the number required by adult human cells (as an example, five). Here we may be encountering a replay of our ancient, billion-year-old evolutionary history that led single-cell protozoa to evolve into the first metazoa and then into ourselves (**Supplementary Sidebar 11.11**).

11.11 Nonmutagenic agents, including those favoring cell proliferation, make important contributions to tumorigenesis

The clinical observations and experimental results that we have read about in this chapter provide us with a crude picture of the genetic and epigenetic changes needed to form a human cancer cell. They fail, however, to reveal precisely how these changes are actually acquired during the course of tumor progression. So now, we turn to these issues—the processes occurring *in vivo* that enable cells to accumulate the multiple alterations needed for tumor formation.

As detailed above, a succession of somatic mutations provides much of the force that drives forward tumor progression. Because many of these changes are caused by the actions of mutagens, this implies that cancer progression is fueled largely and perhaps entirely by the genetic hits inflicted by mutagenic carcinogens. This notion was tested by the development and use of the Ames test and led to the conclusion, illustrated in Figure 2.21, that mutagens are carcinogens, and quite possibly, that carcinogens are mutagens.

In fact, attempts to use the Ames test to search for carcinogenic agents that play significant roles in human cancer causation, doing so through their mutagenicity, have repeatedly failed over the past half century. With the exception of tobacco smoke, ultraviolet radiation, aflatoxin-B1, and ethanol (which becomes mutagenic following its rapid conversion in the liver into acetaldehyde), almost all of the myriad other types of human cancer cannot be associated with prior exposure to specific mutagenic agents (**Sidebar 11.10**).

Sidebar 11.10 The misleading lessons of the Ames test

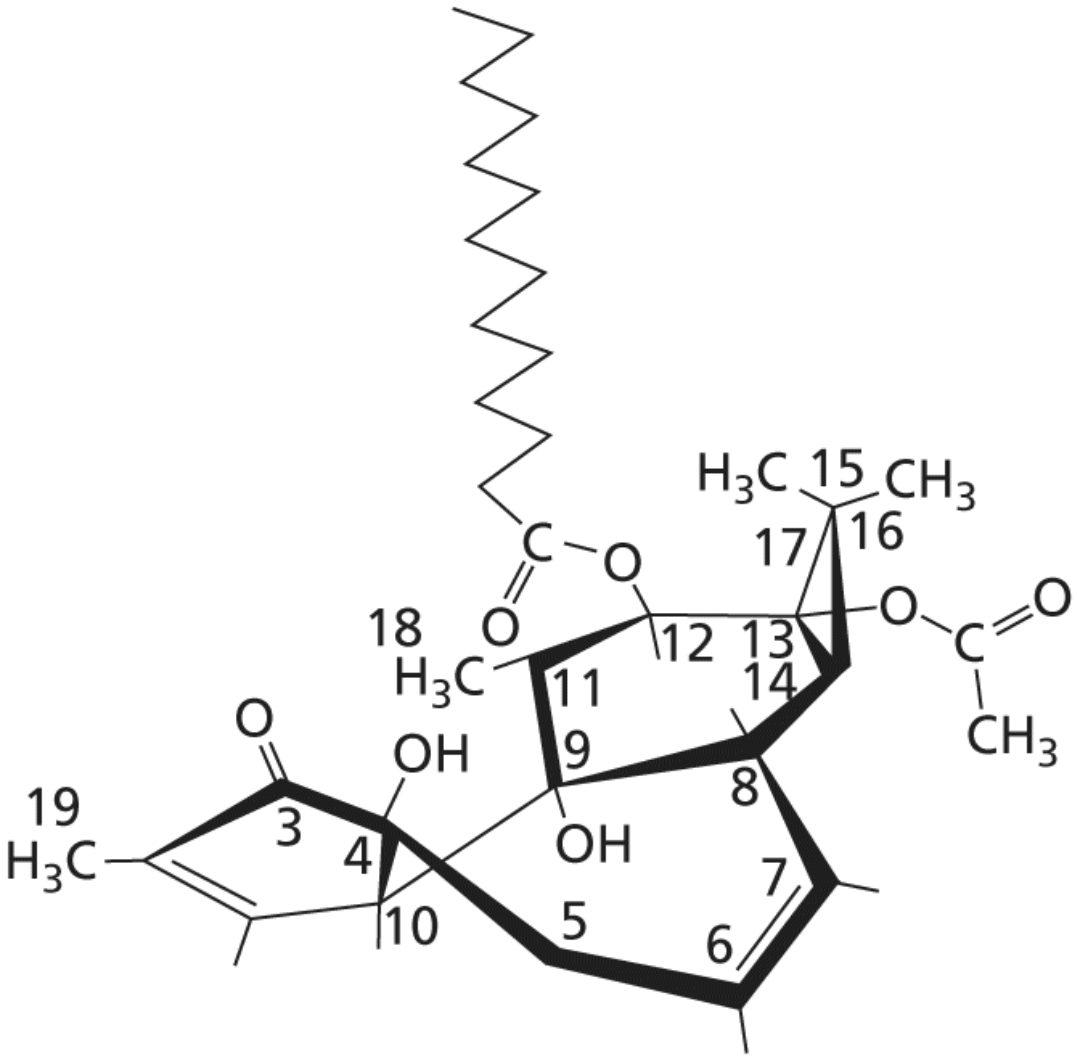
The profound differences in cancer incidence in different human populations (see Table 2.5) provoked extensive searches, many employing the Ames test, to find causative agents in the environment or lifestyle practices. Although Bruce Ames' research that carcinogens act through their mutagenic powers clearly stimulated scientific thinking in the 1970s about the origins of cancer, this thinking has proven to be simplistic in trying to understand human cancer causation. Thus, the failures to

demonstrate mutagenic agents that function as significant causes of common human cancers have provided one indication that human cancer formation is driven by mechanisms other than mutagenic agents experienced during our lifetimes.

Perhaps the most graphic demonstration of this discordance between carcinogens and mutagens has come from an extensive series of experiments in which 20 environmental chemicals known or suspected to be human carcinogens were tested for their carcinogenicity in laboratory mice. All of these chemicals were indeed found to be capable of inducing tumors in mice. However, detailed sequence analyses of the genomes of 188 resulting mouse tumors revealed that 3 chemicals caused significantly elevated mutational burden and were therefore clearly mutagenic, whereas the genomes of tumors induced by the remaining 17 carcinogens gave no indication of increased rates of mutation. Hence, 17 of the tested agents are highly likely to have facilitated tumor development through nongenotoxic mechanisms, as described below. This has left us with the generalization that most, if not all, mutagens can be carcinogenic, but the converse is not true: many—possibly most—human carcinogens are not mutagenic.

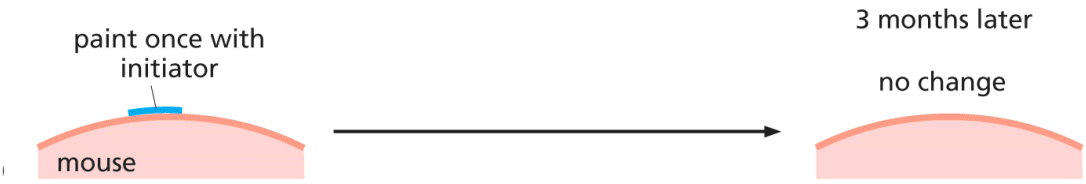
Indications of the importance of nongenotoxic carcinogens first came from attempts in the early 1940s to develop effective experimental methods for inducing skin cancers in mice. The experimental model used in this research depended on exposing mouse skin to highly carcinogenic tar constituents, such as benzo[*a*]pyrene (BP), 7,12-dimethylbenz[*a*]anthracene (DMBA), or 3-methylcholanthrene (3-MC; see **Supplementary Sidebar 2.7**), these being coal tar constituents that were already known or suspected to be highly carcinogenic. For example, mice subjected to daily painting of DMBA on a patch of skin would eventually develop skin carcinomas after several months of this treatment. These echoed decades earlier experiments showing that repeated painting of rabbit ears yielded the same outcome.

But another experimental protocol proved to be even more revealing. Following a single painting with an agent like DMBA, the same patch of skin could be treated on a weekly basis with a second agent, termed TPA (12-*O*-tetradecanoylphorbol-13-acetate; **Figure 11.29**), a potent skin irritant prepared from the seeds of the croton plant. (Another often-used term for TPA is PMA, for phorbol-12-myristate-13-acetate.) Repeated painting of a DMBA-exposed skin area with TPA resulted in the appearance of papillomas after 4 to 8 weeks, depending on the strain of mice being used (**Figure 11.30**). (These papillomas are in many ways analogous to the adenomas observed in early-stage colon cancer progression; see Figure 11.6.)



The chemical structure of 12-O-tetradecanoylphorbol-13-acetate. The core structure consists of three six-carbon rings, two of which share two carbons and the third of which shares a single carbon with one of the other two. The O-tetradecanoylphorbol group on carbon 12 is like an acetyl group but with a 13-carbon chain instead of a simple methyl group.

Figure 11.29 TPA, an important promoter of skin tumorigenesis The stereochemical structure of 12-*O*-tetradecanoylphorbol-13-acetate (TPA), also known as phorbol-12-myristate-13-acetate (PMA), is shown here. TPA is extracted from the seeds of the croton plant, specifically *Croton tiglium*. Its main target in cells is protein kinase C-α (PKC-α), which it activates.

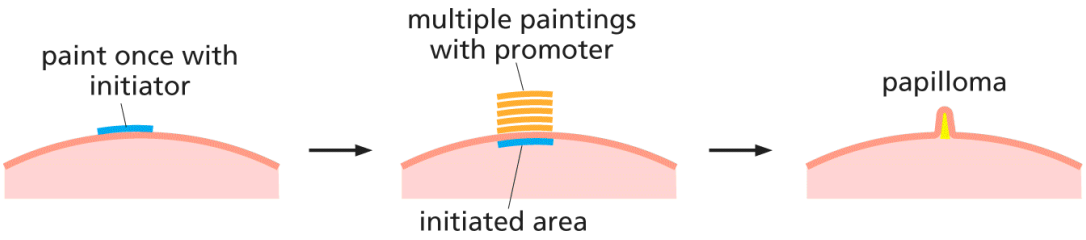


A mouse is painted once with an initiator. After 3 months there is no change.

(A)

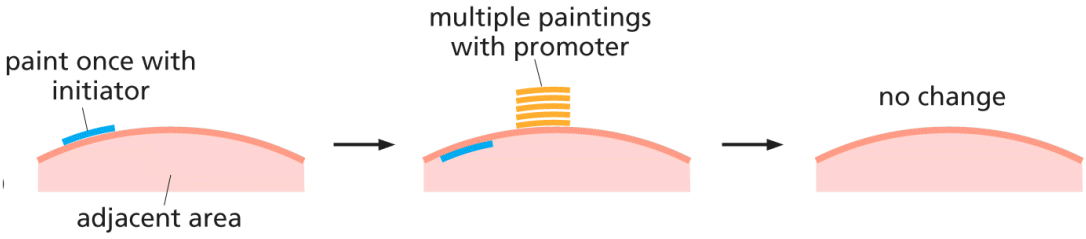
A mouse receives multiple paintings with a promoter. After 3 months there is no change.

(B)



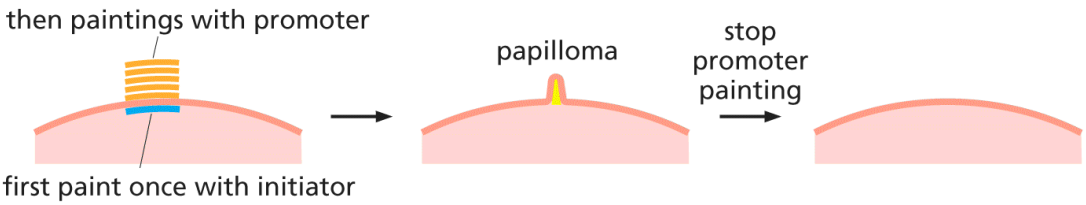
A mouse is painted once with an initiator and then later receives multiple paintings with a promoter over the initiated area. After 3 months there is a papilloma.

(C)



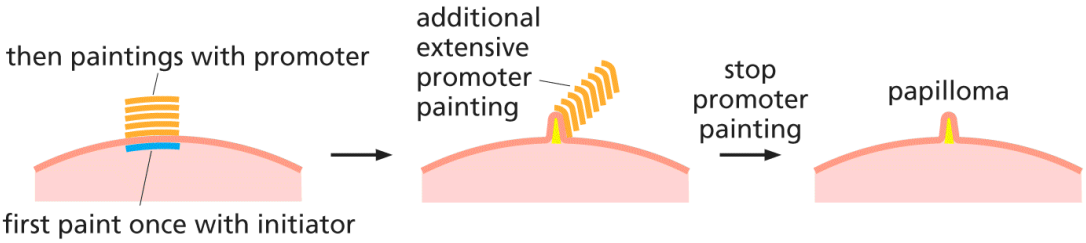
A mouse is painted once with an initiator and then later receives multiple paintings with a promoter adjacent to the initiated area. After 3 months there

is a no change.
(D)



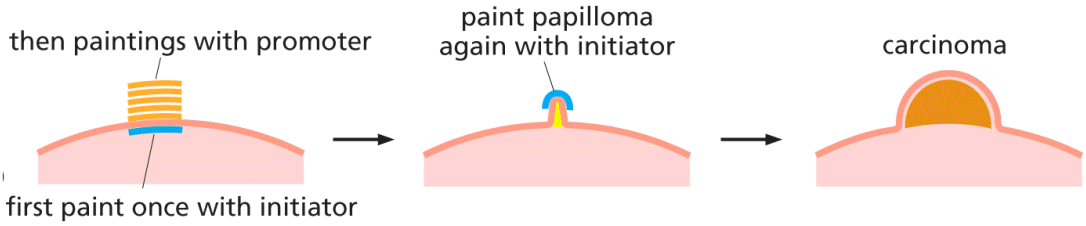
A mouse is painted once with an initiator and then promptly receives multiple paintings with a promoter over the initiated area. Soon, before the three-month mark, there is a papilloma. When the promoter painting is discontinued, after 3 months the papilloma has disappeared.

(E)



A mouse is painted once with an initiator and then promptly receives multiple paintings with a promoter over the initiated area. Soon, before the three-month mark, there is a papilloma. The promoter painting is continued with extensive additional treatments. After three months, the papilloma remains.

(F)



A mouse is painted once with an initiator and then promptly receives multiple paintings with a promoter over the initiated area. Soon, before the three-month mark, there is a papilloma. A second round of initiator is applied, to the papilloma. After three months, the papilloma has developed in to a carcinoma.

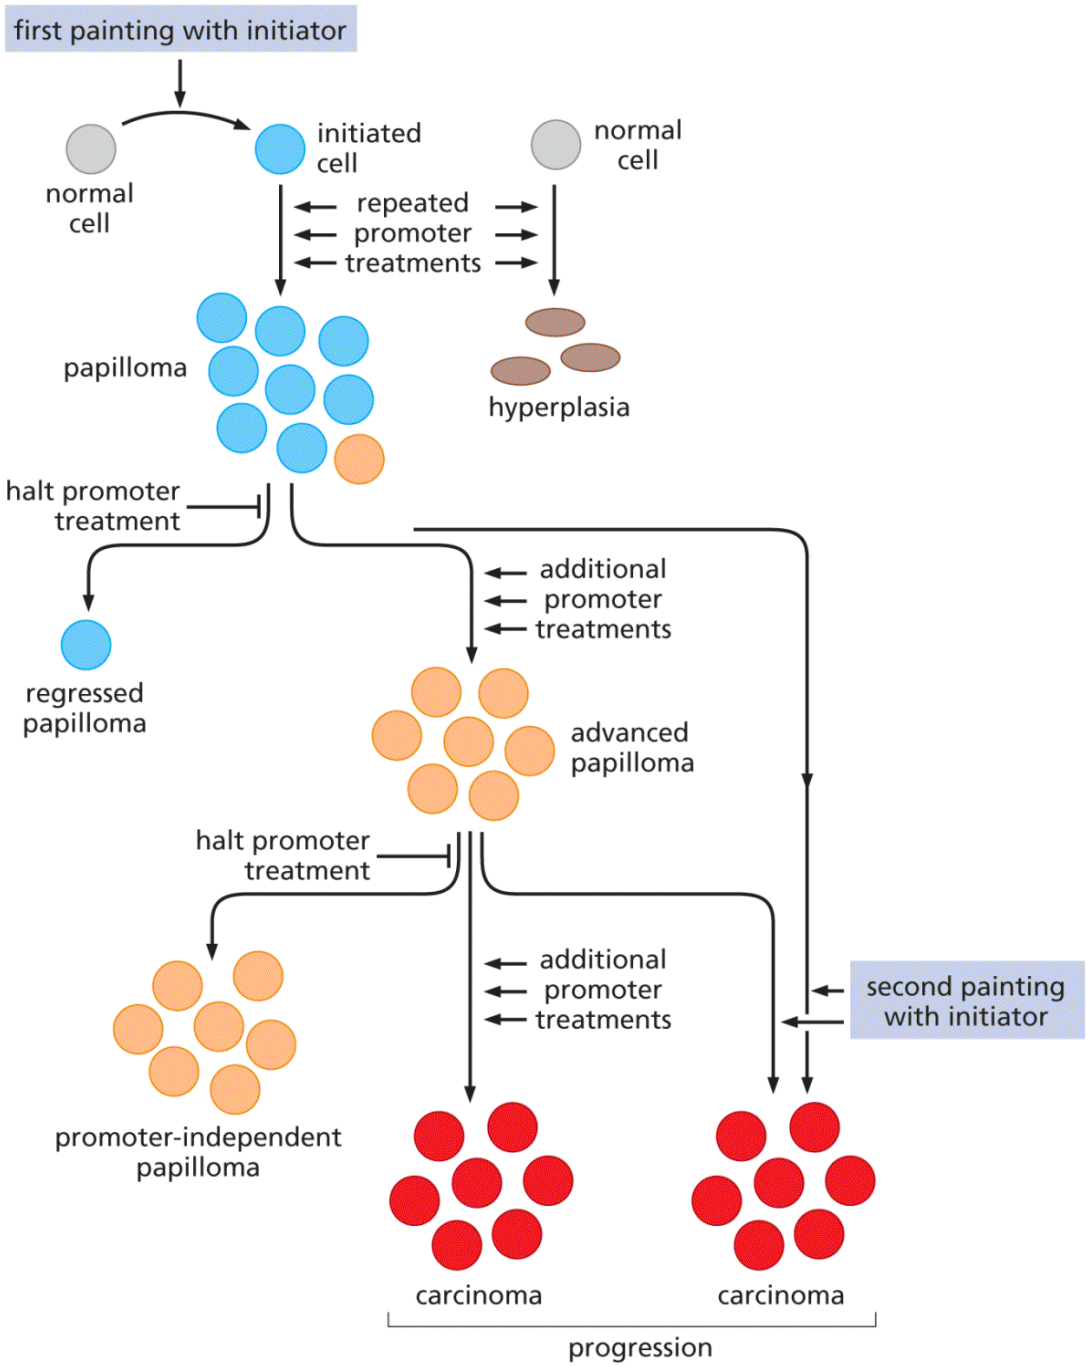
(G)

Figure 11.30 Protocols for inducing skin carcinomas in mice The induction of skin carcinomas by painting carcinogens on the backs of mice requires certain combinations of treatments with initiators and promoters. (A) A single treatment *(blue line*) with an initiating carcinogen, such as DMBA (dimethylbenz[*a*]anthracene), leads to no skin carcinomas 3 months later. (B) Multiple treatments (*orange lines*) with promoting agents, such as TPA (see Figure 11.29), also do not lead to significant numbers of tumors. (C) If an area of skin is painted once with an initiating agent followed by repeated paintings with a promoting agent, a papilloma will often appear several months later. If several months intervene between treatment with the initiating agent and subsequent promoter treatment, papillomas will also appear, indicating that the initiating agent permanently marked an area of the skin. (D) If an area of skin is painted once with an initiating agent and a promoting agent is then used to repeatedly paint another nearby but non-overlapping patch of skin, no papillomas will be seen 3 months later. (E) In a variation of the protocol depicted in panel C, an initiator such as DMBA is applied followed by repeated TPA treatments, which lead to papillomas. However, if repeated painting with the TPA tumor-promoting agent is halted soon after the papillomas appear, they regress, indicating that they are dependent on ongoing promoter stimulation. (F) In another variation of the protocol depicted in panel C, TPA promoter painting is continued for several months after papillomas first appear before being halted. Under these conditions, some of the papillomas will persist, indicating that they have become independent of continued promoter stimulation. (G) If a papilloma is produced by the protocols of panels C or F and the papilloma is then treated with an initiating agent, a carcinoma may appear, even in the absence of further promoter treatment.

At first, the survival and growth of these skin papillomas depended upon continued TPA paintings, because cessation of TPA treatments caused the papillomas to regress (see Figure 11.30E). However, if TPA painting was continued for many weeks, TPA-independent papillomas eventually emerged, which would not regress after cessation of TPA painting and instead persisted for extended periods of time (see Figure 11.30F). Some of these TPA-independent papillomas might, with low probability, eventually evolve further into malignant squamous cell carcinomas of the skin after about 6 months.

Importantly, in the absence of prior DMBA treatment, repeated painting with TPA alone failed to provoke either papillomas or carcinomas (see Figure 11.30B). Even more interesting, an area of skin could be treated once with DMBA and then left to rest for a year, giving no outward indication of having been treated. If this particular patch of skin was then treated with a series of TPA paintings (as in Figure 11.30C), it would “remember” that it had been exposed previously to DMBA and respond by forming a papilloma.

These phenomena could be rationalized as follows (**Figure 11.31**). A single treatment by an initiating agent (or initiator) like DMBA left a stable, long-lived mark on a cell or cluster of cells; this mark was apparently some type of genetic alteration. Subsequent repeated exposures of these "initiated" cells to TPA (termed the promoting agent or simply the promoter) allowed these cells to proliferate vigorously while having no comparable effect on nearby cells that had not experienced prior DMBA painting and were therefore considered to be uninitiated. (Note that use of the word "promoter" in this context is unconnected with its other meaning—namely, the DNA sequences controlling the transcription of a gene.) The localized proliferation of initiated cells that was encouraged by the promoter would eventually produce a papilloma. However, as mentioned above, if TPA painting was halted after several months, many papillomas would disappear, indicating that the effects of the promoter were reversible and therefore likely to impose a *nongenetic* effect on the cells in the papillomas. Clearly, this nongenetic effect, whatever its nature, could collaborate with the apparent genetic alteration previously created by the initiator to drive the proliferation of cells, causing them to form a papilloma.



The scheme of initiation and promotion of epidermal carcinomas in mice. The first painting with initiator converts a normal cell into an initiated cell. Repeated promoter treatments then stimulate repeated growth and division cycles that result in a papilloma in which a few cells have a heightened proclivity toward further progression. In a normal cell, repeated promoter treatments would have only produced hyperplasia. If promoter treatment is now simply halted, the papilloma cells will regress. On the other hand, a second painting with initiator will advance

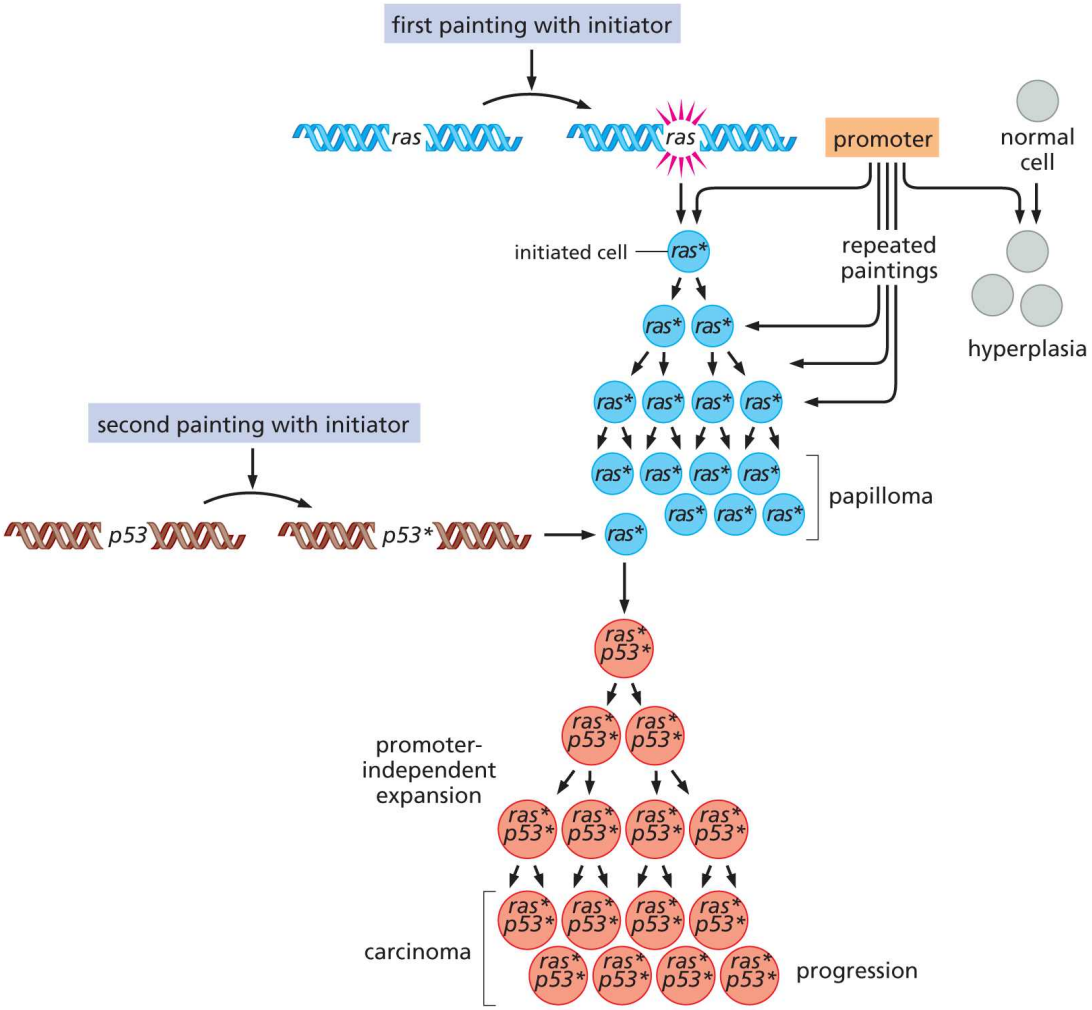
the papilloma to the carcinoma stage. But thirdly, repeated treatment with promoter may simply be continued until most or all cells in the papilloma are of the kind that has a heightened progression proclivity. Now if promoter treatment is simply halted, the papilloma will become promoter-independent. But if yet more repeated promoter treatments are applied, or if a second painting of initiator is applied, the papilloma will progress and become a carcinoma.

Figure 11.31 Scheme of initiation and promotion of epidermal carcinomas in mice The observations of Figure 11.30 can be rationalized as depicted here. The initiating agent converts a normal cell (*gray, top left*) into a mutant, initiated cell (*blue*). Repeated treatment of the initiated cell with the TPA promoter generates a papilloma (*cluster of blue cells*); among these papilloma cells may be ones with a heightened proclivity to progress further (*orange cell*). TPA treatment of normal, adjacent cells (*gray, top right*) may create localized hyperplasia, but papillomas are not formed. Further treatment of the initially formed papilloma can be halted (*middle left*), in which case most papillomas regress (*not shown*) but a subset may persist as promoter-independent papillomas (*bottom left*). Further repeated treatment of this more progressed papilloma with TPA eventually yields, with low frequency, a carcinoma (*bottom middle, red cells*). Alternatively, exposure of the initially formed papilloma to a second treatment by the initiating agent yields, with much higher frequency, cells that form a carcinoma (*bottom right, red cells*).

As we read above, if the initiated cells were treated with the TPA promoter for many months' time, eventually some papillomas would evolve to become TPA-independent; in this case, even after TPA withdrawal, the papillomas continued to increase in size and some eventually developed into skin carcinomas. This permanent change in cell behavior seemed to reflect, once again, the actions of a second, independent, cell-heritable alteration, that is, an apparent second mutation. Indeed, this evolution to a carcinomatous state could be strongly accelerated by treating a papilloma with a second dose of the initiating agent, already suspected to be a mutagen (see Figure 11.30G). This third step in tumorigenesis (coming after initiation and promotion) is termed progression; this term is used more generally, throughout this chapter and elsewhere, to indicate the stepwise evolution of cells to an increasingly malignant growth state.

Four decades after the mouse skin cancer induction protocol was first developed, the identities of the genes and proteins that are the main actors in this skin tumorigenesis model were discovered (**Figure 11.32**). As long suspected, the DMBA used as the initiating agent is indeed a potent mutagen in the context of skin carcinogenesis. Because it is a randomly acting mutagen, DMBA creates an almost-limitless number of mutations throughout the genomes of exposed cells. However, the skin tumors that emerge invariably bear point-mutated H-*ras* oncogenes (see Section 4.3), indicating that this particular mutant allele (among the hundreds of millions of mutant alleles

created by DMBA) confers some uniquely powerful selective advantage on keratinocytes in the skin.



A diagram of genes and proteins involved in mouse skin carcinogenesis. The first painting with initiator converts an r a s proto-oncogene into an active r a s oncogene. Repeated paintings with promoter then stimulate repeated growth and division cycles that start with a single initiated cell carrying the mutated r a s allele and end with a papilloma formed of such cells. In a normal cell, repeated promoter applications would only produce hyperplasia. A second painting with the initiator then causes mutation of the p53 allele. A cell containing both the mutant r a s allele and the mutant p53 allele now begins repeated growth and division cycles without any application of promoter. Eventually the resulting cells form a carcinoma.

Figure 11.32 Genes and proteins involved in mouse skin carcinogenesis The phenomena of initiation and promotion (see Figures 11.30 and 11.31) can be

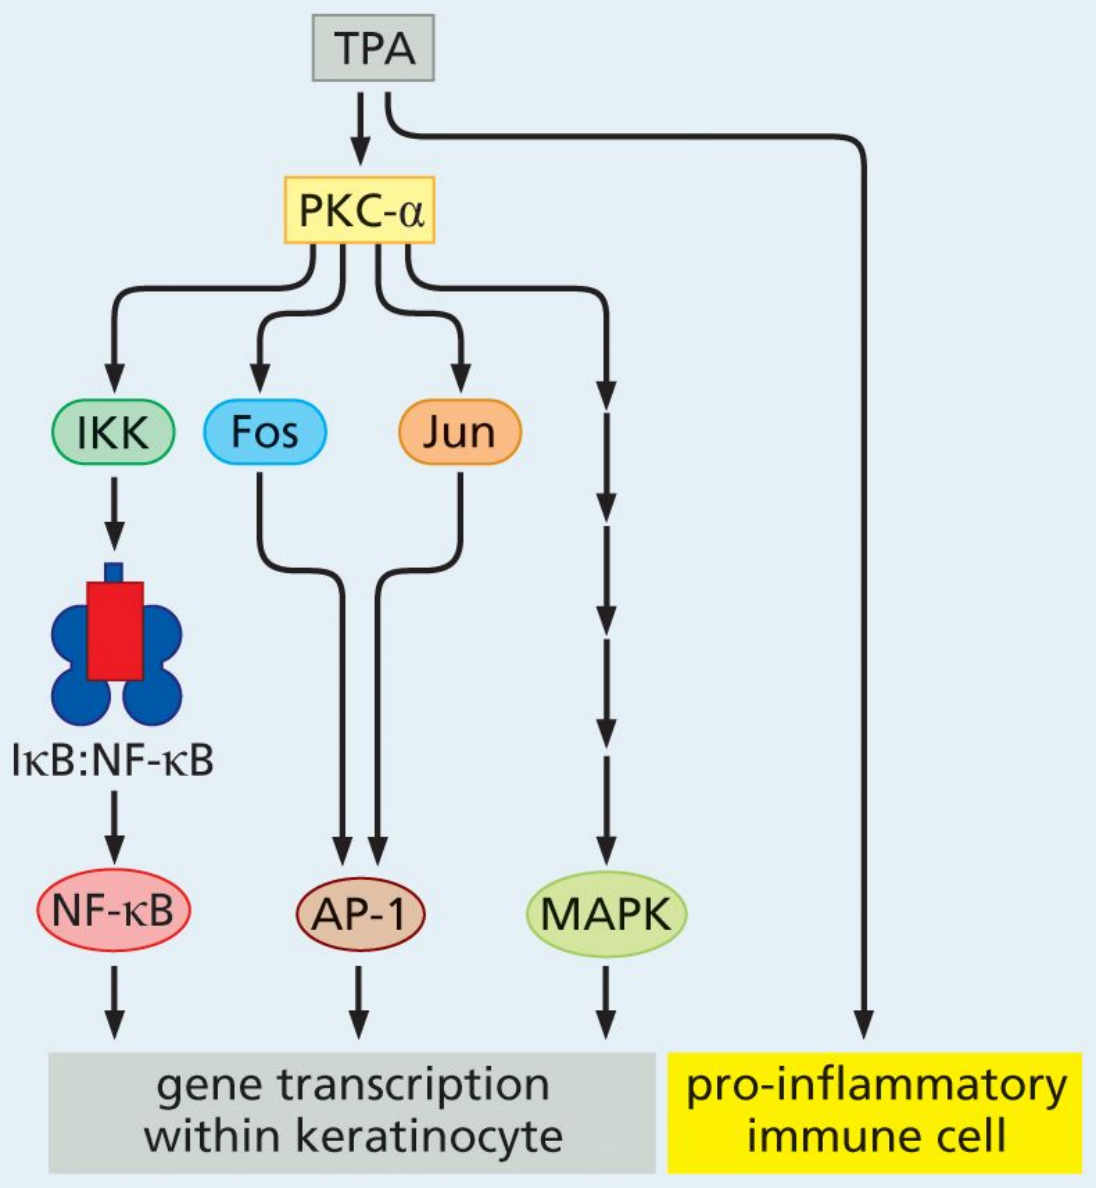
understood at the genetic level in the manner illustrated here. The initiating agent acts as a mutagen to convert a *ras* proto-oncogene into an active *ras* oncogene (*top left*). This initiation, on its own, has little apparent effect on the behavior of the keratinocyte bearing this mutant allele. However, in the presence of repeated stimulation by a promoting agent (*top right*), the *ras*-bearing cell is induced to pass through repeated growth-and-division cycles, leading to the formation of a papilloma (*blue cells*). Conversely, a cell lacking a *ras* oncogene (*gray, top right*) is not stimulated by the promoting agent and may only generate a localized hyperplasia in response to repeated exposure to this agent. If the papilloma is exposed a second time to a mutagenic initiating agent (*left*), a second genetic lesion, often involving the mutation of the *p53* tumor suppressor gene, is created. This mutant *p53* allele (*p53**) collaborates with the *ras* oncogene to create a population of cells (*red-orange*) that no longer depend on the promoter and are capable of forming a carcinoma. Not shown here is the amplification of the *ras* oncogene, which also occurs as tumor progression proceeds.

Moreover, the subsequent repeated treatments with TPA, the promoting agent, act to reversibly activate a kinase (see Sidebar 11.11), which functions synergistically with the already-activated H-*ras* oncogenes to drive the proliferation of initiated, oncogene-bearing cells, yielding a papilloma. Treatment of the papilloma with TPA over an extended period of time may generate a papilloma that can persist even after TPA treatment is halted. Alternatively, if cells in a papilloma are exposed, once again, to an initiating agent like DMBA, this papilloma may progress into a carcinoma, whose cells now carry, in addition to the H-*ras* oncogene, a mutant *p53* gene. Accordingly, the eventual emergence of a promoter-independent, autonomously growing carcinoma depends on the actions of a *second mutational event* that occurred either spontaneously or through the actions of an experimentally applied mutagen (**Sidebar 11.11**).

Sidebar 11.11 Signaling biochemistry of initiation and promotion

If we were to describe these phenomena at the level of signal-transduction biochemistry (**Figure 11.33**), we would say that the TPA promoter functions as a potent stimulator of cell proliferation through its ability to activate the cellular serine/threonine kinase known as protein kinase C-α (PKC-α), which we encountered briefly in the context of cytoplasmic signal transduction (see Section 6.6). More specifically, TPA acts as a functional mimic of diacylglycerol (DAG), the molecule that cells generate endogenously (see Figure 6.11B) as a means of activating protein kinase C (PKC). The downstream effectors of PKC-α collaborate with the H-*ras* oncogene, in still-poorly understood ways, to drive proliferation of initiated keratinocytes whose descendants form papillomas and, on rare occasion, progress to carcinomas. In fact, TPA is only one example of a diverse spectrum of tumor-

promoting agents to be described here. In the case of mouse skin carcinogenesis, these observations leave us with the conclusion that tumor promoters like TPA, which do not directly alter the genomes of cells, are nevertheless important in propelling multi-step tumorigenesis forward. Moreover, they impress upon us the notion that an agent that contributes to cancer formation—a carcinogen—need not be a mutagen.



Proliferation of keratinocytes driven by T P A activated protein kinase. Besides directly activating pro-inflammatory immune cells, T P A also activates P K C-alpha, which in turn activates I K K, F o s, Jun, and through a series of steps not shown, also activates M A P K. I K K activates the I kappa B N F-kappa B complex, which activates N F-kappa B. F o s and Jun both activate A P 1. N F-kappa B, A P 1, and M A P K all promote gene transcription within keratinocyte.

Figure 11.33 Activation of Fos, Jun, and NF-κB by PKC-α The precise mechanism by which an activated *ras* oncogene acts synergistically with TPA-activated protein kinase C-α (PKC-α) to drive the proliferation of keratinocytes is poorly understood. It is clear that once PKC-α is activated by binding TPA, it is able to stimulate transcription via several distinct signaling pathways, including those involving the NF-κB and AP-1 transcription factors and the ERK/MAPK enzyme. This depiction of intracellular, cell-intrinsic signaling within a keratinocyte does not address what are likely to be even more important effects of TPA and similar promoters on the tissue microenvironment around the keratinocyte, notably the cellular components of inflammatory immune cells that congregate in areas of promoter-exposed skin. These various promoter-induced responses, then taken together, have not yet yielded a coherent explanation of why TPA stimulates the proliferation of *ras* oncogene-bearing, initiated keratinocyte, while having minimal effect on nearby wild-type keratinocytes.

Actually, the processes depicted in Figure 11.30 and Figure 11.31 reveal that tumor promoters can act in two distinct mechanistic ways. They may drive the preferential proliferation and clonal expansion of already-initiated, mutant cells, making it possible that—sooner or later—low probability events, such as random mutations of certain genes, may strike the large cell populations of cells produced by this initial clonal expansion. (Because these random events occur with a low probability per cell generation, a large, expanded cell population is required before such a secondary mutational event is likely to occur in one or another cell.) Ostensibly, these later mutational events enable descendant cells to acquire a critical second mutant allele that *collaborates* with the initial, primary mutation created by the initiating agent; more specifically, this new mutation can collaborate with the initially sustained mutation to drive neoplastic proliferation, yielding tumor outgrowth.

Independent of this function of driving preferential clonal expansion of already-mutated cells, some promoters can act in an alternative fashion to favor tumorigenesis simply by driving endless rounds of cell proliferation, doing so even in cell populations that lack previously acquired, oncogenic initiation events. Because passage through a cell cycle, on its own, results in mutations at a low but measurable frequency per cell generation (as described in the next chapter), this mitogenic effect is itself indirectly mutagenic and thus carcinogenic.

Finally, it is essential for us to integrate the phenomenon of tumor promotion with the scheme depicted in Figure 11.14. More specifically, it is clear that tumor promoters can increase the *rate of clonal expansion* of already-mutated cells; the resulting expansion rate may be the critical, rate-limiting determinant that governs the time intervals between successive clonal expansions. Consequently, in the context of human tumor pathogenesis, the incidence of various tumors may be determined by whether or

not such clonal expansions occur rapidly enough to generate full-blown tumors within an average human life span. Recent work shows that the accumulation of random mutations occurs at similar rates in various tissues that nevertheless spawn cancers at vastly different frequencies; this suggests, once again, that nongenetic processes often represent rate-limiting determinants of tumor formation, doing so by governing the rapidity of tumor formation and thus, during a lifetime, the incidence of cancer in various human tissues.

These realizations forced a reinterpretation of how diet and lifestyle factors (found by epidemiologists to be important determinants of human cancer incidence) actually work. Rather than exposing the body's tissues to potent mutagens, many if not most of these factors, seem to act through their ability to drive forward certain clonal expansions that elicit nonmutagenic, tumor-promoting mechanisms.

11.12 Mitogenic agents, key governors of human cancer incidence, can act as tumor promoters

The experimental model of mouse skin carcinogenesis, as described above in some detail, is not used today by many researchers to study the dynamics of tumorigenesis. Nevertheless, at the conceptual level, it proved highly useful decades ago in revealing the role of nongenotoxic carcinogens in fostering carcinoma progression, and more specifically for its powers in illustrating the principles of tumor initiation, promotion, and progression. This scheme was a revelation to many, in that it demonstrated that cancer formation cannot be attributed simply to mutagens that either enter the body from outside or are generated by endogenous metabolic processes that damage the genomes of human cells (as described in Chapter 12). Still, the experimental model of mouse skin carcinogenesis tells us almost nothing about how analogous tumor-promoting mechanisms actually operate within the human body to create cancer.

In fact, a diverse array of biochemical and biological mechanisms appear to be responsible for the tumor promotion that leads to human cancers, complicating attempts at experimental modeling in laboratory mice. (**Sidebar 11.12**). As we learned in Chapter 2, the incidence rates of various types of human cancer vary dramatically between different human populations globally, indicating that exposure to carcinogenic agents experienced in different environments exerts enormous influence on the development of various types of cancer (see Table 2.5). However, as mentioned above, searches for environmental carcinogens that are mutagenic, including agents present in the human food chain, have been most frustrating, and researchers attempting these identifications have, for the most part, emerged empty-handed. Hence, the variability in cancer incidence (and resulting mortality) must be traced, in large part, to

nonmutagenic carcinogens. (The role of nonmutagenic factors is emphasized by the fact that, with the exception of cigarette smoke and UV radiation, most lifestyle factors identified in Figure 2.19 as important factors in cancer causation have no obvious mutagenic function.)

Sidebar 11.12 Limitations of GEMMs

In Sections 7.10 and 11.8 we read about the powers of transgenic mouse models of human cancer pathogenesis (often termed genetically engineered mouse models or GEMMs) to shed light on how tumors may develop in the human body. At the same time, the discussions in the present chapter reveal certain profound limitations of these models that are not readily addressed by experimentally introduced modifications of the germ-line genomes of these laboratory mammals. One obstacle to successful modeling comes from the observations, as described in Section 11.10, that far fewer introduced genes are required to transform an adult mouse cell than to transform a corresponding human cell. This indicates, on its own, that the wiring of the intracellular signaling circuitry of mice is organized in slightly different ways in mice than it is humans.

A second significant difficulty arises from the fact that certain critical determinants of cancer development are often not genotoxic processes, that is, processes creating mutant alleles, but instead nongenotoxic mechanisms, specifically those that serve to promote clonal expansions, such as those described here. In many cases, the nature of the tumor-promoting mechanisms that govern human cancer incidence remain elusive. And in many others, even when their identities are known, such mechanisms cannot be easily recapitulated in mice because of the complex differences between mouse and human physiology. For example, if chronic inflammation within a tissue represents an important tumor-promoting mechanism, it is challenging to re-create an inflamed tissue microenvironment in a mouse that accurately echoes the corresponding state in a human tissue. These considerations represent significant limitations to GEMMs that may or may not be addressed by future research.

Among known human tumor promoters, arguably the most intensively studied are those involved in breast cancer pathogenesis. Of central importance are the steroid hormones—estrogen, progesterone, and testosterone. In the female body, for example, estrogen and progesterone are involved in programming the proliferation of cells in reproductive tissues. The monthly menstrual cycles of women between menarche and menopause result in the proliferation and then regression of the cells forming the epithelia of the ducts in the mammary gland. The endometrial lining of the uterus undergoes similar cycles of proliferation and regression.

Epidemiology makes it clear that the more menstrual cycles a woman experiences in a lifetime, the proportionately higher is her risk of developing breast cancer. By one estimate, lifetime breast cancer risk decreases by 20% for each year that menarche is delayed during adolescence. [The most compelling illustration of the importance of the timing of menarche has come from studies of identical (monozygotic) twins, both of whom eventually developed breast cancer; the twin whose menarche occurred earlier had a 5.4-fold greater risk of being the first to be diagnosed with this disease.] Women who stop menstruating before age 45 have only about one-half the risk of breast cancer of those who continue to menstruate to age 55 or beyond.

Removal of the ovaries—the primary source of estrogen in the female body—causes breast cancer risk to plummet. A dramatic example comes from the results of a Dutch study, which has shown that women who enter menopause before the age of 36 due to the side effects of chemotherapy for Hodgkin's lymphoma have a 90% decreased risk of subsequently developing breast cancer. Conversely, postmenopausal women who contract breast cancer have on average a 15% higher level of circulating estrogen than unaffected women.

The effects of estrogen on breast cancer are surely complex, and it appears that this hormone acts on other cells in the mammary gland besides the epithelial cells. Still, it is evident that estrogen, and perhaps other hormones such as progesterone and even prolactin, periodically induce cell proliferation in a way that ultimately enables the progression of initiated mammary epithelial cells (MECs) into the carcinoma cells found in the

various subtypes of breast cancers. (Some have argued that metabolites of estrogen are mutagenic, and that these metabolites contribute to breast cancer development; if so, estrogen's mutagenic effects on breast cancer development are surely dwarfed by its power to promote the proliferation of MECs.)

11.13 Chronic inflammation often serves to promote tumor progression in mice and humans

Tumor promoters work in diverse ways to expedite multi-step cancer progression. They share the ability to drive the clonal expansion of initiated cells, positioning these cells to acquire additional cell-heritable changes (including mutations and shifts in epigenetic state). Their diversity derives from the various biochemical and cellular mechanisms of action that enable them to expedite tumor formation. The steroid hormones cited above may act largely as pure mitogens directly driving the proliferation of potentially neoplastic epithelial cells. More common, however, are tumor-promoting mechanisms that do not impinge directly on the progenitors of future neoplastic cells, but instead perturb the tissue microenvironment surrounding such cells.

This other class of tumor-promoting mechanisms often acts by creating various forms of inflammation, thereby assembling a supportive tissue microenvironment for the clonal expansion of initiated tumor cells. And in contrast to the steroid hormones described above, the mechanisms-of-action of these inflammatory states do indeed draw on the lessons taught by the mouse skin carcinogenesis protocols in Section 11.11. More specifically, the TPA promoter that was employed experimentally in mouse skin carcinogenesis was initially chosen because it is a potent irritant of mouse skin and thus an inducer of localized inflammation, including the recruitment of large numbers of neutrophils into promoter-treated skin. Moreover, experimental strategies that inhibit inflammation also block or significantly reduce TPA's tumor-promoting powers in the skin. Some forms of inflammation may operate chronically over extended periods of time, whereas others, being integral components of wound-healing programs, may act only transiently as tissues undertake to heal themselves following various types of damage. (Thus, wounding of the skin is at least as effective as TPA painting in promoting papilloma formation.)

Various types of experiments can be cited to reveal the key role inflammation plays in tumor promotion. As one illustrative example, when cells of a human colonic adenoma cell line were implanted subcutaneously into immunocompromised Nude mice, they were found to be non-tumorigenic. However, when they were introduced into these mice together with an attached fragment of plastic, localized stromal inflammation was induced by the plastic and the adenoma cells grew out to eventually form tumors. The tumorigenic phenotype of these cells persisted even after they were subsequently

transplanted (without the plastic) to another host animal, indicating that their neoplastic proliferation was now driven by certain cell-heritable genetic or epigenetic alterations or both. Yet other experimental strategies can illustrate this point, as described in **Supplementary Sidebar 11.12**.

Chronic localized inflammation plays a clear role in the pathogenesis of a diverse array of human carcinomas (**Table 11.3**). For example, those arising in the gallbladder are usually associated with a decades-long history of gallstones and resulting inflammation of the epithelial lining of the gallbladder (**Figure 11.34A**). Similarly, hepatocellular carcinomas (HCCs), which are common in East Asia, are associated with chronic hepatitis B virus (HBV) infections and accompanying inflammation of the liver (Figure 11.34B, left panel). In many infected individuals, HBV infection is well established in the liver early in life and continues in a chronically active form for decades. The resulting hepatitis may have relatively few outward effects on the individual, because the ongoing HBV-induced killing of hepatocytes (the cells forming the bulk of the liver) is compensated by an equal proliferation of surviving cells. Nevertheless, these chronic infections yield chronic localized inflammation incurred as the immune systems of the infected individuals attempt unsuccessfully to eliminate the virus, and the dying and dead cells killed by the virus release molecules that provoke further inflammation.

Table 11.3 Inflammatory conditions and tumor development

Human tumor	**Inflammatory condition or inflammation-provoking agent**
bladder carcinoma	schistosomiasis, chronic cystitis
gastric carcinoma	*H. pylori*–induced gastritis
hepatocellular carcinoma	hepatitis B/C virus
bronchial carcinoma	silica, cigarette smoke
mesothelioma	asbestos

Human tumor	**Inflammatory condition or inflammation-provoking agent**
ovarian carcinoma	endometriosis
colorectal carcinoma	inflammatory bowel disease
esophageal carcinoma	chronic acid reflux
papillary thyroid carcinoma	thyroiditis
prostate carcinoma	prostatitis
lung carcinoma	chronic bronchitis
gallbladder carcinoma	chronic cholecystitis

A comparison of two histology images of liver tissue, infected with chronic hepatitis B on the left and with chronic hepatitis C on the right. The two images are very similar with areas of densely packed nuclei and areas that are less dense.

(B)

Figure 11.34 Chronic inflammation leading to cancer (A) A graphic demonstration of chronic inflammation leading to cancer is provided by carcinomas of the epithelial lining of the gallbladder (*white mass, above*), which are commonly associated with the formation of gallstones arising as precipitates from the bile (*brown masses, below*). (B) Chronic hepatitis B virus (HBV) infection creates continual cell death of hepatocytes together with chronic inflammation, as indicated by the numerous lymphocytes (*small dense nuclei, left panel*). Over a period of decades, these processes can lead to an almost 100-fold increased risk of liver cancer. The inflammation in the liver of someone suffering from chronic hepatitis C virus (HCV) infection is strikingly similar (*right panel*). The inflammatory cells are largely in the right part of this micrograph. These two inflammatory conditions are similar histologically and lead to comparably increased risks of hepatocellular carcinoma (HCC), suggesting that the inflammatory states, rather than some specific aspect of viral function, are responsible for the appearance of HCC in patients infected with either of these viruses. (A, from A.T. Skarin, Atlas of Diagnostic Oncology, 4th ed. Philadelphia:

Elsevier Science Ltd., 2010. With permission from Elsevier. B, left, courtesy of A. Perez-Atayde; right, courtesy of A.K. Bhan.)

Recent research has made it clear that chronic hepatitis C virus (HCV) infections act in a similar way to increase liver cancer rates. Although the two viruses (HBV and HCV) are totally unrelated to one another with respect to genome structure and replication cycles, they evoke very similar biological outcomes through their shared ability to create chronic infections, cytotoxicity, and inflammation in the liver (see Figure 11.34B). (Significantly, a variety of other types of chronic liver injury, including that inflicted by alcoholism, are also associated with increased incidence of hepatocellular carcinoma, although the relative risks are vastly less than those associated with lifelong HBV infection.)

HBV, acting as a tumor promoter, can also function synergistically with aflatoxin-B1, a potently mutagenic compound that is made by *Aspergillus* fungi that proliferate on moldy peanuts, nuts, and corn stored under conditions of high humidity (see Figure 2.21). This combination of HBV infection plus aflatoxin exposure proves to be deadly. In one, relatively small prospective epidemiologic study carried out in Shanghai, infection with HBV increased the risk of hepatocellular carcinoma about 7-fold, whereas exposure to aflatoxin-B1–contaminated food yielded about a 3-fold increased risk. When an individual had experienced both agents, the risk of liver cancer increased about 60-fold. A less dramatic but nonetheless compelling parallel came from a 2021 study of the effects of cigarette smoking on those afflicted with inflammatory bowel disease: those who smoked had an almost 2-fold elevated risk of developing colorectal cancer, revealing once again the synergistic effects of initiators (tobacco-derived mutagens) and promoters (long-term inflammation). The parallels between the pathogenesis of these human carcinomas and the actions of initiators and promoters of mouse skin cancer are striking.

OceanofPDF.com

11.14 Inflammation-dependent tumor promotion operates through defined signaling pathways

Table 11.4 lists the diverse array of pro-inflammatory processes that favor tumor formation. The conclusions drawn from this table are reinforced by large-scale studies of populations of adults who took anti-inflammatory drugs, such as aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs) daily over multi-year periods, usually five years. Their rates of cancer development were compared in each case with the rates of cancer development anticipated in the general population as controls. One such study reported such individuals were 46% less likely to develop pancreatic carcinomas, a second reported a ∼30% reduced risk of colorectal carcinomas, and a third reported a 25% reduced risk of developing breast cancer. Two studies have shown that regular use of aspirin (or another NSAID) resulted in about a 40% reduction of stomach cancer (in the region of the stomach outside of the cardia) in individuals who were infected with *Helicobacter pylori*, a bacterium that often inhabits the human stomach; stomach cancer rates in uninfected individuals were not reduced by aspirin usage. Yet other studies indicate reduced death rates associated with ovarian, bladder, and prostate carcinomas in individuals taking daily NSAIDs, largely aspirin. (These outcomes might suggest that NSAIDs, which can also reduce deaths from certain types of cardiovascular disease, should be used routinely as disease preventatives in the general population. However, a note of caution comes from another public health statistic: in 1998, 16,550 deaths in the United States could be attributed to NSAID-induced gastrointestinal bleeding and the death rate remained at this level in the decade that followed.)

Table 11.4 Links between inflammation and cancer pathogenesis

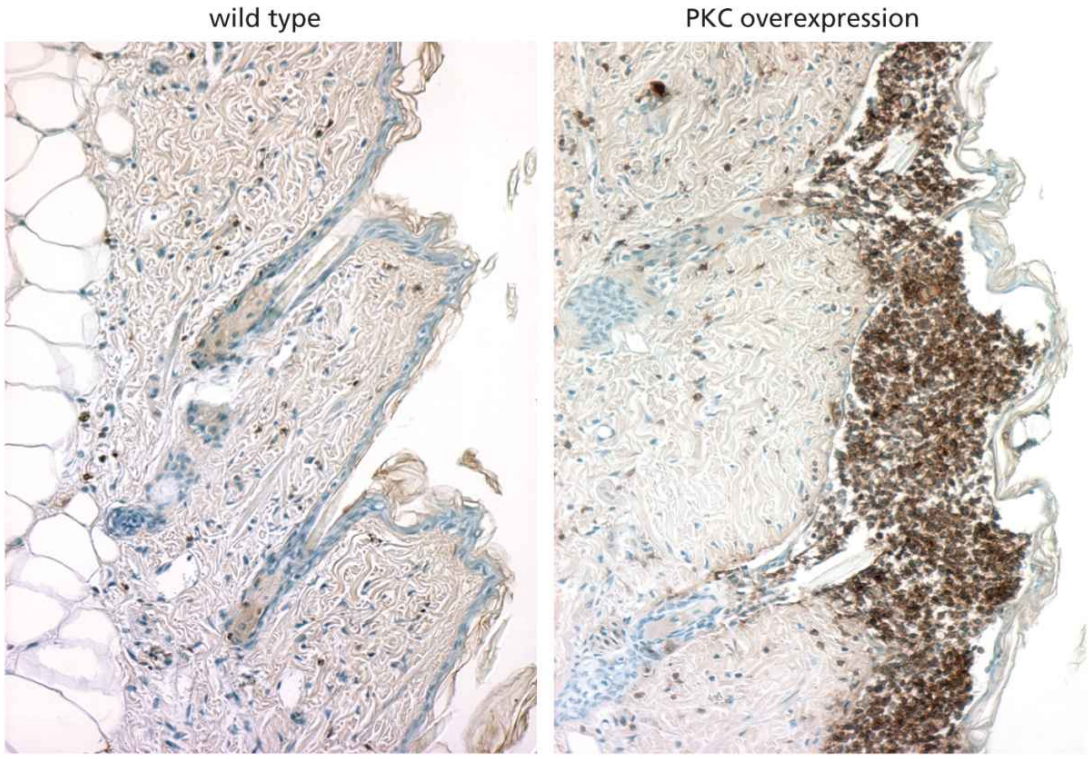
Many inflammatory conditions predispose to cancer
Cancers arise at sites of chronic inflammation
Functional polymorphisms of cytokine genes are associated with cancer susceptibility and severity

Distinct populations of inflammatory cells are detected in many cancers
Extent of tumor-associated macrophage infiltrate correlates with prognosis
Inflammatory cytokines are detected in many cancers; high levels are associated with poor prognosis
Chemokines are detected in many cancers; they are associated with inflammatory infiltrate and cell motility
Deletion of cytokines and chemokines protects against carcinogens, experimental metastases, and lymphoproliferative syndrome
Inflammatory cytokines are implicated in the action of nongenotoxic liver carcinogens
The inflammatory cytokine tumor necrosis factor is directly transforming *in vitro*
Long-term NSAID use decreases mortality from colorectal cancer

From F. Balkwill and A. Mantovani, *Lancet* 357:539–545, 2001. (With permission from Elsevier.)

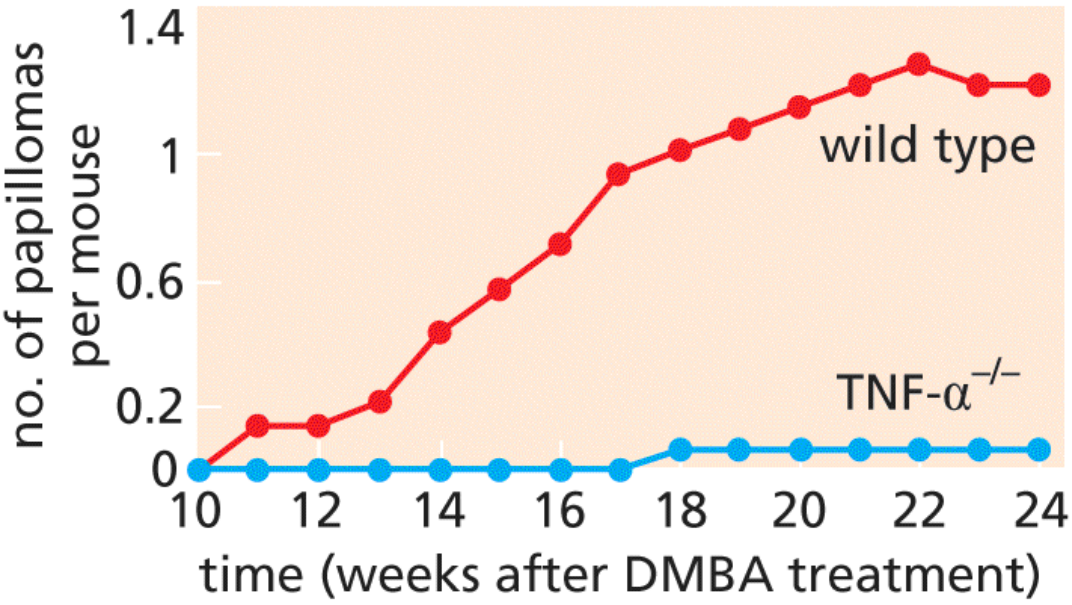
In principle, these diverse epidemiologic observations linking long-term NSAID use with reduced cancer incidence, together with the experiments in mouse skin and liver carcinogenesis, should lead us to the biochemical and cell-biological mechanisms that are responsible for tumor promotion in many tissues. Actually, at the level of signalling biochemistry, our understanding of inflammation and tumor promotion is still fragmentary. In the mouse skin carcinogenesis model, one key clue has come from the identification model of the downstream cellular target of TPA—protein kinase C-α (PKC-α, see Sidebar 11.11). A dramatic functional demonstration of the central role of this enzyme in mediating TPA-induced skin inflammation is provided by mouse skin keratinocytes that are forced to overexpress it: exposure of the genetically altered skin

to TPA results in an inundation of neutrophils in the exposed tissue, these being cells that function as prime instigators of inflammation (**Figure 11.35A**).



A comparison of two histology images of mouse skin tissue. The image on the left is wild type tissue. The image on the right, shows P K C overexpression. Unlike the one on the left, features a thick surface layer of dark cells that look like caraway seeds.

(A)



A line graph with number of papillomas per mouse on the vertical axis and time on the horizontal axis. Wild mice start at zero and climb steadily to about 1.2 papillomas per mouse 22 weeks after D M B A treatment. Homozygous T N F alpha negative mice remain at a very low level, no more than 0.1 papillomas per mouse even 24 weeks after D M B A treatment.

(B)

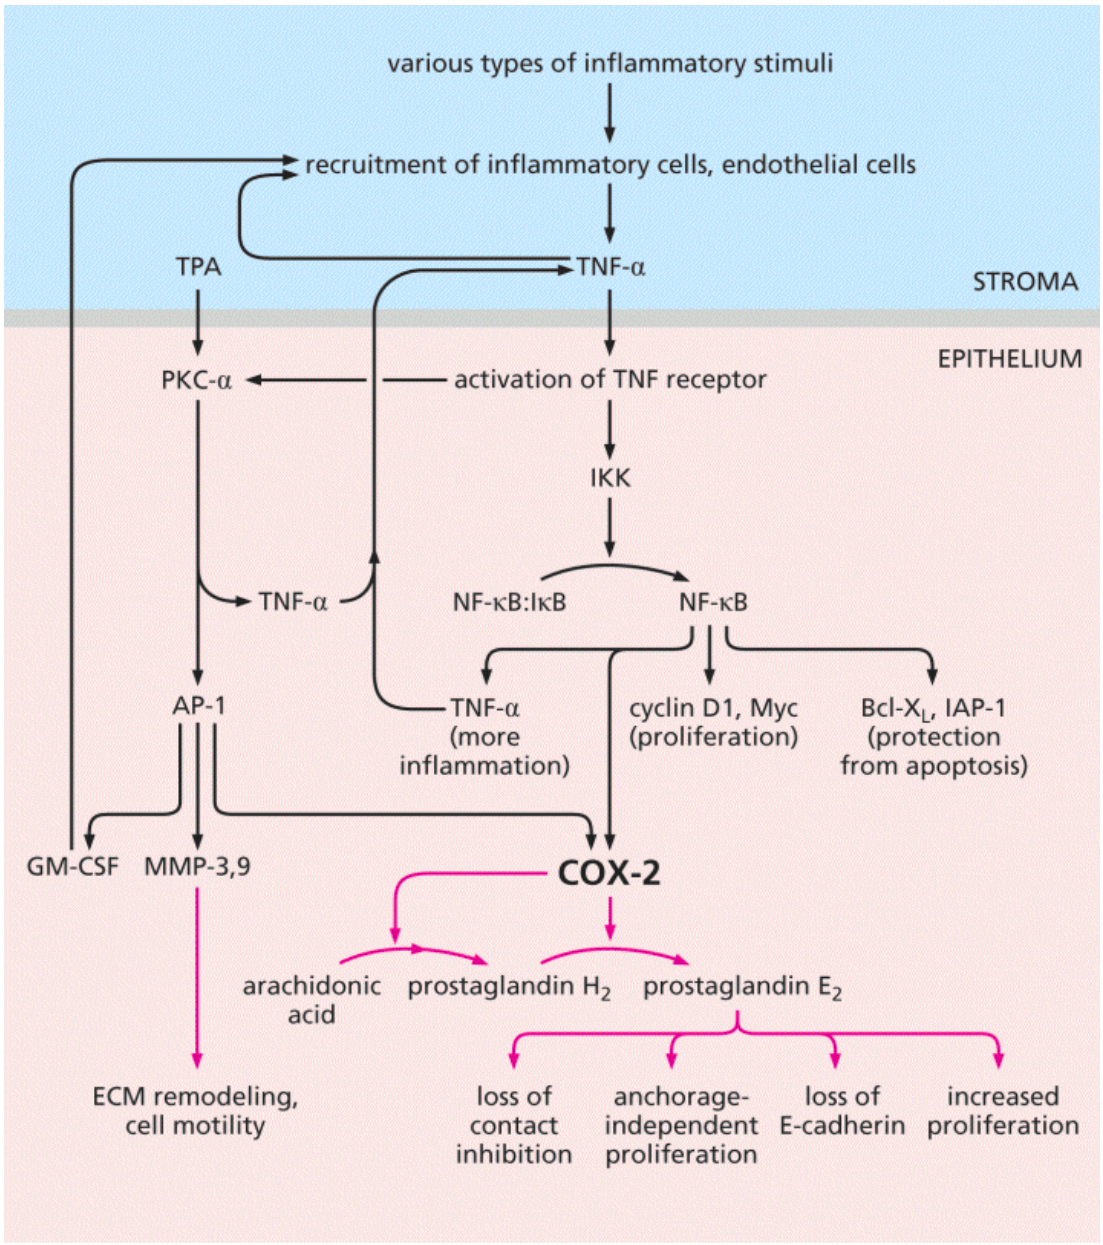
Figure 11.35 Critical regulators of mouse skin induction (A) TPA acts through an intracellular serine/threonine kinase–protein kinase C-α (PKC-α). The inflammatory powers of TPA are revealed in exaggerated form in transgenic mice that overexpress this kinase in their keratinocytes. (This genotype is achieved by constructing a transgene in which PKC-α expression is driven by a keratin 5 transcriptional promoter, which is active specifically in the skin.) Eighteen hours after wild-type or transgenic mice have been treated with TPA, the skin of wild-type mice (*left*) shows relatively few neutrophils (*dark spots*), which are important immune mediators of inflammation. In contrast, the skin of the transgenic mice (*right*) shows extensive neutrophil infiltration. Neutrophils were detected through use of an antibody that recognizes a neutrophil-specific antigen. (B) Tumor necrosis factor-α (TNF-α), which is made in both epithelial and stromal cells of the mouse, is a critical mediator of the TPA-initiated inflammatory response. In mice in which both copies of the gene encoding TNF-α have been deleted in the germ line (and thus deleted from the genomes of all cells), the usually observed induction of skin papillomas—the precursors of skin carcinomas—is almost totally lost. In this experiment, mouse skin was painted once with the DMBA initiator and thereafter at twice-weekly intervals with TPA for the next 15 weeks.

(A, from C. Cataisson et al., *J. Immunol.* 171:2703–2713, 2003. With permission from American Association of Immunologists. B, from R.J. Moore et al., *Nature Med.* 5:828–831, 1999. With permission from Nature.)

TNF-α is a critical mediator of TPA-induced inflammation; thus, TPA-exposed keratinocytes in the mouse skin release this protein, which serves in turn to recruit a variety of pro-inflammatory immune cells to the site of treatment. Mice lacking functional copies of the TNF-α gene respond to a skin carcinogenesis protocol (involving, as before, the DMBA initiator and the TPA promoter) by developing 5 to 10% as many skin carcinomas as wild-type mice (see Figure 11.35B). In the latter animals, TPA treatment elicited TNF-α production in the epidermal keratinocytes, which then induced inflammation in the underlying stromal cells of the dermis. Together, these various observations suggest the following pathway:

TPA → PKC-α→ → IKK → IκB → NF-κB → TNF-α→ inflammation

None of this explains how NSAIDs, such as aspirin, ibuprofen, and sulindac, succeed in blocking tumor promotion and thus tumor progression, including these processes occurring in the *Mdr*$^{-/-}$ mouse model of liver carcinogenesis (**Supplementary Sidebar 11.13**). These drugs and yet other NSAIDs have as their common target the enzyme cyclooxygenase-2 (COX-2; **Figure 11.36**), which is responsible for the biosynthesis of prostaglandin E_2 (PGE_2), a potent low–molecular-weight pro-inflammatory molecule. Actually, the *Cox-2* gene is yet another gene that is strongly induced by TNF-α. Indeed, many of the pro-inflammatory effects of TNF-α enumerated above depend on its ability to induce COX-2 expression and, in turn, strong increases in PGE_2 production. **Supplementary Sidebar 11.14** describes multiple lines of evidence supporting the scheme depicted in Figure 11.36.



A model of epithelial inflammation and tumor promotion. In the stroma, various types of inflammatory stimuli promote the recruitment of inflammatory cells and endothelial cells. These release T N F alpha, which activates the T N F receptor, initiating a cascade within the epithelium that results in E C M remodeling, cell motility, loss of contact inhibition, anchorage-independent proliferation, loss of E-cadherin, and increased proliferation. T N F alpha plays a role at multiple points.

Figure 11.36 A model of epithelial inflammation and tumor promotion The information from skin and liver tumor promotion, as illustrated in Figures 11.32 and 11.34B, can be integrated into a more general model. Inflammatory stimuli, including chronic viral infections, organ injury, irritants (e.g., tobacco smoke), cell

necrosis, and senescence, result in recruitment of a variety of inflammatory cells into areas of inflammation. These cells, as well as endothelial cells in the vicinity, release TNF-α (a key actor in multiple types of tumor promotion) and various cytokines that together activate the NF-κ B pathway in epithelial cells. This activation results in the production of more TNF-α, anti-apoptotic proteins (e.g., Bcl-X_L, IAP-1, and IAP-2), and mitogenic proteins (Myc, cyclin D1), as well as COX-2. Prostaglandins synthesized by COX-2 (*pink arrows*) induce multiple cancer cell phenotypes, including loss of contact inhibition, increased proliferation rate, and anchorage-independent growth. The TPA skin tumor promoter (*left*) converges on this pathway through the activation of PKC-α; in addition, TPA-activated PKC-α can induce mitogenic signals by activating the Fos, Jun, and thus AP-1 transcription factors (see Section 6.5). Not illustrated here is the production of prostaglandin E_2 by a variety of stromal cells. Together, these actions of inflammatory cells and of TPA create phenotypic states in epithelial cells that closely resemble those induced by many oncoproteins, enabling initiated cells to launch clonal expansions that eventually result in the acquisition of additional mutant alleles by their descendants.

Taken together, these diverse observations suggest that in initiated cells (e.g., Figure 11.30), tumor-promoting mechanisms can collaborate with an already-acquired, activated oncogene in a way that resembles the collaboration between two oncogenes (see Section 11.8). Thus, initiated tumor cells may rely on this form of collaboration until their descendants eventually acquire additional oncogenes and therefore no longer depend on the readily reversible effects of tumor promoters for their continued proliferation and survival. Finally, it seems increasingly likely that the diverse mechanisms of tumor promotion share in common the ability to activate tissue wound-healing programs that are hardwired in the regulatory circuitry of individual cells, much like the actions of certain oncogenes. Because transient inflammation is an intrinsic component of these programs, this focuses further attention on various pro-inflammatory mechanisms as critical components of human tumor formation.

A wide variety of agents have, by now, been classified as human tumor promoters (**Table 11.5**). All are presumably able to promote expansion of initiated clones. Some carcinogenic agents, such as the benzo[*a*]pyrene (BP) described earlier, when applied to laboratory animals as single agents, are able on their own to induce tumor formation after repeated applications. They thereby appear to function as both initiators and promoters of tumorigenesis and consequently have been called complete carcinogens. We can imagine, for example, that certain mutagenic agents are also cytotoxic at high concentrations and thus able to act as tumor promoters by killing cells, thereby inducing the compensatory proliferation of surviving cells in a target tissue. However, such agents are likely to play minor roles in human carcinogenesis. Most genotoxic

carcinogens enter into human tissues at concentrations that are far too low to evoke cytotoxic effects. Hence, the tumors incited by these agents seem to depend heavily for their formation on other substances that function as pure tumor promoters.

Table 11.5 Known or suspected human tumor promoters and their sites of action

Agent or process	**Cancer site**
Hormones	
Estrogen	endometrium
Estrogen and progesterone	breast
Ovulation	ovary
Testosterone	prostate
Drugs	
Oral contraceptives, anabolic steroids	liver
Analgesics	renal pelvis
Diuretics	kidney
Infectious agents	
Hepatitis B/C viruses	liver
Schistosoma haematobium—blood fluke	bladder

Agent or process	**Cancer site**
Schistosoma japonicum—blood fluke	colon
Clonorchis sinensis—liver fluke	biliary tract
Helicobacter pylori—bacterium	stomach
Malarial parasites	B cell
Tuberculosis bacillus	lung
Chemical agents	
Betel nut, lime	oral cavity
Chewing tobacco	oral cavity
Bile	small intestine
Salt	stomach
Acid reflux	esophagus
Physical or mechanical trauma	
Asbestos	mesothelium, lung
Gallstones	gallbladder

Agent or process	Cancer site
Coarsely ground corn	stomach
Head injury	meninges
Chronic irritation or inflammation	
Tropical ulcers[a]	skin
Chronic ulcerative colitis	colon
Chronic cystitis	bladder
Chronic pancreatitis	pancreas

The recognition that tumor promotion plays a major role in human cancer incidence has major implications for identifying human carcinogens. To begin, there are no laboratory tests comparable to the Ames test that can readily detect tumor-promoting mechanisms and quantify the potency of these mechanisms in order to assess their contributions to human cancer burden. Even the use of mouse models of disease offers little insight, because most mechanisms of tumor promotion differ dramatically between mice and humans as a consequence of diverged metabolisms and physiologies (see Sidebar 11.12). On the rare occasions when tumor-promoting actions can be identified through use of laboratory mice, it has become clear that it is difficult to generate dose-response curves that are translatable into actual disease-causing potential. Thus, although the Ames test has revealed a largely linear relationship between the dose of a mutagenic chemical and the risk of disease, there is no reason to believe that such linearity governs the behavior of tumor-promoting mechanisms, where threshold effects are likely to operate, resulting biological effects above a certain concentration or dose but essentially no effects at concentrations/doses 10- or

100-fold lower. Accordingly, agents or exposures that evoke clear biological responses in laboratory mice when applied at high concentrations to these animals may well have no significant biological responses at the vastly lower concentrations to which humans are routinely exposed.

These difficulties have had profound implications for the risk assessments of various agents to which humans are routinely exposed, and have led to the banning of certain substances that are highly unlikely to ever have contributed to the formation of even a single human tumor. These difficulties have left only one strategy that is likely to generate useful risk assessments of human exposures: epidemiological studies that correlate disease incidence with estimated exposure, the latter often extending over decades of time.

11.15 Metabolism is the elusive heart of the cancer process

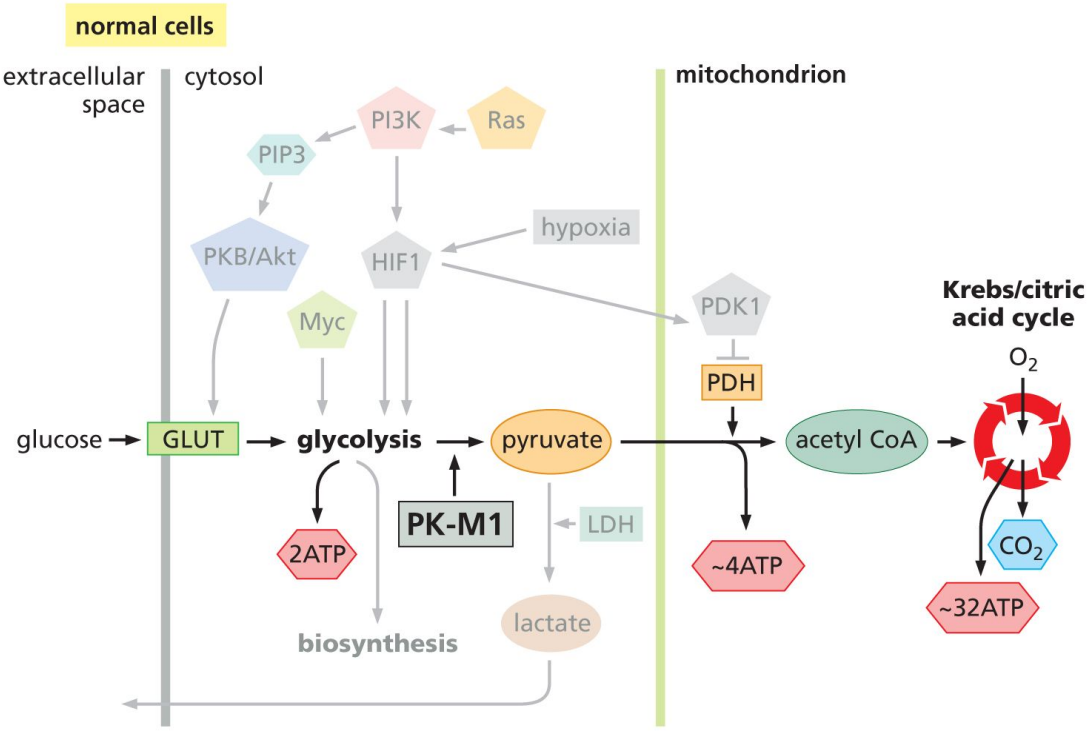
Throughout this chapter we encountered the various steps through which normal cells pass en route from normalcy to full-fledged neoplasia, acquiring a series of cell-biological phenotypes along the way. There is, in addition, one aspect of the neoplastic cell phenotype that threads its way through all of these stages and affects them in myriad ways. Only now do we confront this common thread: cancer cells exhibit altered metabolism from the earliest to the last stages of multi-step tumor progression. Indeed, as these cells evolve progressively toward high-grade neoplasia, their internal biochemistry—involving both energy metabolism and the intermediary metabolism of biosynthesis—shifts in concert.

Here, we encounter a fundamental ambiguity that has dogged the field of cancer metabolism research since its inception. Do changes in metabolism represent a fundamental, intrinsic component of the neoplastic cell state that drives cancer cell behavior or, alternatively, is the altered metabolism of cancer cells simply one of the myriad downstream consequences of the neoplastic state? Given the pleiotropic consequences of cell transformation, are these well-documented metabolic shifts, as described below, *causes* or *consequences* of the growth state of cancer cells?

In fact, the peculiarity of tumor cell biochemistry was already appreciated a century ago: the energy metabolism of most cancer cells differs markedly from that of normal cells, as first reported in 1924 by Otto Warburg, who was later honored with a Nobel Prize for discovering the respiratory enzyme now known as cytochrome *c* oxidase. By then, it was already apparent that in the absence of adequate oxygen (hypoxia), mammalian cells would resort to glycolysis in contrast to the process that we now term oxidative phosphorylation, which operates during normoxic conditions. Glycolysis occurs in the cytosol, whereas oxidative phosphorylation is confined to the mitochondria.

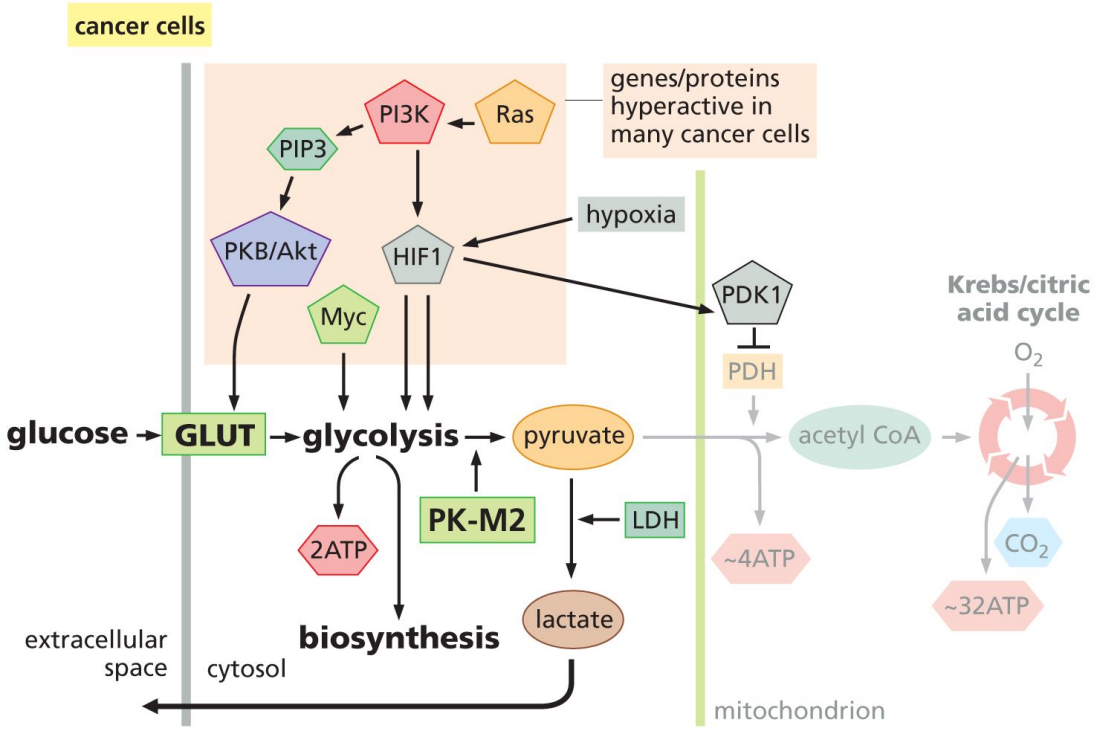
As was more thoroughly documented in the decades that followed, normal cells that experience aerobic, normoxic conditions break down glucose into pyruvate in the cytosol through the process of glycolysis and then dispatch the pyruvate into mitochondria, where it is broken down further into carbon dioxide in the tricarboxylic acid (TCA) cycle (also known as the Krebs cycle and the citric acid cycle; **Figure 11.37**). Under anaerobic or hypoxic (low oxygen tension) conditions, however, normal cells are limited to using only glycolysis, generating pyruvate that is reduced to lactate, which is then secreted from cells. Warburg discovered that even when exposed to

ample oxygen, many types of cancer cells appeared to rely largely on glycolysis, generating lactate as the breakdown product of glucose (Figure 11.37) and secreting it into the extracellular space.



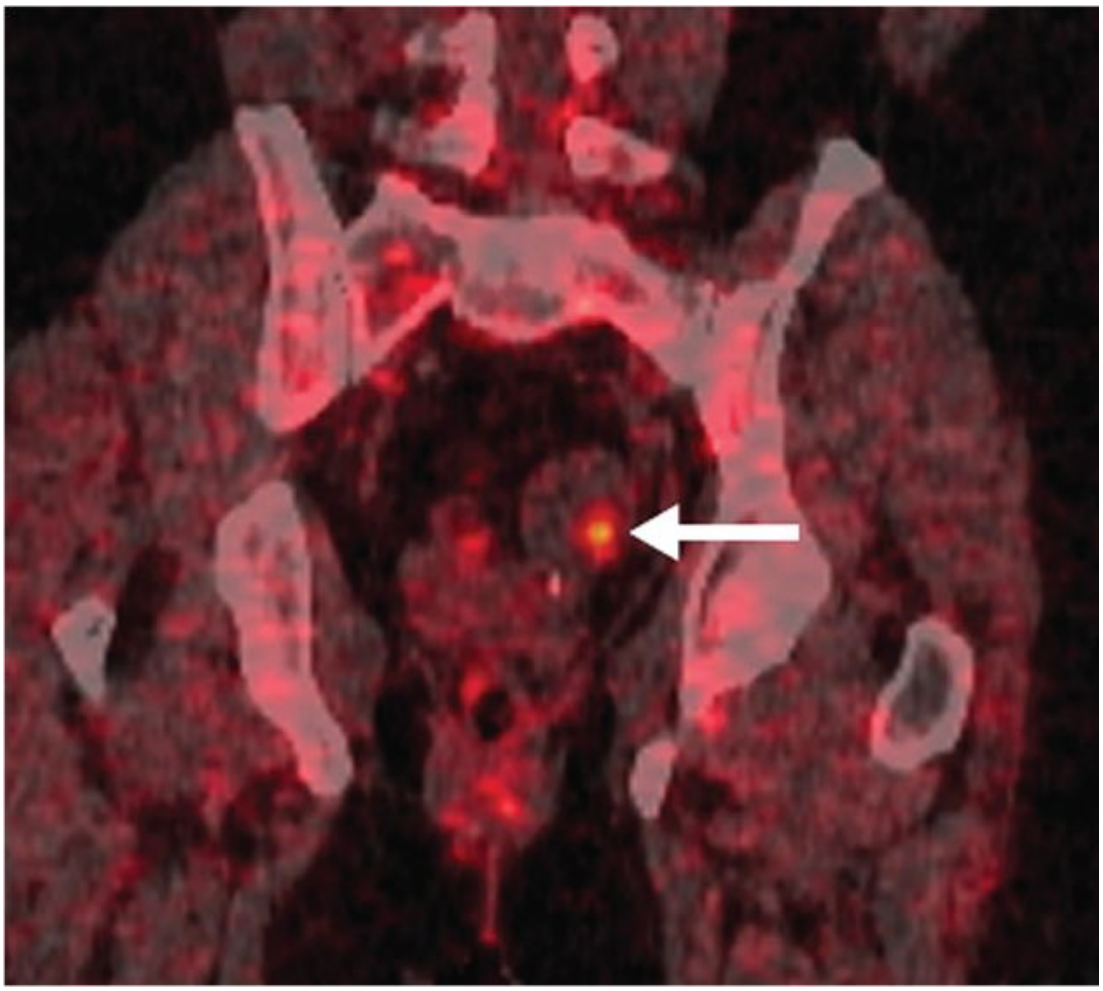
A diagram shows that in normal cells, glucose entering the cytosol undergoes glycolysis and 2 A T P are released. In the last step, P K M 1 produces pyruvate that enters the mitochondria. P D H converts it to acetyl Co A which generates about 4 A T P. Acetyl Co A enters the Krebs or citric acid cycle and there generates approximately 32 A T pees.

(A)



A diagram shows that in cancer cells, glucose entering the cytosol undergoes glycolysis, but in the last step, P K M 2 produces pyruvate that is converted into lactate, which ultimately is ejected from the cell.

(B)



A tomography image of internal that is mostly red but contains a few bright orange spots. The largest of these has a white arrow pointing to it and is located in the center between two bones.

(C)

Figure 11.37 Deregulation of energy metabolism during the course of neoplastic transformation (A) In most normal nonproliferating cells having access to adequate oxygen, glucose is imported into the cells by glucose transporters (GLUTs) and then broken down by glycolysis and the citric acid cycle. During the last step of glycolysis, pyruvate kinase form M1 (PK-M1) ensures that its product, pyruvate, is imported into the mitochondria, where it is oxidized by pyruvate dehydrogenase (PDH) into acetyl CoA for processing in the citric acid cycle. Altogether, the mitochondria can generate as much as 36 ATP molecules per glucose molecule. (B) In cancer cells, including those with access to ample oxygen, the GLUT glucose transporters import large amounts of glucose into the cytosol, where it is processed by glycolysis. However, as the last step of

glycolysis, pyruvate kinase M2 (PK-M2) causes its pyruvate product to be diverted to lactate dehydrogenase (LDH-A), yielding the lactate that is secreted in abundance by cancer cells. Because relatively little of the initially imported glucose is metabolized by the mitochondria, as few as 2 ATPs are generated per glucose molecule. Moreover, many of the intermediates generated during glycolysis are diverted toward biosynthetic uses. This mode of metabolic regulation resembles the metabolic state of normal, rapidly dividing cells, which also divert a significant portion of their glycolytic intermediates to biosynthetic pathways. Enzymes are in rectangles, glucose metabolites are in ovals, low–molecular-weight compounds are in hexagons, regulatory proteins are in pentagons. (C) 2-Deoxy-2-(^{18}F)fluoro-D-glucose positron-emission tomography (FGD-PET) makes it possible to visualize tumors in the body that have concentrated large amounts of glucose because of the hyperactivity of the GLUT1 transporter in the associated cancer cells. In the case shown here, FDG-PET revealed a small tumor (bright orange; arrow) in the region near an ovary of a woman who was under treatment for breast cancer but was otherwise without symptoms. X-ray-computed tomography (CT) was used at the same time to image the outlines of the tissues of this patient. This highly sensitive technology provided the first indication of an incipient ovarian cancer in this patient. (C, from R.A. Milam, M.R. Milam and R.B. Iyer, *J. Clin. Oncol*. 25:5657–5658, 2007. With permission from Wolters Kluwer.)

The use by cancer cells of "aerobic glycolysis," as Warburg called it, would seem to make little sense energetically, because the breakdown of one molecule of glucose yields only two molecules of ATP through glycolysis. In contrast, when under aerobic conditions glycolysis is followed by oxidation of pyruvate in the citric acid cycle, which allows 33 to 36 ATPs to be harvested from the breakdown products of a single glucose molecule. Actually, most types of normal cells in the body have continuous access to O_2 conveyed by the blood and therefore metabolize glucose through this energetically far more efficient route. The tendency of cancer cells to apparently limit themselves largely to glycolysis, even when provided with adequate oxygen, stood out as exceedingly unusual behavior.

In the 1950s, Warburg proposed that this altered energy metabolism was the central driving force in the formation of cancer cells, a notion that was discredited in the decades that followed, as described repeatedly in the preceding chapters of this book. Nonetheless, the process of aerobic glycolysis that he uncovered has stood the test of time, being found to operate in a wide variety of human cancer cells. Indeed, it is now thought to represent one of the many characteristics directly associated with cell transformation.

This aerobic glycolysis, sometimes called the Warburg effect, remains a subject of much contention, as its rationale in cancer cell biology has never been fully resolved: Why do as many as 80% of cancer cells metabolize most of their glucose via glycolysis when completion of glucose degradation in mitochondria by the citric acid cycle would afford them vastly more ATP to fuel their own growth and proliferation? Is aerobic glycolysis required for maintenance of the cancer cell phenotype, or does it represent nothing more than a side effect of cell transformation that plays no causal role in cell transformation and tumor growth? At least one more of Warburg's claims was refuted in recent decades: he claimed that the Krebs/TCA cycle (which we now know operates within the mitochondria) was essentially shut down in cancer cells experiencing normoxia, but this turned out not to be the case. Although glycolysis is clearly a dominant metabolic force in many types of cancer cells, the mitochondria and their Krebs/TCA cycles function quite well in most types of cancer cells.

One explanation of aerobic glycolysis comes from the observation that the cancer cells within a tumor often have inadequate access to oxygen, as we will discuss in detail in Chapter 13. The resulting hypoxic state limits cancer cells to glycolysis and thus to inefficient ATP production—just as normal cells would be limited under these conditions. Because of the Warburg effect, cancer cells would seem to be well adapted to this oxygen starvation, because glycolysis operates normally under hypoxic conditions. Still, this fails to explain why cancer cells, even when provided with abundant oxygen, do not take advantage of this oxygen to generate ATP in far larger quantities but instead continue to funnel much of their glucose through glycolysis without dispatching the end products of glycolysis into the mitochondria, as would occur in normal cells operating under normoxic conditions.

Many cancer cells also exhibit a second, associated abnormality: they import an enormous amount of glucose from the extracellular space. This behavior is observed in many types of cancer cells, including both carcinomas and hematopoietic tumors; they express greatly elevated levels of glucose transporters, particularly GLUT1, which span the plasma membrane and drive the high rates of glucose uptake by these cells. High levels of GLUT1 gene expression have been found to be driven by now-familiar oncogenes, notably *myc*, *ras*, and *src*, as well as the hypoxia-inducible HIF-1α transcription factor. Radiologists take advantage of this elevated glucose uptake by injecting into the circulation radiolabeled glucose [2-deoxy-2-(^{18}F)fluoro-D-glucose, FDG] and observing its rapid concentration in tumors through positron emission tomography (PET; see Figure 11.37). The import of large amounts of glucose by the GLUT1 and other transporter proteins offers cancer cells one clear biological advantage when they are residing within tumors. While glucose is present in abundance in tissue culture media, it is scarce in tissues throughout the body's normal tissues. This scarcity imposes a major constraint on the proliferation of many normal cell types that cancer cells can, however, overcome through their ongoing efficient

importation of large amounts of this carbohydrate. Thus, many types of oncogene-transformed cell enjoy only a minimal growth advantage (relative to normal cells) *in vitro*; only when such transformed cells are growing *in vivo* as components of tumors does their growth advantage, specifically the advantage afforded by their expression and utilization of GLUT1, become apparent.

One compelling rationale for the use of aerobic glycolysis derives from the fact that glycolysis actually serves a second role independent of ATP generation: the intermediates in the glycolytic pathway function as precursors of many molecules involved in cell growth, including the biosynthesis of nucleotides and lipids. By blocking the last step of glycolysis, cancer cells ensure the accumulation of earlier intermediates via feedback reactions in this pathway. These glycolytic intermediates can then be diverted into critically important biosynthetic reactions, such as those leading to the formation of macromolecules and lipids whose high-level production is clearly central to successful rapid cell proliferation. This behavior contrasts with that of normal cells, which are generally not actively proliferating, do not require large-scale biosynthetic reactions, and depend largely on ATP to sustain their metabolic activity. (By some estimates, normal cells use more than 30% of their imported glucose to make ATP, whereas cancer cells use only ∼1% of their glucose for this purpose—a striking contrast in metabolic organization.)

A complete rationale for why cancer cells use aerobic glycolysis is still not in hand. However, independent of how this question is resolved, there is yet another: how do cancer cells actually manage to avoid mitochondrial processing of glucose metabolites? Pyruvate kinase (PK) catalyzes the last step of glycolysis—the conversion of phosphoenolpyruvate to pyruvate. As noted above, this end product of glycolysis is normally destined for import into the mitochondria, where it is broken down in the citric acid cycle (see Figure 11.37). The M1 isoform of PK typically is expressed in most differentiated adult tissues, whereas the M2 isoform is expressed by early embryonic cells, rapidly growing normal cells, and cancer cells. For reasons that are still poorly understood mechanistically, the commonly expressed M1 isoform of PK ensures that its product, pyruvate, is dispatched from the cytosol directly into the mitochondria, whereas the M2 isoform that is expressed instead in cancer cells causes its pyruvate product to be diverted away from the mitochondria, reduced to lactate in the cytosol, and ultimately secreted. Of interest to cancer cell biology, the M2 isoform of PK that predominates in cancer cells can interact physically with proteins containing phosphotyrosine residues that are abundant in cancer cells (see Sections 5.2 to 5.6). This interaction causes a shutdown of the catalytic activity of this PK, resulting in turn in the accumulation of glycolytic intermediates that are then diverted into various biosynthetic pathways, the latter being termed anabolic reactions. Relative to the M1 form of PK, the M2 enzyme has a very slow turnover number, which contributes to the backup of glycolytic intermediates and their diversion into biosynthetic pathways. Also, the low catalytic activity of the M2 isoform of PK favors

the formation of lactate rather than pyruvate, explaining the high levels of lactate secretion by cancer cells.

Experimental evidence indicates that the growth of tumors actually depends on the expression of the M2 form of PK and on the elevated expression of both the glucose importer GLUT1 and lactate dehydrogenase-A (LDH-A) enzyme, the latter being involved in reducing pyruvate to lactate, which is then secreted (see Figure 11.37B). When any one of these is inhibited, tumor growth slows down, sometimes dramatically. Observations like these provide the first indications that the unusual glucose metabolism of cancer cells creates a physiological state on which cancer cell growth and proliferation depend.

We should also note one other characteristic of cancer cell metabolism—the important role of glutamine. It serves as a critical source of nitrogen for various types of cells and a precursor of the nitrogenous bases that form both RNA and DNA. Moreover, once deamidated, the resulting glutamate molecules are then employed in the biosynthesis of various other amino acids. In fact, glutamine is considered a "nonessential amino acid," because normal cells are perfectly capable of synthesizing it on their own (rather than depending absolutely on the import of this amino acid from various nutrient sources). It turns out, however, that import of large amounts of glutamine from extracellular sources is critically important to the proliferation of normal cells and, even more so, neoplastic cells. This requirement for large amounts of imported glutamine is far more than might be predicted from the use of this amino acid in assembling proteins. This peculiarity already featured in the formulation of tissue culture media more than half a century ago, where high concentrations of glutamine in the media were found to be critical to the robust proliferation of both normal and neoplastic cells *in vitro*.

To conclude, it is important to emphasize that the expression of the Warburg-like, aerobic glycolysis is not an invention of neoplastic cells, as was thought at one point. Instead, it is very clear that highly proliferative normal cells also exhibit the complex metabolic shifts described above that have been associated with cancer cells. From the perspective of signal transduction biochemistry, this similarity makes sense, because exposure of normal cells to various mitogenic growth factors (as described in Chapter 5) triggers dramatic increases in the import of glucose via the GLUT1 transporter as well as a number of the changes in glycolysis that are also associated with cancer cell metabolism.

11.16 Synopsis and prospects

This chapter returns time and again to the theme that the development (that is, the pathogenesis) of a human tumor is a process involving a succession of distinct steps occurring one after the other, each making cells progressively more aggressive. The end product of this succession is a human cell that is altered in multiple distinct ways that together constitute the phenotype of a neoplastic cell. This phenotype is created by deregulation of multiple cellular control systems, including deregulation of cell proliferation, evasion of anti-proliferative signals, the ability to escape detection and elimination by the immune system, a heightened resistance to cell-death programs such as apoptosis, shifts in glucose metabolism, and an ability to multiply without any limits to the number of successive cell generations—the last trait representing the state of immortalization.

The complexity of this process is a direct reflection of the development of multiple anti-neoplastic mechanisms that have been hardwired into the circuitry of our cells and tissues. Many of these mechanisms were developed as our small, short-lived mammalian ancestors evolved progressively over the course of 100 million years into the long-lived, large organisms that we have become. In our own species, such evolution created organisms that experience 10^{16} cell divisions in a lifetime, each of which represents an opportunity for genetic and epigenetic disasters, notably mutations and disruption of normal differentiation programs. This greatly increased risk of biological chaos necessitated the co-evolution of anti-neoplastic mechanisms at both the cellular and organismic level, that is, the erection of multiple concentric lines of defense against cancer. These multiple barriers represent the foundation of the present chapter, because the completion of each of the steps of multi-step tumor pathogenesis reflects the successful breaching of one or another of these multiple anti-neoplastic barriers.

As argued here, each of these steps of multi-step progression involves the clonal expansion of the descendants of a cell that has acquired one or another advantageous phenotype, doing so as a direct consequence of a somatic mutation or a cell-heritable shift in epigenetic state. According to this model, each of these clonal expansions continues until one or another cell in the now-expanded population acquires yet another heritable shift in phenotype that renders this particular cell even more capable of surviving and proliferating than its neighbors in the expanded clonal cell population (see Figure 11.14).

Ideally, this scheme of a succession of multiple clonal expansions should yield a logical framework with which to understand the complexity of human cancer pathogenesis. However, this framework, as compelling as it might be, still does not allow us to truly understand the daunting complexity of human cancer pathogenesis. The scope of this problem is illustrated by the recently expanded powers of genomic sequencing, which have generated a bewildering array of germ-line mutations and somatically mutated human genes. The largest repository of this information, named COSMIC, reported in 2020 that mutant alleles of more than 1% of the genes in the human genome (and therefore more than 200 genes) have been implicated in various ways in cancer causation. More than 90% of these are involved via somatic mutations and 20% are borne as mutant cancer-predisposing genes in the germ line, with half of the latter being involved via both genetic mechanisms of cancer causation. Importantly, these genomic analyses do not even include the considerable contributions of epigenetic alterations to the acquired phenotypes of human cancer cells; recall that such nongenetic controls may even be responsible for display of the *majority* of the distinct phenotypes of cancer cells.

Given the possible combinatorial interactions of these various mutant genes (beyond calculation), the various distinct differentiated cell types involved (far more than 200), and the participation of a multitude of epigenetic programs in driving tumor progression forward (a number entirely unknown), how can we possibly distill these various factors into a simple, accessible, and compelling depiction of how human cancers are formed?

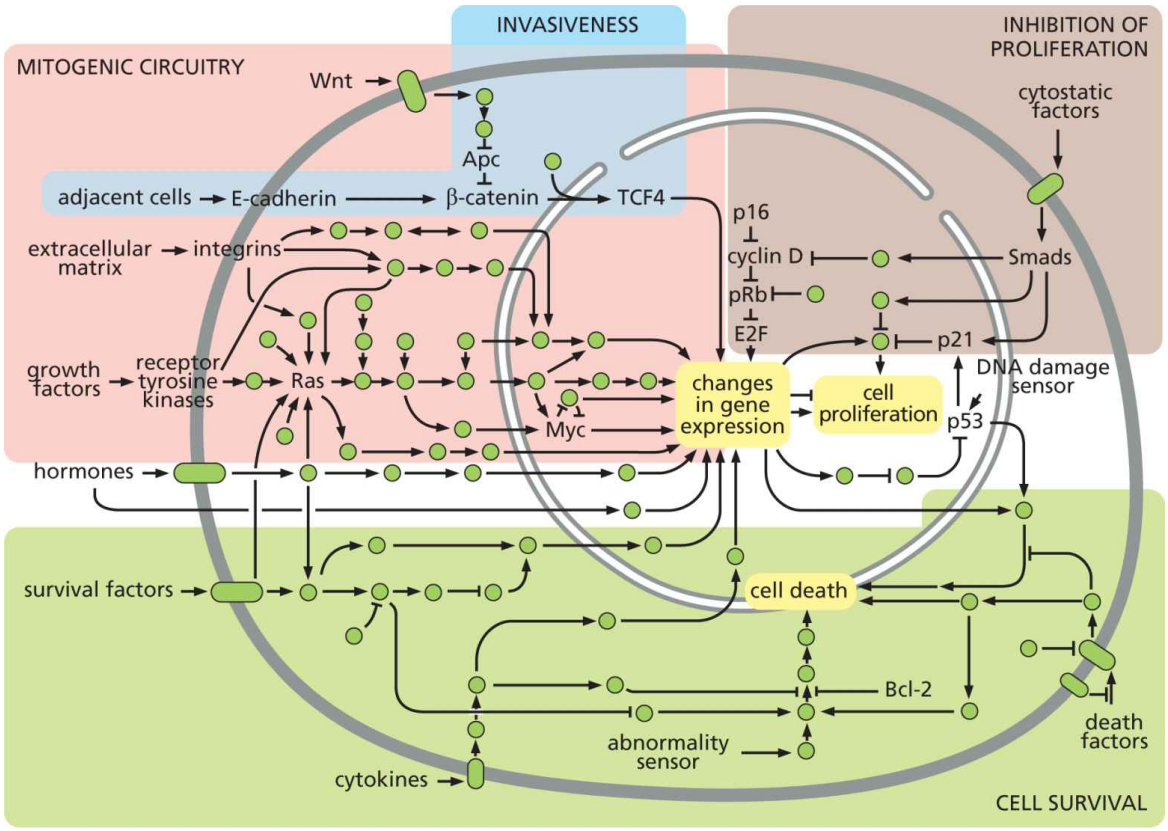
In fact, in this chapter we have come across two approaches to begin to address this seemingly intractable problem. In the first, the experimental transformation of human cells through various introduced genes suggests the operations of a limited number of intracellular signaling circuits that must be perturbed in order for a fully normal human cell to grow as a malignant cell; four to five such pathways appear to be critical, at least in the cells of human solid tumors (see Figure 11.28). An entirely different approach is to define instead a limited number of cell-biological *phenotypes* that are commonly shared by a diverse array of human cancer cell types; such phenotypes have been termed “cancer hallmarks” and help us to understand cancer cell biology in terms of cell physiology (**Sidebar 11.13**).

Sidebar 11.13 Cancer hallmarks—the distinguishable phenotypes of cancer cells

Attempts at enumerating the cell-biological traits shared in common by a diverse array of human cancer cell types has yielded a relatively short list of cellular phenotypes, most having been long-recognized. These are: (1) a reduced dependence on exogenous mitogenic growth factors (see Chapters 5 and 6); (2) an acquired resistance to proliferation-inhibitory signals, such as those conveyed by TGF-β (see Chapter 8); (3) the ability to multiply indefinitely, that is, immortalized cell proliferation (see Chapter 10); (4) a reduced susceptibility to apoptosis (see Chapter 9); (5) the ability to generate new blood vessels—angiogenesis (see Chapter 13); (6) the acquisition of invasiveness and metastatic ability (see Chapter 14); and a seventh whose universality remains less well documented but increasingly seems to be observed among human solid tumors: (7) the ability to evade elimination by the immune system (see Chapters 15 and 16). In addition, (8) the role of aerobic glycolysis, as described in Section 11.15 increasingly seems intrinsic to the pathogenesis of many types of cancer.

Beyond these, two other processes have been cited that, although not intrinsic to the biology of cancer cells themselves, are nevertheless important for the *acquisition* of the eight hallmark phenotypes. Thus, our discussion of clonal evolution and succession concluded that in order for these events to occur at reasonable frequency, mutation rates within evolving pre-neoplastic cell populations must be abnormally high (as described in the next chapter). In the absence of such increased mutability, clonal populations of these cells may not have sufficient time to accumulate the multiple genetic alterations that are required in aggregate for cancer formation. Yet another enabling process featured prominently in this chapter: inflammation increasingly seems to play a role in creating tissue microenvironments that are favorable for tumor promotion, which accelerates the completion of individual steps multi-step tumorigenesis, allowing the process as a whole to reach completion in a human life span.

In principle, these two very different ways to approach cancer cell biology may one day be interconnected, specifically by assigning distinct cancer cell traits to “subcircuits” of the type that are depicted in **Figure 11.38**. If so, perhaps we will be able to portray tumor progression as the progressive deregulation of a number of distinct subcircuits within the cell. Nonetheless, it is clear that an overarching synthesis of these two analytical approaches is still elusive, indicating that the development of a unifying “theory of cancer” still lies in the distant future.



A detailed schematic of the signaling circuitry within a single cell. A complex network of influences is shown connecting receptors in the plasma membrane to proteins within the cytoplasm and within the nucleus. Sectors of the network are shaded in different colors to indicate what they control: cell survival, mitogenesis, invasiveness, or inhibition of proliferation. External influences on the network include death factors, survival factors and cytokines as inputs to the cell survival circuitry; growth factors, adjacent cells, the extracellular matrix, and W n t as inputs to the mitogenic circuitry; and cytostatic factors that relate to inhibition of proliferation. Centrally important activities, associated with the nucleus, include cell survival, cell proliferation, and changes in gene expression.

Figure 11.38 The intracellular signaling circuitry and collaboration between cancer-associated genes The design of the signal-transduction circuitry of mammalian cells has been uncovered, piece by piece, over the past four decades. The diagram here indicates only a portion of the proteins *(green circles)* that play critical roles in modulating the flow of signals through the various circuits operating within our cells. As indicated here by the various shadings, growth-promoting, mitogenic circuit (*light red*), the circuit governing growth-inhibitory signals (*light brown*), the circuit

governing apoptosis (*light green*), and the circuit governing invasiveness and metastasis (*light blue*) can be assigned to distinct regions in the map of the master circuitry of the mammalian cell. (Note that the circuit governing mitogenesis/proliferation overlaps in part with that governing cancer cell invasiveness, indicating that a common set of proteins mediates both biological responses.) In principle, each of the distinct stages of multi-step tumor progression and each driver gene mutation can be mapped to one of these subcircuits. In practice, this remains challenging because of numerous cross-connections between individual subcircuits, our still-incomplete enumeration of functionally critical signaling proteins, and our fragmentary understanding of how individual signaling proteins operate and interact with one another. Moreover, additional subcircuits still need to be mapped out. By implication, all of these subcircuits need to be perturbed or deregulated in order for a normal human cell to become transformed into a tumorigenic derivative. (Adapted from D. Hanahan and R.A. Weinberg, *Cell* 100:57–70, 2000. With permission from Elsevier.)

Among the multiple obstacles to progress is the realization that the Darwinian model of tumor progression is hard to validate in detail. We are hard-pressed, at least at present, in measuring the time intervals between clonal expansions. Some may occur far more rapidly than others and may be influenced by the biology of the individual in which these processes occur, including factors such as inborn genetic susceptibility and various aspects of lifestyle, obesity, and diet. Such time intervals are surely crucial to cancer formation because, by necessity, they govern the time-to-completion of the process as a whole and thereby determine whether or not it creates clinical disease in a human life span.

In Sections 11.13 and 11.14, we read that the great majority of human carcinogens are likely to drive cancer formation through their ability to *accelerate the rates* of multi-step tumor progression rather than through direct effects on the genomes of cells in various target organs. These accelerating mechanisms were portrayed here as acting via their powers to act as non-genotoxic tumor promoters rather than the initiators defined by the mouse skin carcinogenesis model (see Figure 11.30). Indeed, many types of human tumors seem to arise entirely without the contributions of identifiable mutagens originating outside the human body. In such tumors, the genetic damage that is essential to multi-step tumor pathogenesis would, by necessity, be generated entirely by endogenous processes, a topic that we will visit in great depth in the next chapter. Stated differently, in most human tissues, the numbers of endogenously generated mutations (that is, those created

entirely by mechanisms operating entirely within an affected cell) are likely to dwarf those of exogenous origin, (that is, those created by genotoxic substances that enter into the human body and its cells from outside).

As described in this chapter, some of the clearly validated tumor-promoting mechanisms operate in a purely mitogenic fashion; the actions of steroid hormones come to mind. Far more numerous and likely influential, however, are the tumor-promoting mechanisms that derive from various types of localized tissue inflammation. Thus, chronic or “smoldering” inflammation in the stromal microenvironment of a tissue seems to provide future neoplastic cell populations with the mitogenic signals needed to drive their clonal expansion.

In the case of human tumors, the apparently central roles of tumor promoting mechanisms have left us with two major quandaries. First, we do not have assays for detecting human tumor promoters, which may be present in low, limiting amounts in our tissues. Second, we are unable to quantify the concentrations of these agents, which represent critical numbers in judging their contributions to cancer pathogenesis and the importance of eliminating them from our environment. This depiction of the key roles of tumor promotion and localized inflammation within a tissue ultimately bears directly on the agendas of public health campaigns organized to reduce cancer incidence (and resulting cancer-associated mortality). However, nongenotoxic, tumor-promoting mechanisms are, at least at present, very difficult to recapitulate in the research laboratory. Lacking this ability, we still understand relatively little about these nongenetic mechanisms that are so deeply involved in cancer pathogenesis and thus tumor incidence.

Still, in the case of a defined subset of common human cancers pro-inflammatory mechanisms can be traced directly back to clearly identified causal agents. Their identities of these do indeed suggest effective strategies for reducing cancer incidence. On a worldwide scale, it is estimated that 9% of all cancer deaths arise because chronic infections of the stomach by the bacterium *Helicobacter pylori* often lead to gastric carcinomas, and that 6% of all cancer deaths are associated with liver cancers, most of which are caused by chronic infections by hepatitis B and hepatitis C viruses. The chronic infection of the cervical epithelium caused by human papillomaviruses, notably strains 16, 18, and 45, leads in some women to the cervical carcinomas that account for 5% of worldwide cancer mortality. (The chronic inflammatory effects of these papillomavirus infections may be compounded by certain viral oncogenes.) The identification of these etiologic agents presents an enormous opportunity for reducing worldwide cancer

incidence and mortality: infectious diseases are ultimately far easier to control and prevent (through immunization, antibiotics, and antiviral drugs) than the effects of foodstuffs that we ingest and the tobacco products that we inhale. By some estimates, 450 million people worldwide are infected chronically with HBV, and 200 million are long-term HCV carriers.

This recognition of the widespread influence of pro-inflammatory processes in cancer pathogenesis offers another opportunity. More specifically, future anti-cancer drugs may derive from the recent advances in elucidating the biochemical details of inflammation and its specific contributions to tumor promotion. Cyclooxygenase-2 (COX-2) is clearly at the center of this process, and a number of anti-inflammatory agents (largely NSAIDs) targeting this enzyme are known to be effective in decreasing the incidence of various types of cancer. Ultimately, successes in reducing inflammation pharmacologically may provide the most effective route to reducing human cancer incidence and thus, in the longer term, mortality. At present, however, the ability to directly target anti-inflammatory agents to specific tissues or organs is limited, leaving us with agents that often carry unacceptable side effects.

There are yet other issues encountered in this chapter that bear on attempts to reduce cancer mortality. Here is one question raised by the research we discussed: Do full-blown, multiply mutated tumors continue to depend on the mutant alleles that were created decades earlier by initiating mutagens? Or do these initially acquired mutant alleles become irrelevant later, when subsequently acquired mutant alleles take over the job of programming cancer cell proliferation?

The logic developed in this chapter seems to provide a clear and direct answer: Mutant alleles acquired late in multi-step progression should never be functionally redundant with those acquired earlier, simply because these late alleles do not confer advantageous phenotypes beyond those that cancer cells have already developed earlier. Accordingly, early mutations and mutant alleles should not be obviated by later ones, and these early mutations remain critical to ongoing robust tumor growth. Transgenic mice shed some light here. In some of these mouse models, the initiating transgenic oncogenes, such as *myc* and *ras* (see Section 11.8), have been inactivated by a variety of experimental tricks long after substantial tumors have formed. As it turns out, the effects on tumor growth that have been observed to date are conflicting. More often than not, these tumors collapse rapidly when deprived of the initiating oncogenes that led originally to their formation. Hence, in these cases, the mutant oncogenic alleles continued to be critically important both for the initiation of the neoplastic cell state as well as

the maintenance of this state long afterward. Stated differently, the mutant alleles that were acquired in later steps of multi-step tumorigenesis did not render the earlier ones unnecessary. However, in several research reports, shutdown of the initiating *neu*, *myc*, or *wnt* oncogenes long after tumors had formed led, after short remissions, to the regrowth of these tumors. In these cases, the initiating oncogenes were clearly no longer needed for the expansion of the relapsing tumors.

These observations would seem to hold important implications for the development of new types of anti-cancer therapeutics, a topic that we will return to in Chapter 17. For example, if a mutant *ras* allele is found in a human tumor cell genome, can this tumor be cured by drugs targeted to the Ras oncoprotein, or has this oncoprotein, which almost certainly played a key role in the early steps of tumor formation, become irrelevant, later on, to the continued proliferation and survival of the cells in this tumor?

In spite of our rapidly expanding understanding of cancer pathogenesis, as described in this chapter, we still do not have the means to impose control on most kinds of aggressive human cancers. The images in Figure 11.16 reveal starkly the major difficulty of current anti-cancer therapy—the fact that the extensive diversification of cell populations within individual tumors seems, almost inevitably, to yield therapy-resistant subpopulations of cells that erupt and drive clinical relapses in patients whose tumors previously responded to therapy. We still lack the means to compensate for the rapid pace of this intra-tumoral evolutionary diversification and therefore lack the ability to deliver the definitive cures that so many seek. So, this chapter does not end on a high note, but that is where we are and may be for a long time to come.

OceanofPDF.com

Key concepts

- The process of tumor formation is complex, with multiple steps involving multiple alterations of cells and their physiological control mechanisms.
- The complexity of this process is reflected in the long time periods required for most human cancers to develop.
- These changes involve both the activation of oncogenes and the inactivation of tumor suppressor genes.
- The number of steps required to experimentally transform human cells is larger than is needed to transform cells of laboratory mice.
- These alterations affect multiple distinct regulatory circuits within cells and function in a complementary fashion to create the neoplastic cell phenotype.
- Some of these changes occur as the direct result of the actions of exogenous mutagens, and exposure to such mutagens may represent a “rate-limiting” determinant of tumor progression.
- In most instances, however, the rate of tumor progression may be governed by the actions of nonmutagenic tumor-promoting agents, which may determine the rate of expansion of mutant cell clones.
- In many human cancers, these critical nonmutagenic, tumor-promoting stimuli include chronic mitogenic stimulation and inflammation.
- The multiplicity of steps required for human cancers to arise is not known, in part because certain changes may occur rapidly and therefore may not be “rate-limiting,” whereas others may require a decade or more to complete.
- Multi-step tumor progression can be depicted as a form of Darwinian evolution occurring within tissues. However, because some of the critical changes occurring during tumorigenesis are epigenetic, and because the rate of genetic diversification can occur very rapidly, the classic depictions of linear Darwinian evolution must be modified.
- In most, but not all, transgenic models of tumorigenesis, the initiating changes continue to be required for continued survival of a tumor, long after the process of tumor progression has reached completion.

- The number of genetic changes found in the genomes of human cancer cells vastly exceeds the number required for tumorigenesis to reach completion, complicating identification of the critical genetic changes that affect driver genes and are causally important in tumor formation.
- The discovery of cancer stem cells greatly changes our concepts about the mechanisms of multi-step tumorigenesis, because these self-renewing cells (or closely related progenitor cells), rather than the bulk populations of cancer cells, may be the objects of genetic alteration and clonal selection.

Thought questions

1. Knowing the various genetic and epigenetic changes that occur during multi-step tumorigenesis, which would be likely to be readily uncovered and which may be difficult to identify? Describe the reasons for these assignments.
2. Some tumor suppressor genes inactivated during multi-step tumorigenesis may be readily identified because of LOH in the chromosomal region carrying them, whereas others may be difficult to identify in this way. Describe the factors that allow or complicate this identification.
3. What arguments favor the notion that all of us carry myriad clones of initiated premalignant cells throughout the body?
4. What arguments can be mustered that favor the notion that most human carcinogens act as promoters rather than initiators of tumorigenesis?
5. What different approaches can be used to estimate the number of steps in multi-step tumor progression, and how is each of these approaches flawed?
6. How does the current available information about multi-step tumor progression provide insights into strategies for the prevention of clinically detectable cancers?
7. What mechanisms enable chronic viral infections to exert a carcinogenic influence on a tissue?
8. Describe the various mechanisms of tumor promotion and the features that they share in common and those that distinguish them from one another.

Supplementary Sidebars

Supplementary Sidebar 11.1 Mathematics of multi-step tumor formation

Epidemiologists have developed formulas to predict the frequency of various cancers as a function of age. These formulas indicate that, depending upon the cancer type, disease incidence (the rate at which the disease is diagnosed) and mortality rates occur as a function of a^4 to a^7, where a represents the age of patients at initial diagnosis. For epithelial cancers as a whole, the risk of death from cancers increases approximately as the fifth or sixth power of elapsed lifetime (**Figure S11.1**). Algebraic functions like these are interpreted quite simply. If the probability of an outcome is indicated by a^n, then $n+1$ independent events, each occurring randomly and with comparable probability per unit of time, must take place before the ultimate outcome—in this case a diagnosed tumor—is achieved. The incidence of a disease like colon cancer begins to shoot upward only in the seventh and eighth decades of life, indicating that each of these events occurs with a very low probability each year. More specifically, each event is likely to occur on average once every 10 to 15 years, and the entire succession of events may usually require 40 to 60 years to reach completion.

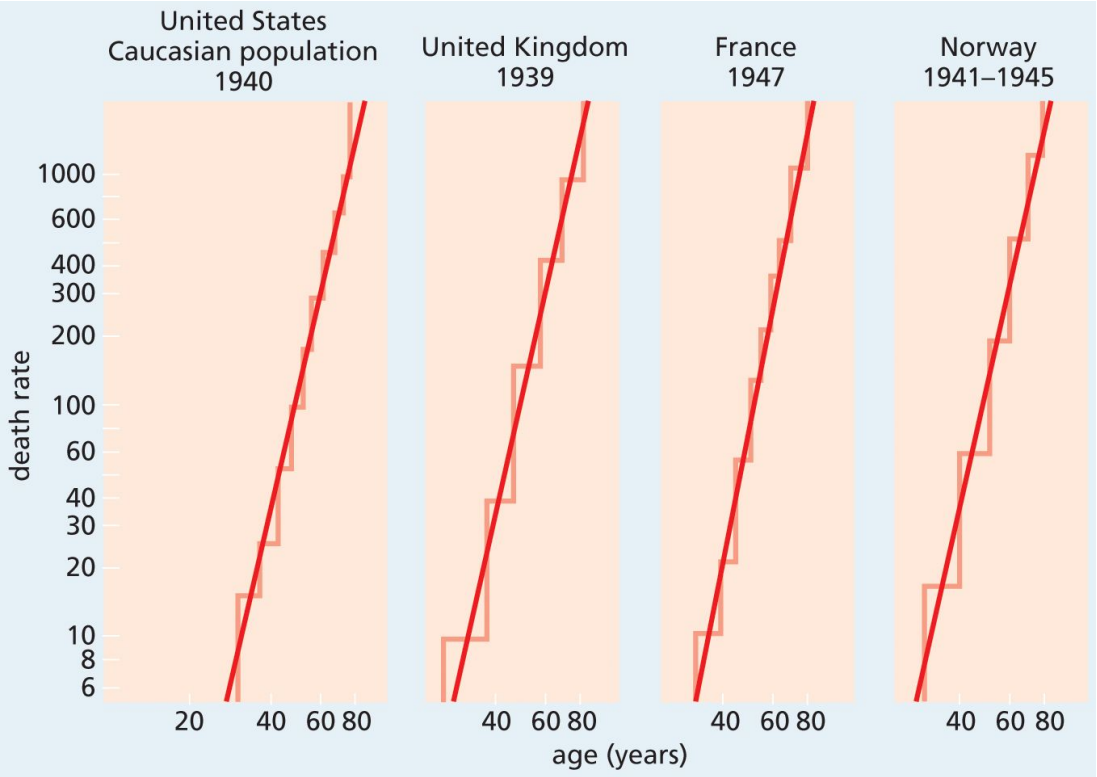

Figure S11.1 Kinetics of tumor formation in different countries: age at death from various epithelial cancers The graphs indicate the general mortality from cancer from 1939 to 1947 in four countries where public health statistics were kept with some precision. These log–log plots of male cancer death rates (deaths per 100,000 population, *ordinate*) at different ages (*abscissa*) have a slope indicating that completion of five or six rate-limiting events is required to produce a lethal cancer. For example, a slope of 5 indicates six rate-limiting events, whose nature is not revealed by these analyses. Interestingly, these slopes are remarkably similar among different countries. The slopes differ slightly with different types of cancer (*not shown*). (From A.G. Knudson, *Nat. Rev. Cancer* 1:157–162, 2001; reproduced from C.O. Nordling, *Br. J. Cancer* 7:68–72, 1953. With permission from Nature.)

These calculations provide us with only a very rough estimate of the complexity of multi-step tumor progression. In fact, some critical steps may occur far more rapidly than others but not register in these calculations of the kinetics of tumor progression, which reflect only the influence of the slowest, *"rate-limiting"* steps. For this reason, it seems likely that the actual number of events required to form most tumors is actually higher than is predicted by use of this a^n formula. [Consider the notion that later steps in multi-step tumor progression require less time to complete than earlier steps because (1) the cells in later growths, having acquired multiple oncogenic mutations, have learned how to proliferate faster, decreasing the time of each clonal expansion, and (2) the genomes of cells are likely to have become more mutable (as discussed in Chapter 12).]

Additionally, the strong age dependence of almost all cancers forces epidemiologists to calculate *age-adjusted incidence*, which corrects for the fact that the age distributions of different human populations differ markedly. A calculated age-adjusted incidence can tell us, for instance, what the probability is of a 60-year-old woman in the United States contracting breast cancer during the course of a year compared with the risk experienced by a woman of the same age living in Egypt, Kazakhstan, or Portugal. At the same time, age-adjusted incidence measurements enable us to make meaningful comparisons in a specific population over an extended period of time—for example, the age-adjusted colon cancer risk of the U.S. population in 1930 compared with that of the successor population in 1990.

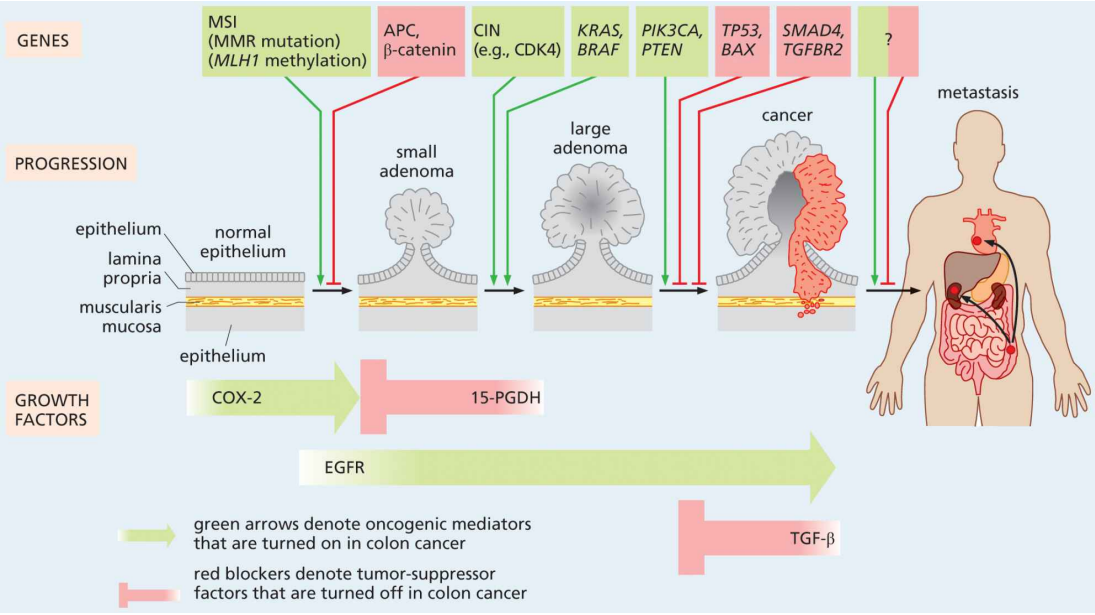
Supplementary Sidebar 11.2 Will curing cancer extend human life span?

The long timetable of tumor formation and cancer-induced deaths helps to explain the late onset of most cancers. This timing has an important and unexpected public health

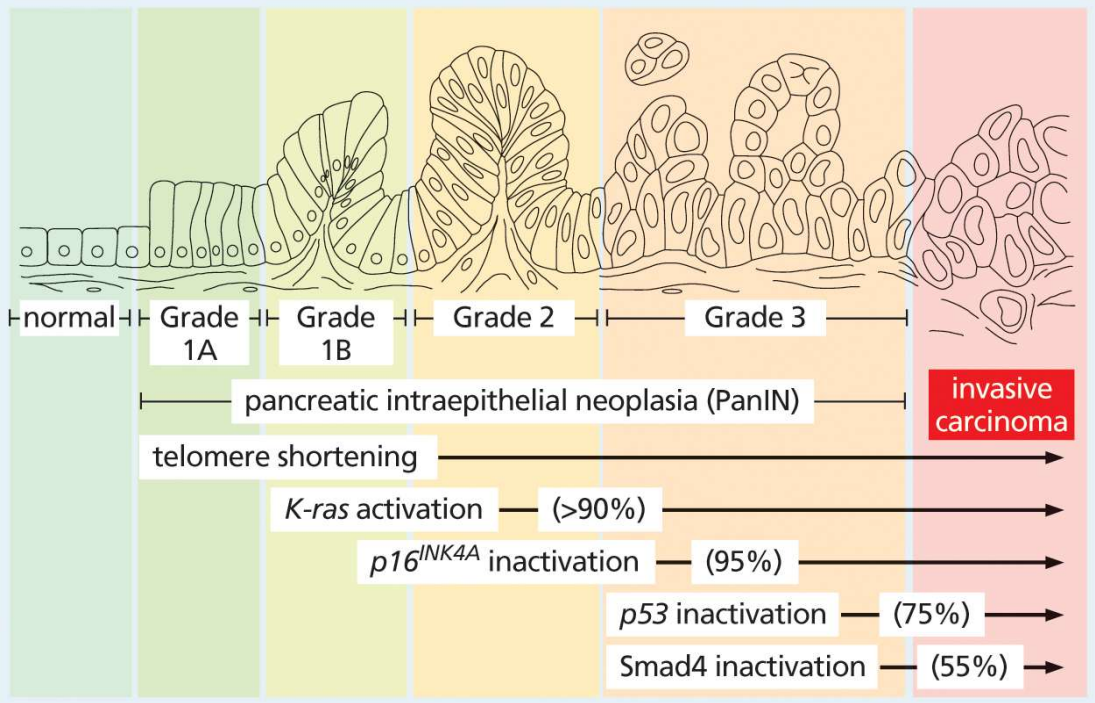
implication: curing all cancers will have a relatively small effect on expected life span. A decade or more before most individuals have lived long enough to contract cancer, they often succumb to other maladies, such as heart disease. A calculation based on cancer-related deaths in the Netherlands in 1990 indicated that if all such deaths were eliminated, this would extend life expectancy only 3.83 years for men and 3.38 years for women.

Supplementary Sidebar 11.3 A more detailed accounting of the somatic mutations driving colorectal and pancreatic cancer formation

In the two decades time after the initial depiction of the genetic progression of colorectal carcinomas was first published, a more detailed accounting of the genetic changes was produced through the sequencing of colorectal tissues that progressed to various extents toward the state of high-grade malignancy (**Figure S11.2A**). In addition, a detailed "genetic biography" of human pancreatic carcinomas is presented in Figure S11.2B.



(A)



(B)

Figure S11.2 Detailed genetic biographies of colorectal and pancreatic carcinomas The advent of high-speed genomic sequencing made it possible to map out the genetic biographies of various human tumors. The most detailed information has come from analyses of colorectal and pancreatic carcinomas. (A) As seen here, there is a preferential sequence in the mutations and epigenetic alterations acquired by colorectal cells in their long march toward high-grade malignancy. The involvement of changes in the APC and β-catenin pathway occurs almost universally in these tumors as the initial step, in large part because these changes compromise the outward migration of enterocytes from the crypts, which traps cells in these crypts and allows their progeny to acquire additional mutations that eventually lead to an aggressive primary carcinoma, labeled here as "cancer." One of these changes, "CIN," involves chromosome instability, which also contributes to the genetic chaos accumulated in the carcinoma cells of high-grade tumors. Of note, a subset of these changes involves promoter methylation rather than changes in nucleotide sequence, in which changes are epigenetic rather than genetic. Moreover, changes in the APC/β-catenin pathway are almost always mutually exclusive. Thus, if the gene encoding APC is mutated, mutations affecting the structure of β-catenin are rarely seen; this indicates that the two types of mutations are functionally redundant, and that the mutation of one of these genes obviates the need of the other to undergo mutation. Similarly, the functional redundancy of the *KRAS* (= K-*ras*) and *BRAF* (= B-*raf*) genes is explained by the organization of the shared signaling pathway as illustrated in Figure 6.9. Of note,

it is increasingly unlikely that additional somatic mutations are required in order for the cells forming a primary colorectal carcinoma cell (here labeled “cancer”, *pink*) to invade locally and disseminate to distant tissues; these subsequent changes are often, if not always, achieved by non-genetic programs that are discussed in detail in Chapter 14. (B) The most orderly succession of genetic and epigenetic changes documented to date occurs during the development of common adenocarcinomas of the pancreas; that is, as these growths progress through increasingly high histologic grades, almost all acquire an activated K-*ras* oncogene early in tumor progression, followed thereafter by loss of *p16*INK4A and then *p53* tumor suppressor gene function. Of note, the great majority of the key changes driving pancreatic carcinoma progression occur before the precursor lesions (pancreatic intraepithelial neoplasias; PanINs) undergo conversion into invasive carcinomas. (A, from S.D. Markowitz and M.M. Bertagnolli, *N. Engl. J. Med.* 361(25):2449–2460, 2009. With permission from Massachusetts Medical Society. B, courtesy of R. Hruban.)

Supplementary Sidebar 11.4 Profound transdifferention in glioblastomas

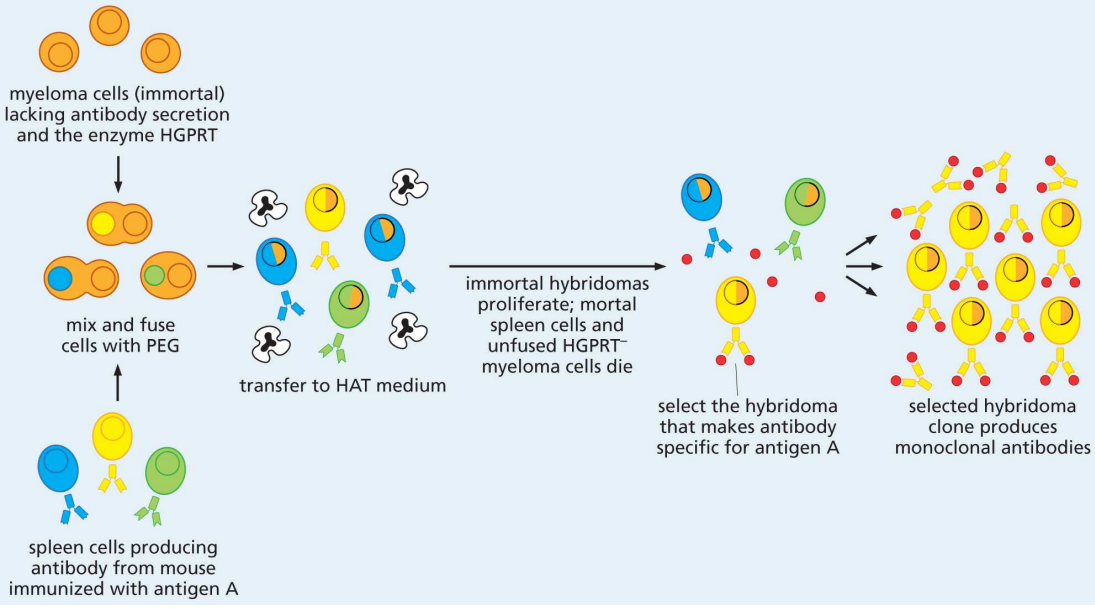
The common glioblastomas brain tumors are termed more properly glioblastoma multiforme to indicate that these tumors typically include a variety of morphologically distinct neuroectodermal cell types (see Figure 2.8)—almost certainly the reflection of oligopotent stem-like cells within an individual tumor differentiating into a number of distinct cell types (see Figure 11.23). The most extreme example of this apparent epigenetic plasticity is illustrated by the strategy that many glioblastomas employ to generate their own microvasculature: rather than recruiting normal endothelial cells (which form capillaries) from the tumor-bearing host (discussed in Chapter 13), the neoplastic cells transdifferentiate into endothelial-like cells (reflecting a process sometimes called vasculogenic mimicry), the latter normally originating in an entirely unrelated embryonic cell lineage. Once formed, the transdifferentiated cells collaborate with the normal endothelial cells of host origin to assemble capillaries, thereby expediting tumor-associated angiogenesis and thus tumor growth. Observations like these suggest another interesting possibility: Might two phenotypically distinct subpopulations of cells within a tumor act symbiotically, each supporting the growth and survival of the other, rather than directly competing with one another? Recent observations of the phenotypic state of two metabolically distinct subpopulations coexisting within an individual tumor provide support for precisely this notion. (This situation might occur when two distinct neoplastic cell subpopulations that share a common genotype adopt distinct phenotypes in order to help one another adapt most effectively to the tumor microenvironment.)

Supplementary Sidebar 11.5 Monoclonal antibodies and fluorescence-activated cell sorting

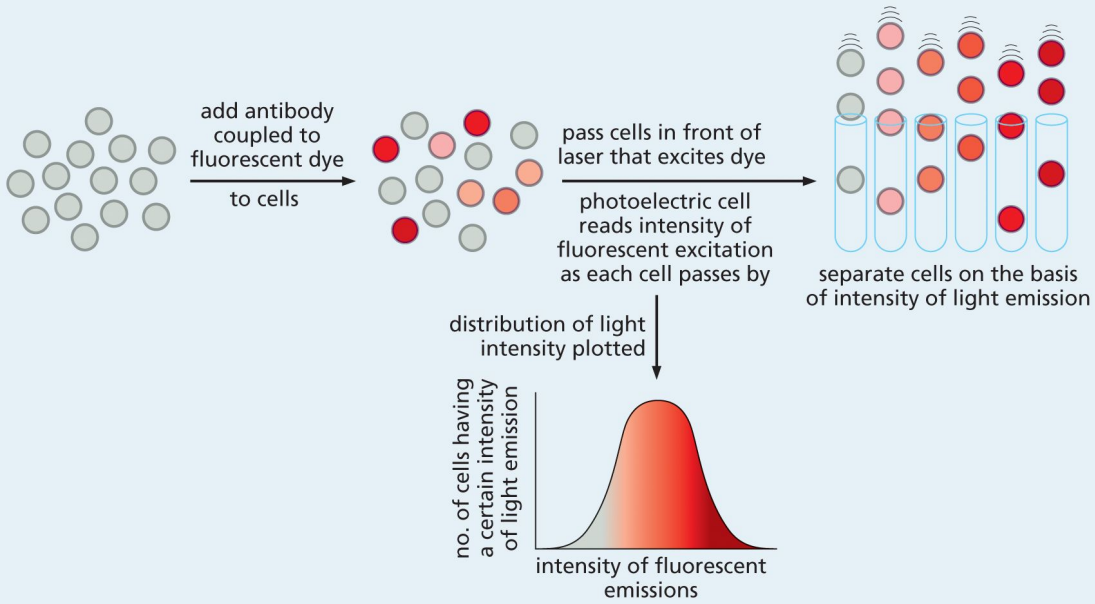
The procedures for analyzing and fractionating cell populations by sorting them according to their display of cell surface proteins depend on the technologies for producing monoclonal antibodies and the instruments of fluorescence-activated cell sorting (FACS; **Figure S11.3**).

The motivation for producing a monoclonal antibody (MoAb) is to generate a pure and homogeneous solution of antibody molecules, all of which are identical to one another and therefore recognize the same antigen with identical avidity. Such a MoAb contrasts with the antibodies that are usually produced by the immune system of an animal in response to immunization with an antigen of interest, usually a protein; these antibodies constitute a complex mixture of antibody species that bind to different epitopes (antigen sites) on the immunizing protein, with differing avidities (binding strengths) and with differing specificities, in that some antibodies may be totally specific for the antigen of interest, whereas others may recognize and bind unrelated proteins and are therefore termed *cross-reactive*.

The serum of an immunized animal may be used to recognize the antigen of interest even though it contains a diverse array of other functionally unrelated antibody molecules; alternatively, the antibody molecules of interest may be greatly enriched through their ability to bind to the antigen of interest followed by their elution from this antigen. In both cases, this complex mixture is considered to be a polyclonal antibody.



(A)



(B)

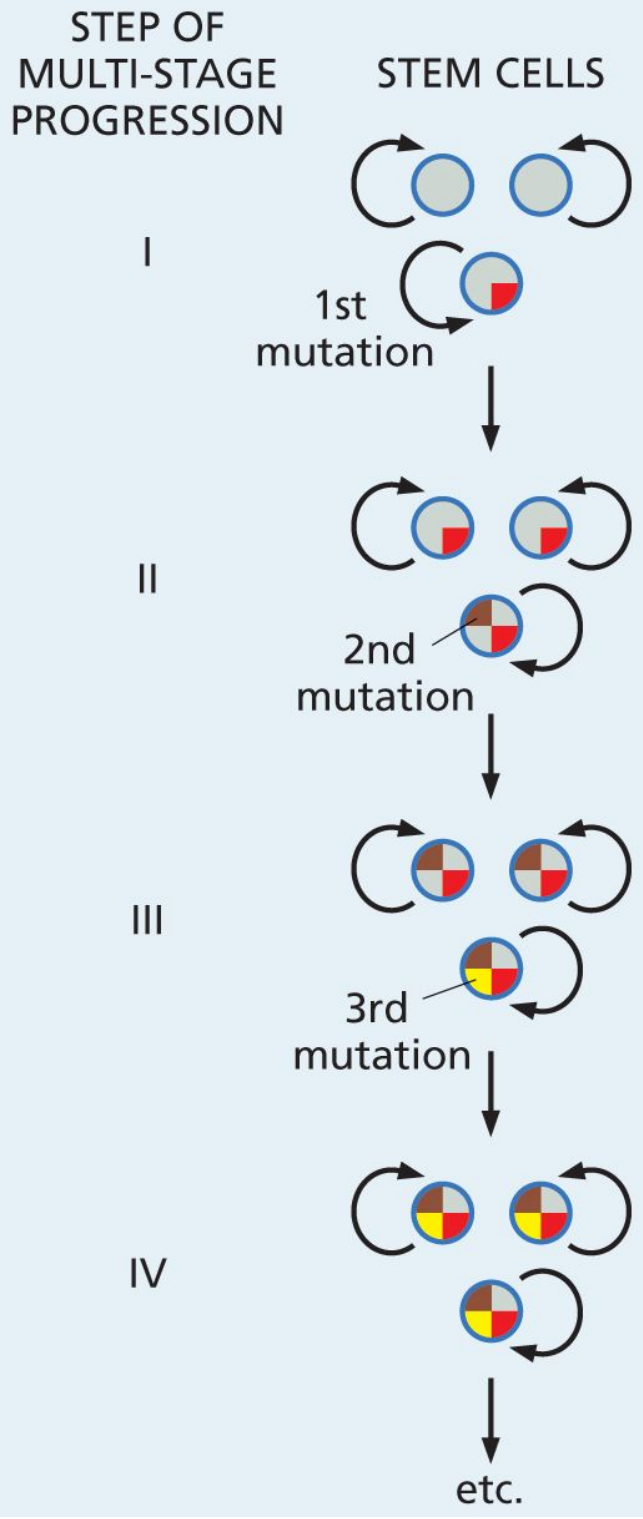
Figure S11.3 Monoclonal antibodies and fluorescence-activated cell sorting (FACS) (A) A mammal is immunized (usually repeatedly) to expand the number of B cells in its spleen that produce antibodies that specifically recognize the immunizing antigen. (Each of these B cells is known to produce a discrete and specific antibody species.) A mixture of B cells (*lower left*) is then prepared from the spleen of this immunized animal and each of these cells is fused using polyethylene glycol (PEG) with a myeloma cell belonging to a special myeloma cell line (*upper left*), whose cells contain dominantly acting oncogenes but lack the ability to make both their own antibodies and the HGPRT enzyme. As a consequence, each of the resulting hybrid cells (*left middle*) contains a genome that (from the B-cell parent) specifies the production of a specific antibody and (from the myeloma parent) confers the ability to proliferate indefinitely in culture. These cells are transferred to a special medium termed HAT (hypoxanthine–aminopterin–thymidine), which selects for the outgrowth of cells that contain both parental genomes. The surviving hybrid cells are then introduced into microtiter plates at such high dilutions that each well of the plate contains at most a single cell (*not shown*). Each founding cell within a well should proliferate and its progeny should secrete antibody into the supernatant culture medium in the well. The medium from each of the wells is screened for the presence of antibody molecules that bind the original immunizing antigen (*middle right*). The cells from a well producing an antibody of interest are retrieved and expanded and constitute a *hybridoma*, i.e., a neoplastic hybrid cell line that produces a single, discrete antibody species, ideally with the desired specificity and antigen-binding affinity termed avidity (*far right*). The antibody produced by this hybridoma cell

population is termed a monoclonal antibody. (B) Cells are treated with a monoclonal antibody that recognizes and binds a cell surface antigen displayed by some but not all of the cells in a population; alternatively, as shown, all of the cells may display this antigen but to differing extents. This antibody is usually coupled with a fluorescent dye, resulting in staining of the antigen-positive cells. Hence, among the cells being analyzed, some express the antigen at higher levels and therefore are stained more strongly by the antibody (*darker red*), whereas others are stained weakly (*pink*) or not at all (*gray*). This mixture of cells, placed in suspension, is then passed in single file past a laser beam that excites the dye (and causes it to emit light) and a photoelectric cell that measures the intensity of fluorescence emission by the dye molecules staining each cell. These measurements may then be integrated and plotted as a distribution of signals, in which case this procedure is often termed "flow cytometry" (*below*). Alternatively, if the labeling procedure has not damaged these cells, they can be separated from one another on the basis of their fluorescence intensity (e.g., through use of an electrical field), which allows the biological properties of these cells to be gauged through other tests (*right*). Often, staining by two different antibodies, each bearing a distinct fluorescent dye, allows the simultaneous measurement of intensities of two different antigens, in which case a different graphing convention is used, as shown in Figure 11.19A. Measurements of fluorescence intensity obtained in this way are usually plotted on a logarithmic scale. More recent innovations of FACS have allowed more than two antigens to be monitored simultaneously (*not shown here*) and the permeabilization of cells to allow access of antibody molecules to intracellular antigens. (A, from K. Murphy et al., Immunobiology, 8th ed. New York: Garland Science, 2011.)

Supplementary Sidebar 11.6 How does multi-step tumor progression actually take place?

The scheme of multi-step tumor progression presented in Figure 11.14 indicates that a normal cell sustains an initiating mutation, which in turn spawns by clonal expansion a new cell population in which all cells carry this initiating mutation. One of these descendant cells will thereafter acquire a second mutation, resulting in a second clonal expansion, and so forth. However, with the discovery of the hierarchical organization of neoplastic tissues (see Figure 11.20B), this scheme must be revised to include cancer stem cells and transit-amplifying/progenitor cells (see Figure 11.22). Because normal epithelial tissues are organized in a hierarchical fashion (involving stem cells, transit-amplifying/progenitor cells, and more differentiated cells) and because the cells within derived fully neoplastic carcinomas appear to be organized in a very similar fashion, it is highly likely that each of the cell populations present in the intermediate stages of multi-step tumor progression is also organized in a hierarchical fashion.

Accordingly, in the simplest version of the revised scheme involving cancer stem cells, an initiating mutation strikes a normal stem cell and the resulting singly mutated stem cells subsequently sustain a second mutation, generating doubly mutated stem cells, which in turn develop into triply mutated stem cells, and so forth. Each of these stem cells generates its own cohort of transit-amplifying and more differentiated descendants. In essence, one stem cell population evolves directly into another, as depicted in **Figure S11.4A**.



STEP OF MULTI-STAGE PROGRESSION

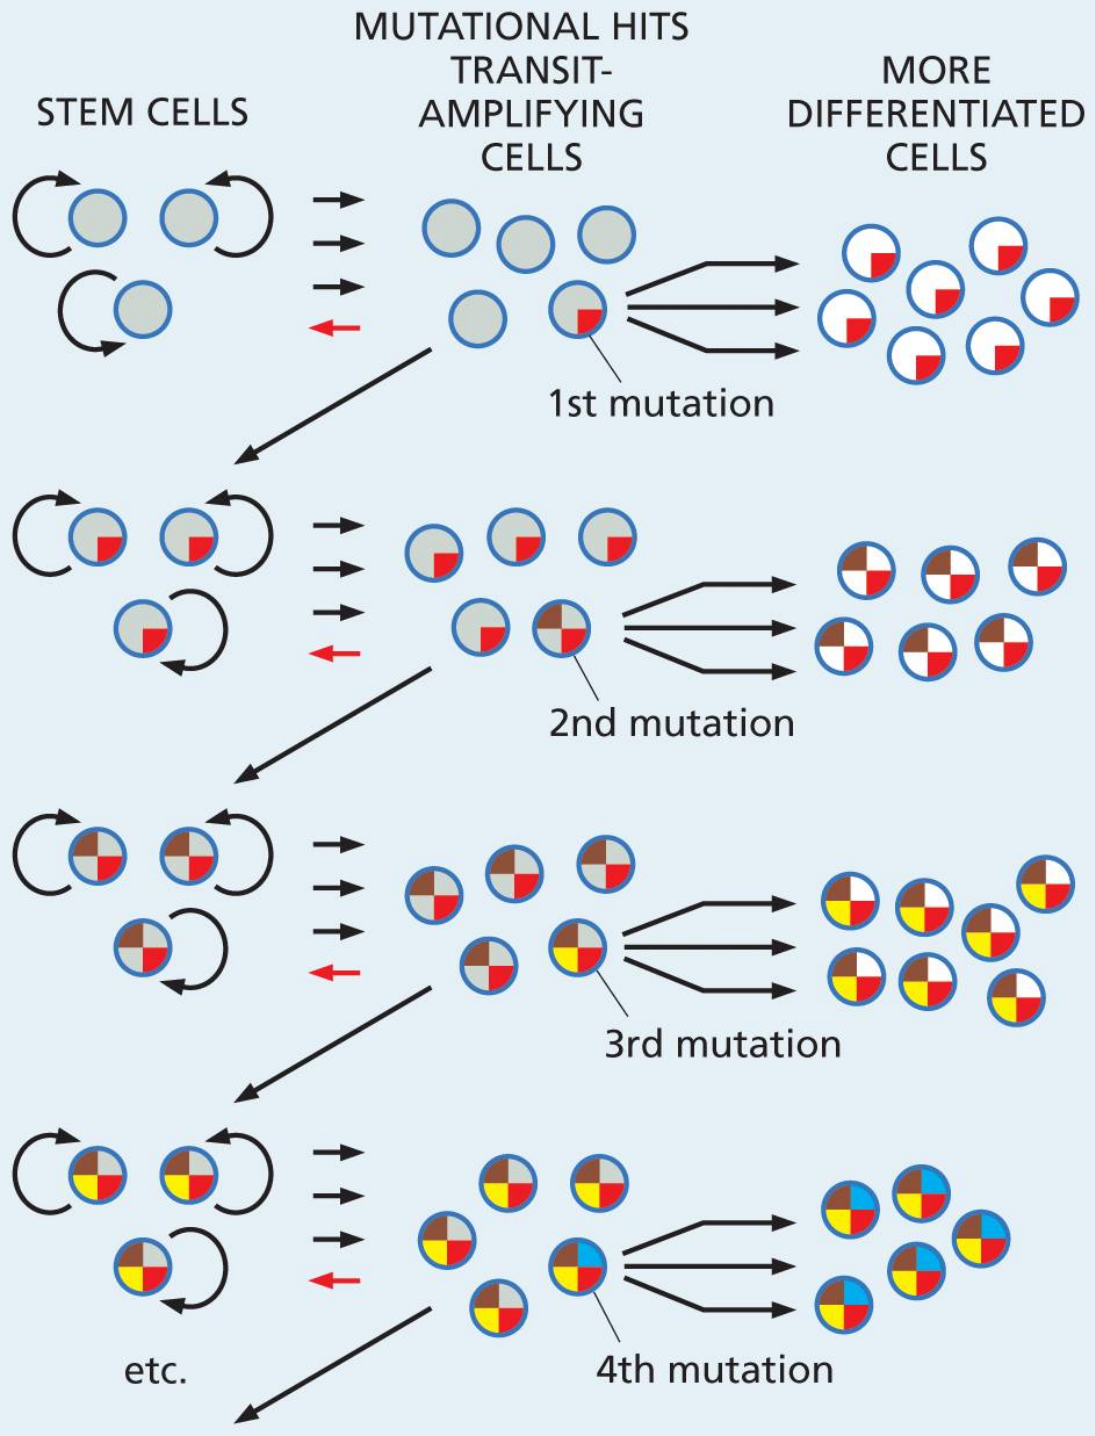
etc.

(A)



(B)

Figure S11.4 Cancer stem cells, spontaneous dedifferentiation, and the actual course of multi-step tumor progression Cancer stem cells (CSCs) must be incorporated into the schemes of multi-step tumor pathogenesis described in this chapter and illustrated in Figure 11.14. (A) The simplest scheme depicts fully

normal stem cells (SCs) evolving directly into initiated SCs that have acquired an initiating mutation (*red sector*). The latter SCs now proliferate and acquire a second lesion (*brown sector*) and evolve directly into a third SC population, and so forth. The more-differentiated derivatives of each of these SC populations, including transit-amplifying and more-differentiated cells, are not depicted here. (B) The scheme shown in panel A, although attractive and plausible because of its simplicity, is complicated by three important considerations: (1) There are generally far fewer SCs than transit-amplifying/progenitor cells in a normal tissue; the likelihood of a mutation occurring is proportional to the number of target cells in a population, implying a far smaller likelihood of cancer-causing mutations being acquired by SCs relative to those arising in the transit-amplifying population. (2) Mutations occur far more commonly in actively proliferating cells, such as those in the transit-amplifying compartment; this contrasts with the state of cells in normal SC compartments, which proliferate only infrequently. (3) Advantageous effects of mutant alleles that confer selective advantage may not be manifest in undifferentiated stem cells. Taken together, these three considerations make the transit-amplifying cells into far more attractive candidates as the cells that sustain mutational hits and thereby acquire advantageous, novel mutant oncogenic alleles. Unexplained by this scheme is the problem of how such advantageous alleles are *fixed* in the genome of the tumor as a whole rather than being lost with the deaths of transit-amplifying/progenitor cells. In fact, this problem is addressed by the observations that non-SCs can dedifferentiate into SCs (*red arrows*), thereby transferring advantageous alleles from the progenitor cell population back into the SC cell pool (see Figure 11.20C). The resulting SCs may then spawn transit-amplifying cells, in one of which a second mutation (*brown sector*) strikes; this cell and its descendants may dedifferentiate into a successor SC population, and so forth. Such back-and-forth alternation between SC and transit-amplifying states appears to address the problems arising from the scheme depicted in panel A.

Although this scheme is logical, it holds several inherent difficulties that cannot be readily reconciled with real-world biology. To begin, it implies that the targets of mutation are, at each stage of tumor progression, individual cells within the stem cell subpopulation. Experience to date indicates that, in general, stem cells represent only a small proportion of the overall cells within a tissue, normal or neoplastic. Because mutations occur at a low rate per cell generation (for example, 1 per 10^6 cell divisions), tumor-promoting mutations are mathematically relatively unlikely to strike this cell population because the *absolute size* of this cell population is small. (In the colonic crypt of the mouse, ∼16 stem cells usually coexist with more than 500 transit-amplifying/progenitor cells.)

A second major difficulty stems from the process of mutation. Mutations generally occur in actively dividing cells and in part are associated with mistakes in DNA replication of one sort or another, as will be discussed in Chapter 12; in rapidly proliferating cells yet other mutations arise from the replication of still-unrepaired DNA. If stem cells divide relatively infrequently, this also decreases the likelihood that they represent the targets of mutation. Taken together, these two factors argue against stem cells as always being the direct targets of the mutations that drive multi-step tumor progression.

A solution to this problem derives from the discovery that the hierarchical scheme depicted in Figure 11.20B requires revision: non-stem cells can, with a certain frequency, dedifferentiate into stem cells. Accordingly, this hierarchical scheme now needs to be redrawn (see Figure 11.20C). This dedifferentiation can occur in both immortalized epithelial cell populations and in their transformed derivatives, both *in vitro* and *in vivo*; it may also occur in fully normal epithelial cell populations.

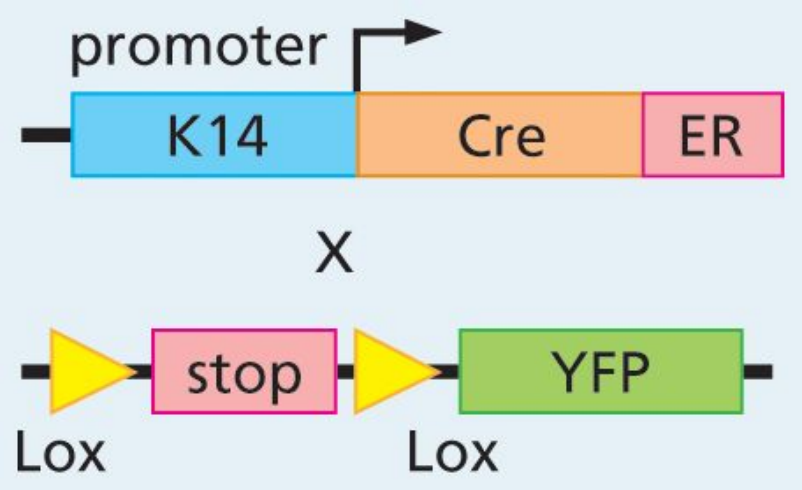
The altered scheme depicted in Figure 11.20C now makes it attractive to embrace a model of how multi-step tumor progression actually proceeds (Figure S11.4B). In particular, mutations strike a cell in the transit-amplifying/progenitor cell populations, which are both far larger than the stem cell populations and are actively dividing, making the occurrence of such a mutation far more probable (relative to a mutation striking a member of the stem cell population). Thus, as the scheme of Figure S11.4B indicates, once a mutation hits a transit-amplifying cell, the dedifferentiation of this cell into a stem cell ensures that the new mutation can now be introduced into the stem cell pool and safeguarded by the cells in that pool; moreover, the mutant cell with this new mutation can now generate transit-amplifying and more-differentiated cells carrying this new mutation. A second mutation that may trigger a subsequent round of clonal expansion will, as before, strike a cell in the newly formed pool of transit-amplifying cells and once again will be introduced into the stem cell pool via dedifferentiation. Experimental validation of this scheme is still required.

Supplementary Sidebar 11.7 Stem cells driving papilloma growth closely echo the behavior of normal stem cells of the skin

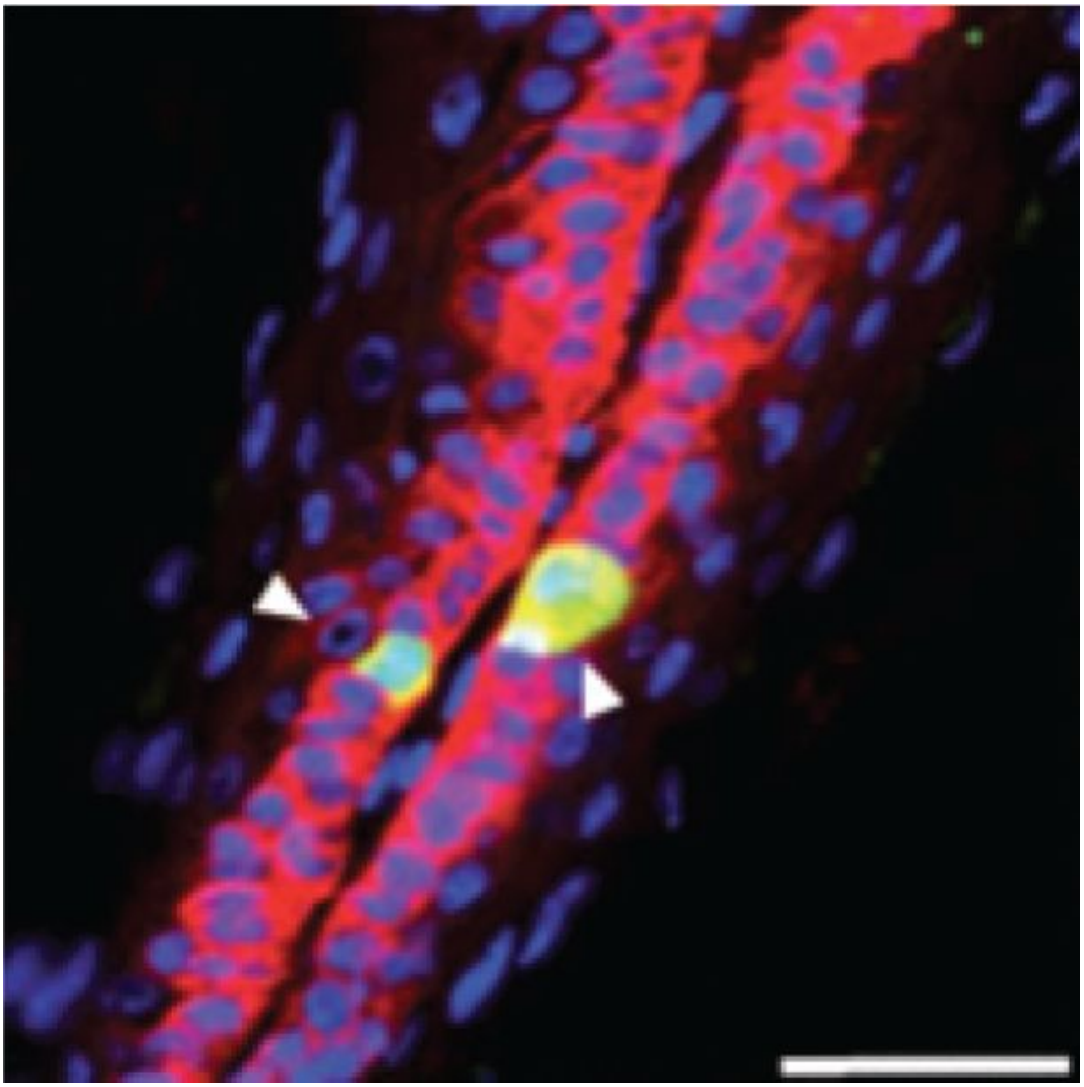
One strategy for demonstrating the validity of the cancer stem cell model derives from the ability to label putative stem cells within a neoplasm and demonstrate that their lineal progeny enter into a variety of states, some more differentiated than that of the putative stem cells. This was undertaken in a mouse model of chemically induced skin papillomas, which is discussed in detail in Section 11.11 and illustrated in Figures 11.30, 11.31, and 11.32. In short, a combination of a mutagenic “initiator” compound can be painted on an area of skin of the mouse followed by repeated paintings with a “promoter” compound. The result is, after a period of time, the formation of a skin

papilloma, which is analogous to an adenomatous polyp in the intestine and is poised to become a malignant skin tumor.

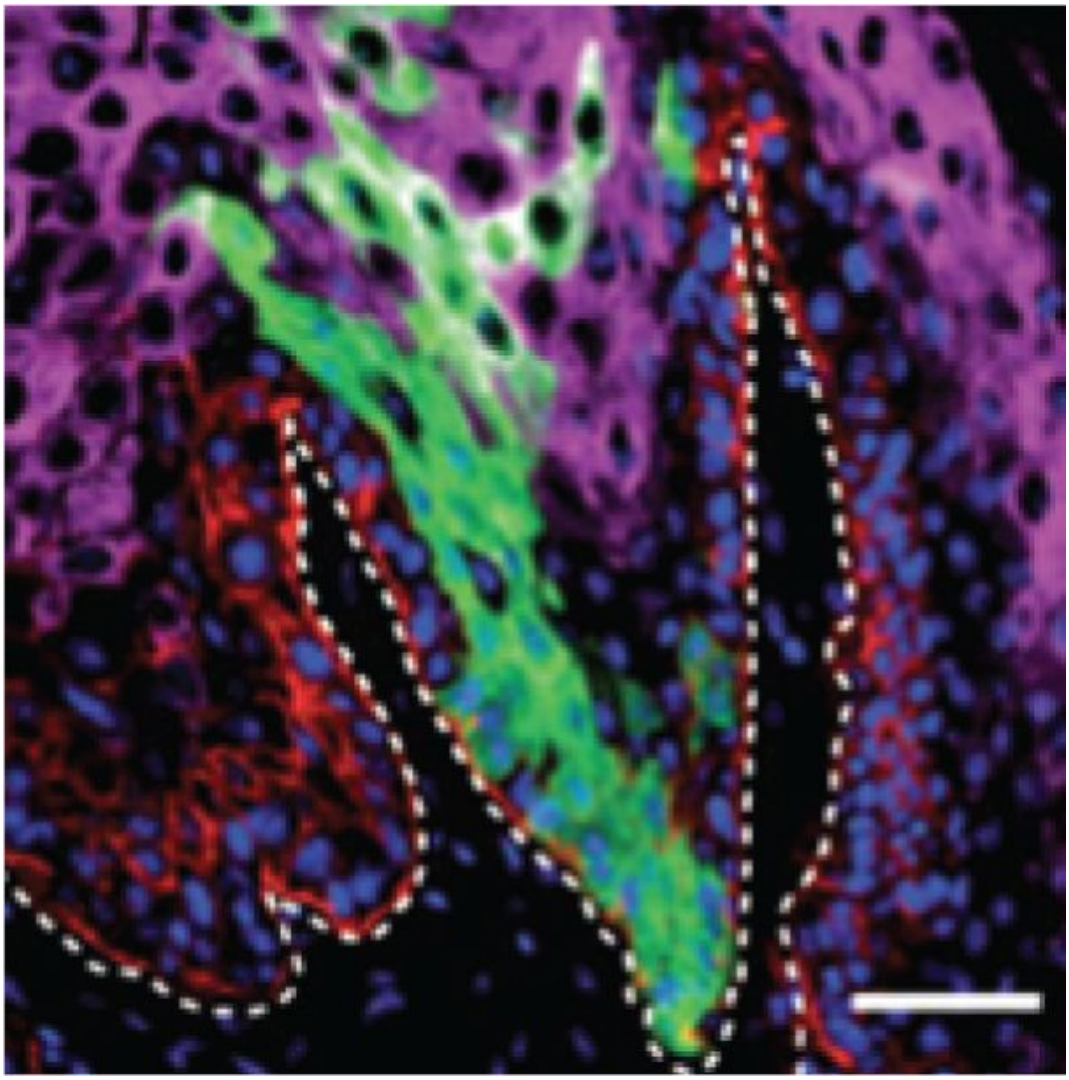
This skin carcinogenesis model was used to determine whether self-renewing stem-like cells in the papilloma generate more differentiated progeny, much like the normal stem cells in the skin. To do so, a labeling strategy was used (**Figure S11.5A**) in which scattered basal cells were labeled through the activation of a YFP reporter (Figure S11.5B), the expression of which could be perpetuated in the descendants of this cell. Two weeks later, labeled descendants of the initially labeled basal cells could be found in a series of intermediate phenotypic states that included the most differentiated keratinocytes in the skin, which undergo cornification—dying and hardening that is part of normal skin development and maintenance (Figure S11.5C). The clear and close resemblance between the observed hierarchy of cell states in the papillomas and in the normal skin provides compelling evidence that there are cells in these neoplastic papillomas that strongly resemble in their properties the behavior of bona fide stem cells in the normal skin. As **Figure S11.6** illustrates, a variety of experimental strategies has been used to localize the stem-like cells within various types of tumors.



(A)



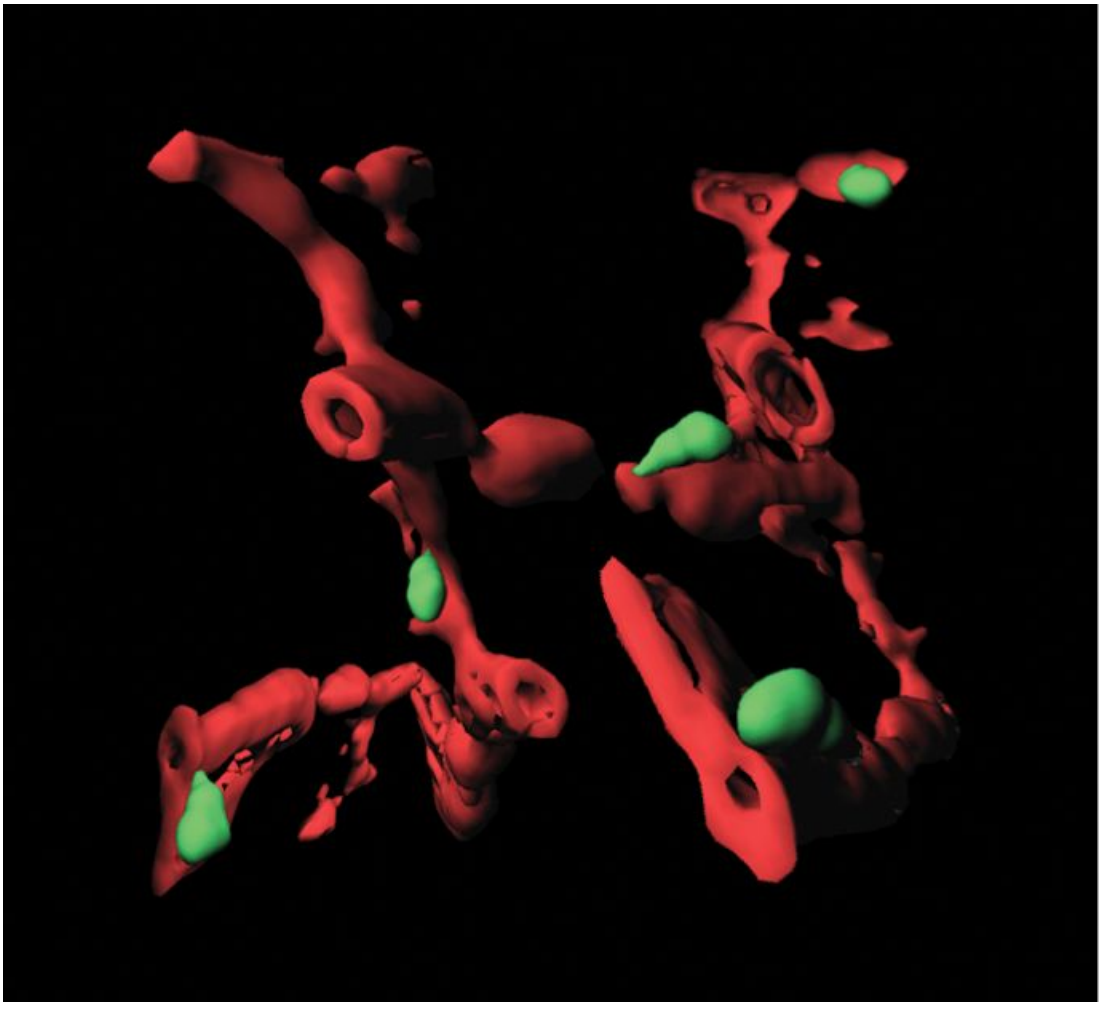
(B)



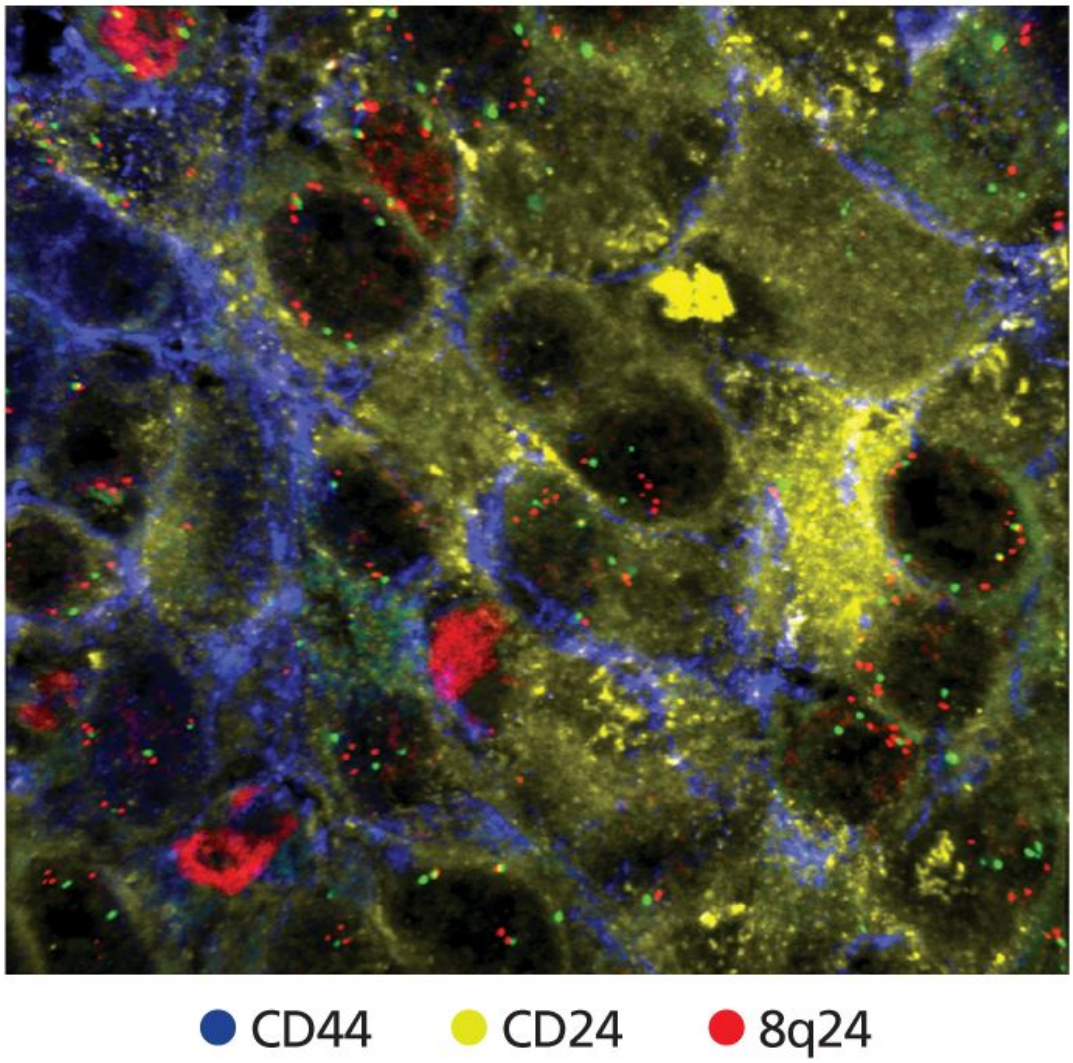
(C)

Figure S11.5 Demonstration of papilloma stem cells and derived differentiated cells As described in Section 11.11, papillomas and carcinomas can be induced in the mouse skin through the application of mutagenic initiators followed by tumor promoters, such as TPA. (A) The expression of a YFP reporter could be induced via an expression construct that confined all expression to the basal cells of the skin using the K14 (keratin 14) transcriptional promoter. This promoter drove expression of a Cre recombinase protein, which itself was generally functionally inactive because of its fusion with a tamoxifen-activatable ER (estrogen receptor). Transient application of tamoxifen would therefore transiently activate the Cre recombinase in basal keratinocytes, which would act, in turn, on a second construct encoding YFP (yellow fluorescent protein). This expression of YFP was usually blocked by an in-frame stop codon that prevented its translation. However, this stop codon could be excised via the transient

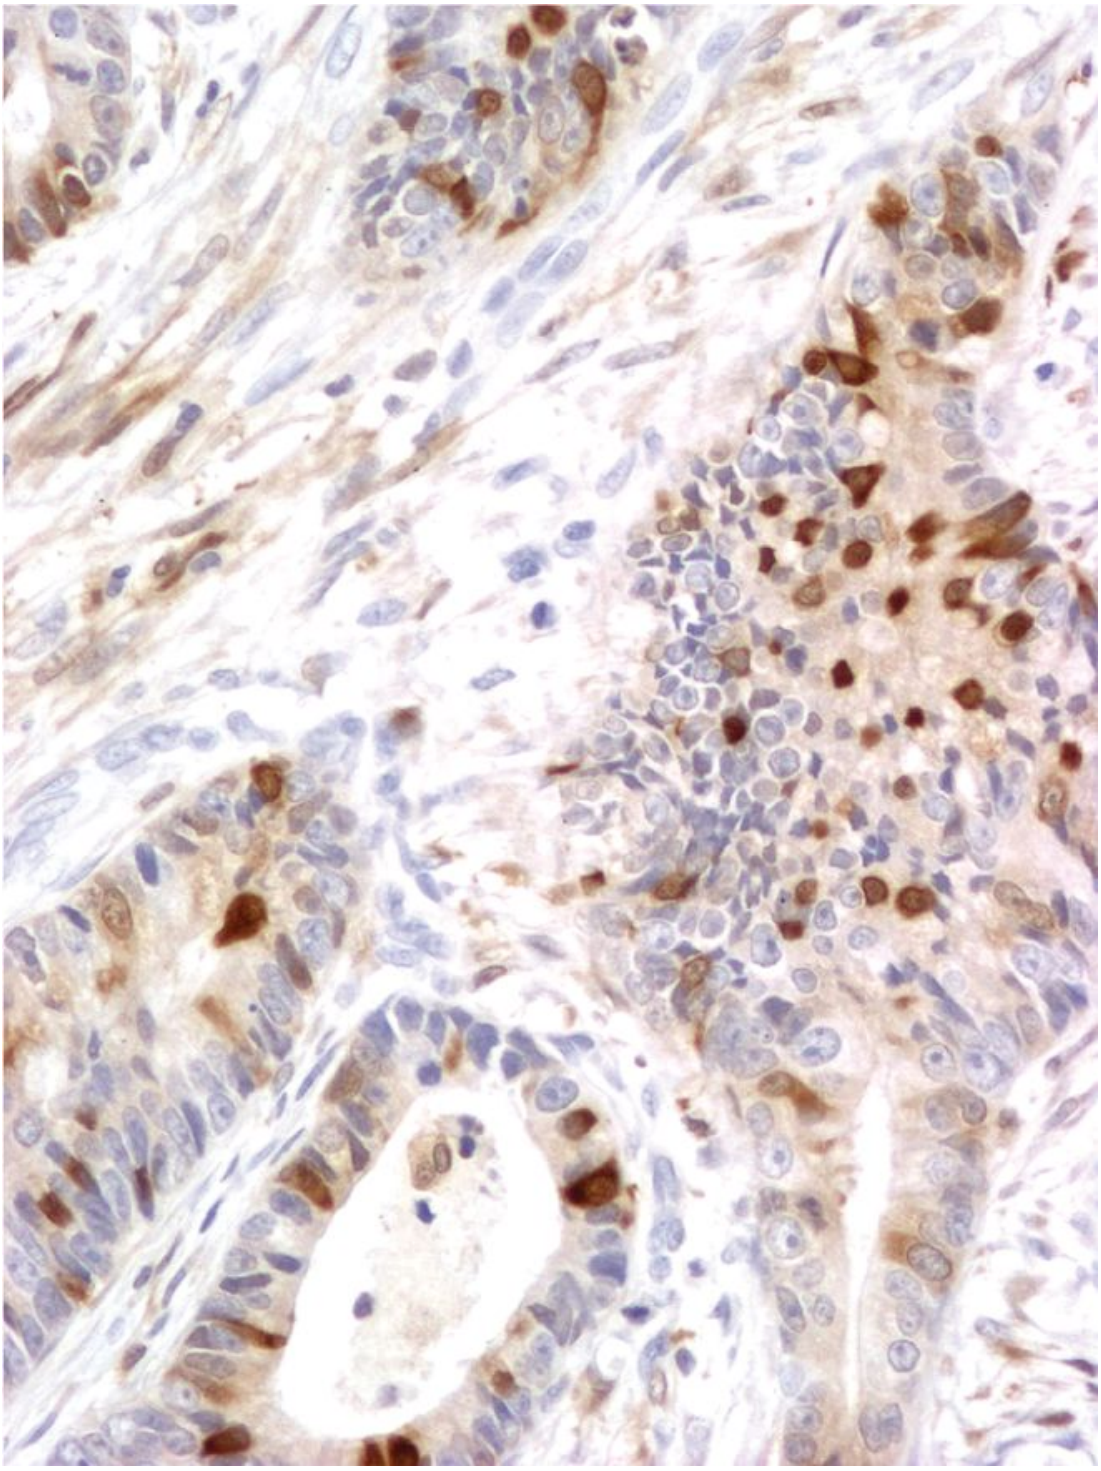
activation of the Cre recombinase protein in a basal cell, resulting in the permanent expression of YFP in that cell and in its lineal descendants. (B) Brief exposure of the basal keratinocytes in intact skin to limiting concentrations of tamoxifen resulted in the sporadic activation of YFP in scattered basal keratinocyte cells (*yellow-green*)—a cell population in which skin stem cells are known to reside. (C) Fourteen days after transient exposure to tamoxifen, YFP expression was detected in the skin through use of an anti-YFP antibody, that is, via immunofluorescence. As seen here, lineal descendants of the basal YFP-positive cells were capable of generating all cell types present in the papilloma, including the terminally differentiated, cornified cells that are present in these growths (*green*). (From G. Driessens, B. Beck, A. Caauwe et al. *Nature* 488, 527–530, 2012. With permission from Nature.)



(A)



(B)



(C)

Figure S11.6 Localization of cancer stem cells within tumors (A) In human gliomas, cancer cells that express nestin, a marker of normal neural stem cells (*green*), exhibit tumor-initiating ability when implanted in host mice and are

therefore termed cancer stem cells (CSCs). These nestin-positive cells are frequently localized near capillaries within these tumors, which express CD34, an endothelial cell marker (*red*). This 3-dimensional image was produced by digitally integrating the microscopic images from a succession of 50μm thick tumor sections. (B) In a lung metastasis of a human breast cancer, the CD44-high cells (*blue*), which are enriched in cancer stem cells (CSCs), are located in different subdomains from the CD24-high cells (*yellow*) that generally have low proportions of CSCs. [A probe for the 8q24 chromosomal region revealed extensive amplification of this region in a subset of these metastatic cells (*red*).] (C) Aldehyde dehydrogenase isoform 1 (ALDH1) has been found to be a useful marker for identifying a variety of normal and neoplastic stem cells. Here, an anti-ALDH1 antibody has been used to localize cells in a primary colon carcinoma that express high levels of this stem cell marker (*dark brown*). (A, from C. Calabrese et al., *Cancer Cell* 11:69–82, 2007. With permission from Elsevier. B, courtesy of H.-J. Kim and K. Polyak. C, from S. Deng et al., *PLoS One* 5:e10277, 2010. © 2010 Deng et al. Supplementary Sidebar 11.8 The Darwinian model of tumor development is difficult to validate experimentally

Although the Darwinian model of tumor development, as depicted schematically in Figure 11.14 is attractive in concept, it remains little more than a theoretical construct. The outlines of this model are undoubtedly true, but its details are very difficult to validate for a number of reasons. To begin, a convincing validation of the Darwinian model would require an identification of the key genetic and epigenetic alterations of cell genomes that are responsible for each clonal expansion and thus for each step of multi-step tumorigenesis. However, the vast number of these alterations accumulated in the genomes of tumors (see Section 11.6) greatly exceeds the number of *clonal successions* that drive tumor progression (see Figure 11.14). Consequently, sequence analyses of the genomes of cells at different states of tumor progression may not converge directly on the critical genetic changes that are responsible for triggering many clonal expansions.

A clear view of this Darwinian model also requires some knowledge of the *kinetics* of each step of the multi-step progression—that is, how long does each step take? Some of these steps, such as the point mutations that activate *ras* oncogenes, may occur with a frequency of 10^{-6} to 10^{-7} per cell generation, although other critical steps, such as loss of heterozygosity (LOH), seem to occur with frequencies 100- to 1000-fold higher. We still do not know with any precision the frequency per cell generation of other critical events, including promoter methylation (estimated by some to be as

frequent as 10^{-4} per cell generation), gene amplification, gene deletion, and losses of entire chromosomes. Hence, some steps of tumor progression may occur so rapidly (compared with others) that they will never be registered as “rate-limiting” steps, discussed in Section 11.1.

With rare exception, these phenomena make it almost impossible to measure the kinetics of individual steps of tumor progression, which in turn makes an enumeration of all the individual steps difficult if not impossible. In principle, the sequencing of entire cancer cell genomes, which has now become routine, offers the prospect of determining at least one key parameter with some precision: the minimum number of somatic mutations required to create a human cancer cell. Recall that driver mutations are by definition critical participants in tumor progression and can be identified because they affect genes that are the objects of recurrent mutations (see Section 11.6); each of these drivers would seem to represent a mutation that was followed by a clonal expansion of the resulting mutant cell and its progeny. With this in mind, one can use whole-genome sequencing to enumerate the number of driver mutations that coexist with the genome of a human cancer cell. Individual lung and colorectal carcinomas often carry five or six such mutations, suggesting this number of mutations as the minimum required for neoplastic growth. Unfortunately, some breast cancer genomes, sequenced in parallel, may give no sign of carrying such multiply mutated genomes. Moreover, the several dozen karyotypic alterations often found in some of these carcinomas represent another confounding element in these calculations. So, even the most advanced technologies do not offer the means to resolve definitively the dynamics of multi-step tumor progression.

Supplementary Sidebar 11.9 Organoids enable the reconstruction of intestinal crypt formation in culture

The invention of organoid culture has made it possible to generate more than a dozen distinct human tissue types on a microscopic scale in three-dimensional culture often with a gelatinous suspension medium including Matrigel, which contains the basement membrane extracellular matrix. In the case of the intestinal crypts, one can observe the morphogenesis of these structures *in vitro* that recapitulate the overall topology of these crypts, including the presence of Lgr+ stem cells and Paneth cells at the bottom and rapidly dividing transit-amplifying cells (**Figure S11.7**). Indeed, these complex structures can be formed from Lgr5+ stem cells that differentiate into the multiple distinct cell types that, in aggregate, are needed to construct these crypts *in vitro.* Because they approximate much more closely actual crypts formed *in vivo* (see Figure 7.20) than do cell culture models in two-dimensional spaces (that is, the bottom of Petri dishes), they can be used to test the requirements of transformation under

conditions that are likely to closely reflect the conditions operative during the formation of colorectal carcinomas.

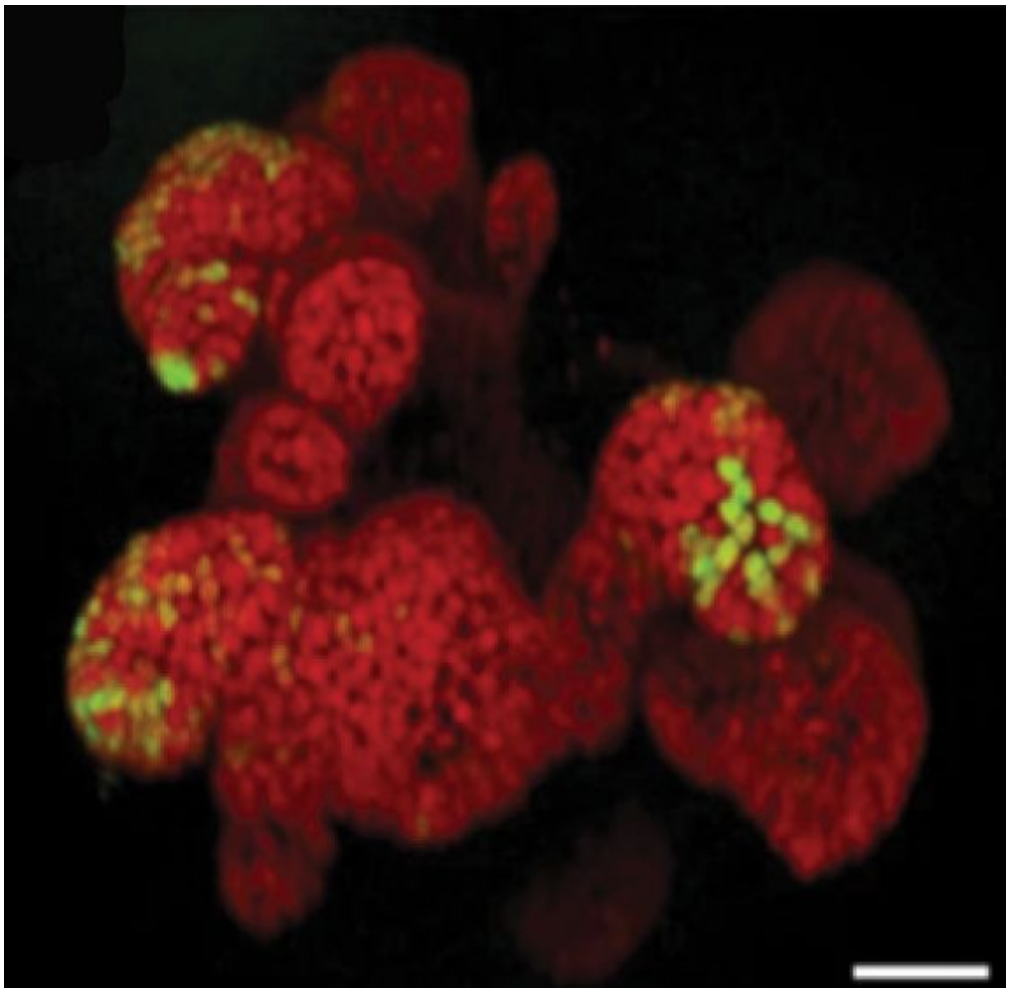

Figure S11.7 Morphogenesis of intestinal crypts from Lgr+ stem cells in organoid culture Structures that closely resemble the crypts found in the small and large intestine can be formed in organoid culture, involving special media in 3-dimensional culture *in vitro*. Such crypts contain the same cell types found in naturally arising crypts *in vivo* and can be used to study, among other processes, the requirements for transformation via mechanisms that are likely to recapitulate such requirements during colorectal carcinogenesis *in vivo*. As seen here, Lgr+ stem cells are labeled with green fluorescent protein (*green*), while all cells are labeled with a To-Pro counterstain (specific for nucleic acids) that renders them *red*. The Paneth cells and rapidly dividing transit-amplifying cells are not specifically labeled here. (From T. Sato et al., *Nature* 459:262–265, 2009. With permission from Nature.)

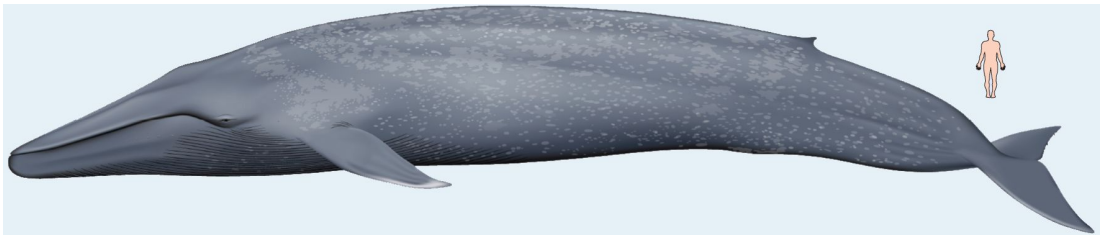
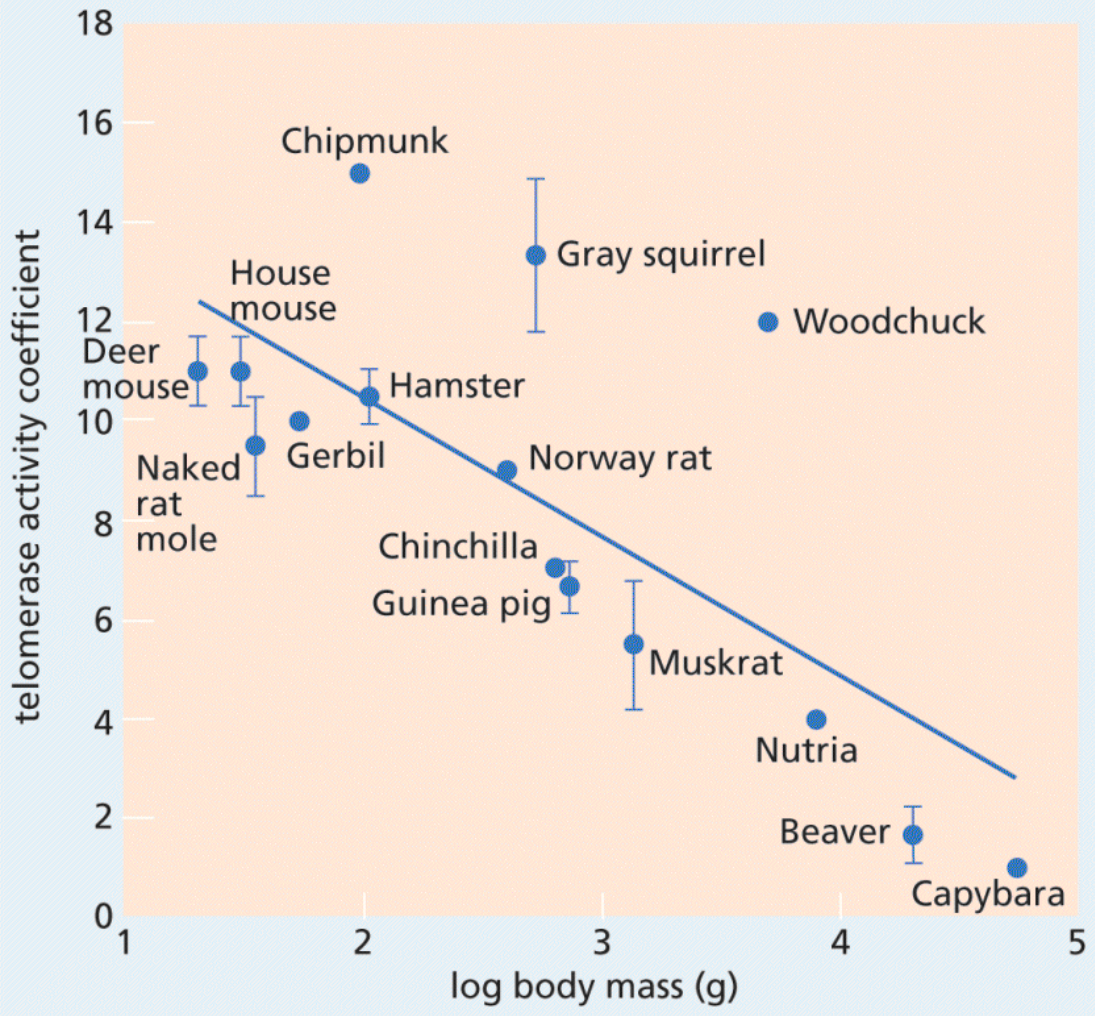
Supplementary Sidebar 11.10 Mammalian cells appear to reduce constitutive telomerase expression in order to forestall tumor outgrowth

The association between body size, longevity and constitutive telomerase expression levels first became apparent when examining telomere configuration in the cells of laboratory mice and humans, where striking disparities immediately became apparent. The normal cells of laboratory mice sport telomeres that may be as much as ten times longer than those of normal human cells and the murine cells express readily detectable levels of the telomerase holoenzyme which is virtually undetectable in corresponding normal cells (see Section 10.9). The differences in constitutive telomere lengths may be attributable to the level of the telomerase enzyme that is normally available to maintain them (although differing mechanisms of telomere degradation may also intervene). These associations deal only with two distantly related mammalian species and may not, on their own, convincingly demonstrate that limiting constitutive telomerase expression in somatic cells represents a mechanism enabling mammals to reduce the spontaneous eruption of tumors. The correlations shown in **Figure S11.8**, however, provide a more convincing case that this strategy has been employed repeatedly over the last 100 million years during the evolution and diversification of members of the order Rodentia, which are very similar to one another in overall body plan, but vary enormously in body size, ranging from mice that may have a mass of 20 g to capybara, which can weight 55 kg—a 2500-fold difference!

(A)



(B)



(C)

Figure S11.8 Mammalian body size, lifespan, and relative risk of cell transformation Although the sizes of individual cells are comparable in various mammalian species, the overall body mass and thus cell number vary enormously. Moreover, individuals in larger species generally live longer than those in smaller species. Because passage through each cell cycle creates the danger of genome alterations, the risks of cancer can vary enormously from one species to the next. (A) The bumblebee bat of Thailand (*top*), said to be the smallest mammal, weighs just 1.5 g, a bit less than the Etruscan shrew (*bottom*); the life span of the bumblebee bat is unknown, whereas that of the Etruscan shrew is thought to be ~2 years. Etruscan shrews reach reproductive age by 3–4 weeks (in contrast to ~12–15 years in humans). (B) The blue whale has a body weight of about 1.3×10^8 g, reaches sexual maturity in 5–10 years and has a life span of about 80 years, much like that of humans (*lower right*). The eight-orders-of-magnitude difference in mass (and therefore cell number) between the bat and the whale together with

the approximately 40-fold difference in lifespan suggests a difference of more than 10^9 in the number of cell divisions that the two organisms experience in a lifetime. (Because the metabolic rate of the small mammals may be as much as 10^3 times higher than the whale's, and because much of the mutational burden of the cell genome derives from by-products of oxidative metabolism, the blue whale may experience only a 10^6-fold in higher intrinsic cancer risk of cancer than the bat.) (C) The relative activity levels of telomerase have been measured as seen here in the normal cells of 14 different rodent species. The clearly observed negative correlation between basal telomerase rate in normal cells and overall body mass adds evidence to the argument that limitations in telomerase activity represent one mechanism in a mammal to reduce the likelihood of cancers arising in its tissues. (A, MerlinTuttle.org/Science Source, and © Dr. Carleton Ray/Science Source. B, courtesy of Uko Gorter. C, from V. Gorbunova, A. Seluanov, Z. Zhang et al., *Nature Rev. Genet.* 15, 531–540, 2014. With permission from Nature.)

Supplementary Sidebar 11.11 Why do pediatric tumors carry so few mutant driver genes?

The documented simplicity of the spectrum of mutant driver genes present in individual pediatric cancers requires explanation, much like the documented differences between mouse and human cell transformation (see Section 11.8). One explanation is that the tissues that develop into pediatric tumors contain small numbers of target cells compared to the corresponding adult tissues and these tumors develop quickly relative to the decades-long development of many adult tumors, that is, they simply do not have the time to accumulate a significant cohort of mutant driver genes. In addition, another argument echoes the logic of why the cells of various mammalian species are more or less readily transformed by introduced oncogenes (see Figure 11.28). Imagine that (1) the small mass of the human fetus averaged over the course of gestation relative to the mass of a fully grown adult (possibly two orders-of-magnitude fewer cells) and (2) the shorter overall elapsed lifetime of the fetus (also two orders-of-magnitude lower), predicts as much as a 10,000-fold smaller cumulative number of fetal cell divisions and a proportionately lower intrinsic risk of cancer development. This "back of the envelope" calculation would dictate, in turn, that fewer layers of anti-cancer biological defenses established in fetal cells should suffice to ward off cancer during the course of gestation. This logic might be invoked to explain the successful formation of pediatric tumors (which are often initiated in fetal cells) bearing only very low numbers of mutationally activated driver genes in their genomes. If so, the mechanisms developed over the course of mammalian evolution to cope with prenatal cancer risk prenatally in mammals may actually have been quite different from those mechanisms that developed to protect adult mammals. One

prediction of this logic, which may have never been tested, is that transfection experiments of the sort used to measure the complexity of transformation (see Figure 11.28) have never been applied to cultured embryonic or fetal cells.

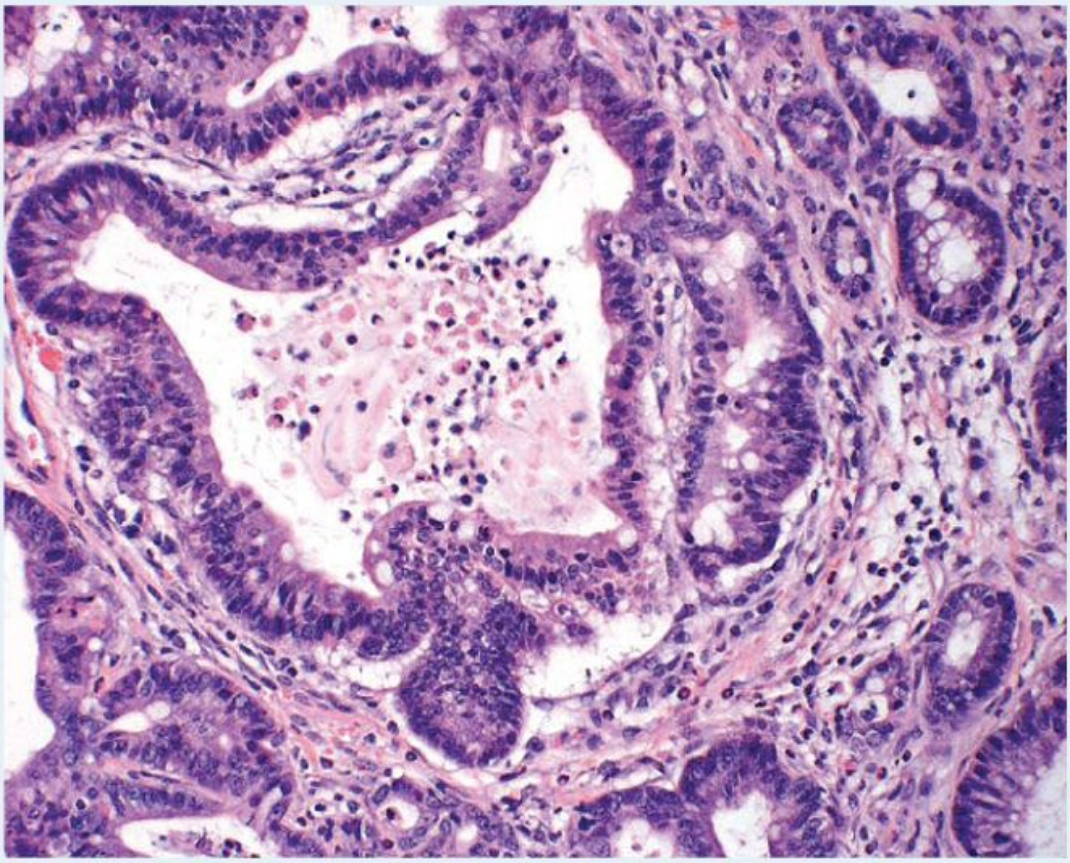
There is, actually, another perspective that may shed light on the conundrum created by pediatric tumors, this one coming from the notion that "ontogeny recapitulates phylogeny." This maxim was coined in the middle of the nineteenth century, being inspired at the time by the observation that the embryos and fetuses of diverse but evolutionarily related species share many morphological features, ostensibly residues of their common evolutionary ancestry. (Although parts of this notion have survived, the study of the details of embryonic development has revealed many deviations from its predictions.) Thus, there appears to be a parallel between the genetic requirements for tumorigenicity and the evolution of metazoan complexity starting with (1) the smallest common ancestor of metazoa (a single-cell eukaryote) and its possible analog in mammals, the ES cell (zero mutant alleles required for tumorigenesis); proceeding to (2) the small, short-lived mammals from which we descend (mutant alleles of two genes being required); and further to (3) adult humans (five mutant genes or signaling pathways needed). In this sense, quite possibly, the echoes of our evolution toward increasing size, life span, and organismic complexity over the past 1.5 billion years seem to be reflected in the increasing numbers of genes required to transform our cells during the course of our own development from an early embryo to a fetus to a newborn child and, eventually, to an adult.

Supplementary Sidebar 11.12 The gut microbiome functions as a tumor-promoting mechanism

An illustration of the prominent role that inflammation plays in colon carcinoma formation has come from the study of mutant mice that lack the ability to make TGF-β1 (which acts, among its diverse functions, to keep various types of immune cells under control, doing so in part through its ability to stimulate formation of the critically important immunosuppressive regulatory T-cells described in Chapters 15 and 16). Such mutant mice tend to develop a lethal autoimmune disease, which results in their death several weeks after birth. In order to spare these mice an early death, their immune systems were crippled by germ-line inactivation of their *Rag2* gene copies, a loss that prevents the formation of the antigen-specific lymphocytes that trigger autoimmune disease as described in Chapter 15. The doubly mutant mice ($Tgfb1^{-/-}Rag2^{-/-}$) now survived far longer but developed areas of inflammation in the colon, as well as colonic adenomas and frank adenocarcinomas, at between 3 and 6 months of age. However, if these doubly mutant mice were reared in a germ-free environment (which yields colons free of the usual bacterial populations), no colonic inflammation was seen and neither adenomas nor adenocarcinomas developed. In a

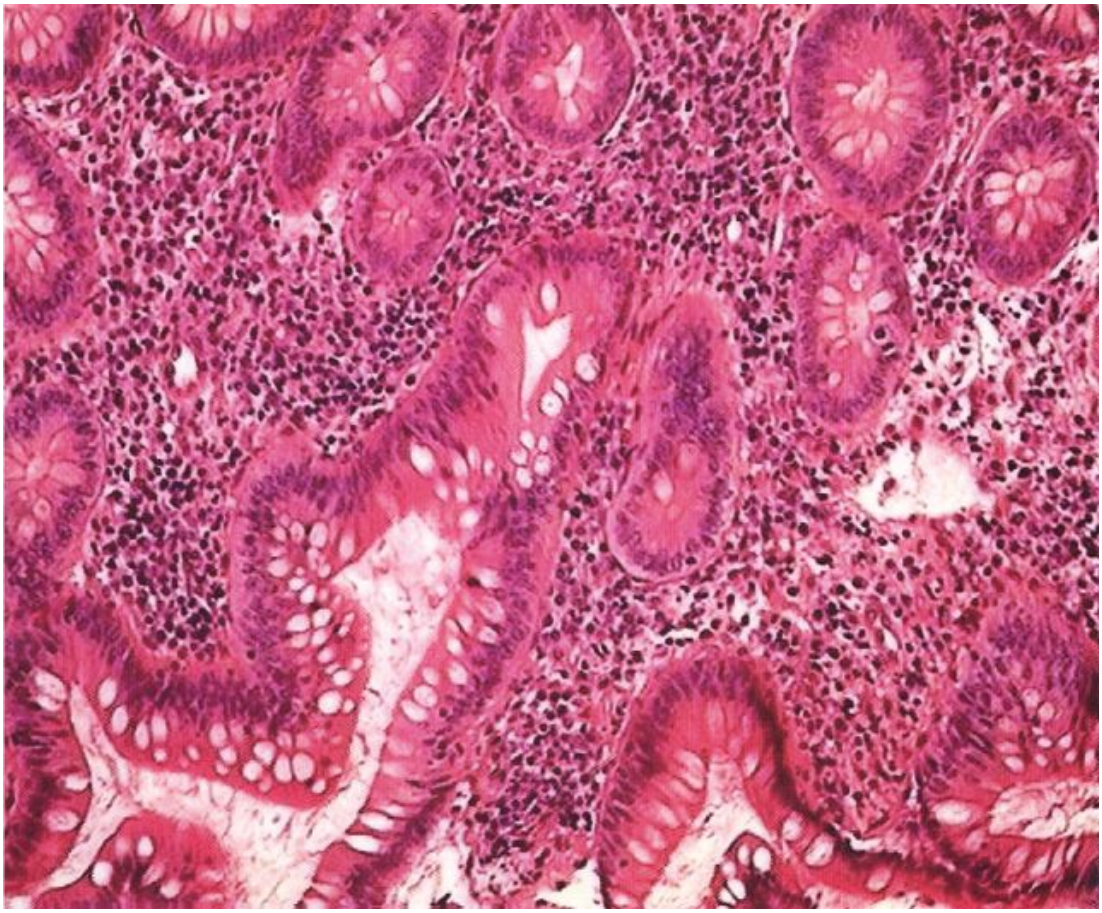
control experiment, when such germ-free mice were introduced into animal quarters harboring *Helicobacter hepaticus* (a bacterium often present in the mouse gut that induces inflammation), once again polyps and carcinomas formed in their colons (**Figure S11.9A and B**). Observations like these indicate that bacterial flora in the gut contribute importantly to inflammation, such as the condition observed in humans suffering from ulcerative colitis, an inflammatory condition that predisposes to colon cancer (for example, Figure S11.9C). Moreover, they suggest but hardly prove that localized areas of colonic inflammation in otherwise-normal individuals contribute to the formation of adenomatous polyps that can eventually progress to carcinomas.

(A)



infected with *Helicobacter hepaticus*

(B)



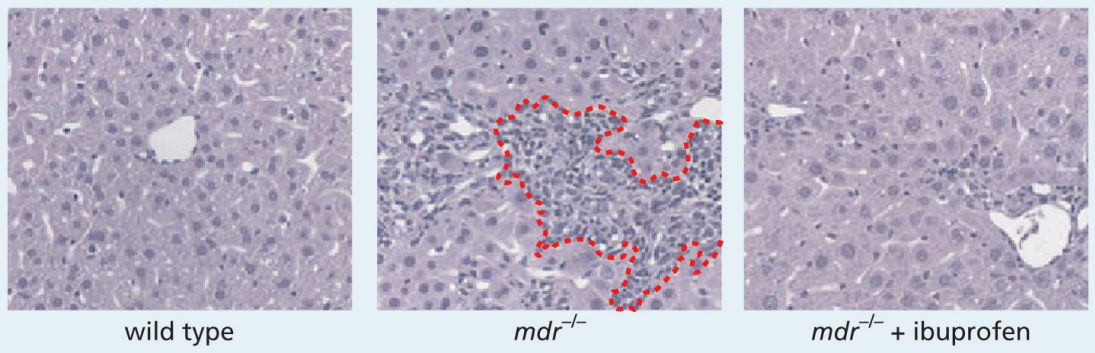
(C)

Figure S11.9 Colonic inflammation and tumor promotion The development of adenomas and carcinomas in the colon depends strongly on chronic inflammation occurring in this organ. Thus, genetically altered mice that lack the ability to make TGF-β1 (which acts to suppress certain types of immune reactions) succumb early in life to overwhelming autoimmune disease. (A) However, if their immune system is crippled through the inactivation in their germ line of the gene encoding the Rag-2 enzyme, which is required for generating functional antibody and T-cell receptor genes (see Chapter 15), these mice survive when they are housed in a germ-free (that is, sterile) facility. Under such conditions, their intestinal epithelium is quite normal histologically. (B) In contrast, if these doubly mutant mice are housed in a facility in which *Helicobacter hepaticus* bacteria are present, their colons become infected with these bacteria and they develop adenomas and carcinomas. This indicates that the chronic inflammation created by these intestinal bacteria is essential to the formation of the observed colonic lesions. (C) Human ulcerative colitis involves chronic inflammation of regions of the colonic mucosa, which leads after many years to substantially increased risk of colon carcinoma. In this condition, the stromal areas between the colonic crypts are

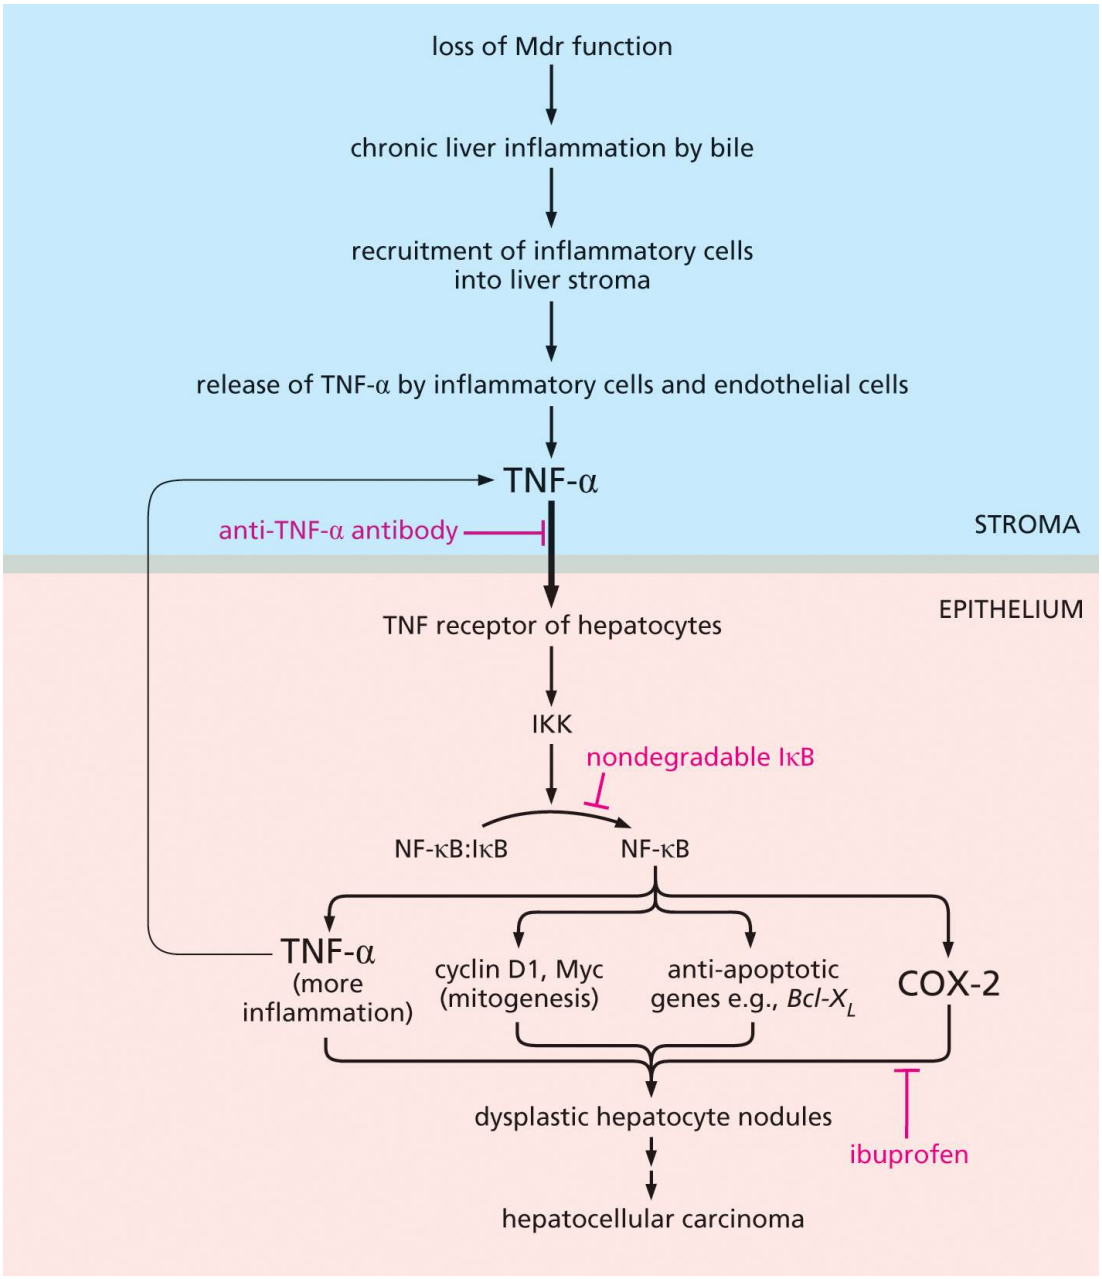
infiltrated with large numbers of lymphocytes, which are associated with inflammation (*small, dark purple nuclei*). (A and B, from S.J. Engle et al., *Cancer Res.* 62:6362–6366, 2002. With permission from American Association for Cancer Research. C, courtesy of D. Lamarque.)

Supplementary Sidebar 11.13 Experimentally induced inflammation in the liver drives tumorigenesis

In another illustrative mouse tumor model, liver carcinogenesis was provoked through deletion of the *Mdr* (multi-drug resistance) gene in the mouse germ line; loss of this gene and its encoded product leads to accumulation of toxic bile acids in the liver and resulting chronic liver inflammation. Affected mice develop nodules of dysplastic hepatocytes, localized hepatocellular carcinomas (HCCs), and eventually metastatic HCCs (**Figure S11.10A**).



(A)



(B)

Figure S11.10 Experimentally induced inflammation acts via NF-KB to induce hepatocellular carcinomas In one mouse model of liver carcinogenesis, deletion of the *mdr* (multi-drug resistance) gene causes chronic liver inflammation, which generates dysplastic foci among the hepatocytes, some of which progress to form hepatocellular carcinomas. (A) An infiltrate of inflammatory cells in the liver of an *mdr*$^{-/-}$ mouse (*outlined*, *center panel*) contrasts with cells in the normal liver (*left panel*) and the liver of an *mdr*$^{-/-}$ mouse that has been treated with a potent anti-inflammatory drug, ibuprofen (*right*

panel). Such areas of inflammatory infiltrate appear to be critical to the formation of dysplastic foci and thus to the subsequent formation of hepatic carcinomas. (B) This diagram summarizes the sequence of changes that appear to generate hepatocellular carcinomas (HCCs) in this mouse model. Loss of the *mdr* gene leads to an accumulation of bile acids that induce a state of chronic liver inflammation; this attracts inflammatory cells to the liver stroma that proceed to release TNF-α. This ligand impinges on the TNF receptors (see Figure 9.29) displayed by hepatocytes within the liver's epithelial compartment. The TNF receptors respond by activating IKK, which induces NF-κB signaling, which then drives expression of anti-apoptotic genes (such as *bcl-*x_L), proliferative genes (such as the one encoding cyclin D1), and the gene specifying TNF-α; expression of additional TNF-α leads to amplification of the inflammatory response. Together, the proteins encoded by these genes facilitate the progression of the dysplastic nodules to hepatocellular carcinomas. This progression can be blocked by antibodies reactive with TNF-α as well as a dominant-negative, nondegradable IκB. (The precise identities of the inflammatory cells that are recruited to the stroma and that are responsible for signaling to the hepatocytes are unclear, in part because they represent a complex mixture of macrophages; T cells, including NKT cells, cytotoxic T cells, and T_{regs}; NK cells; myofibroblasts; and, frequently, B cells, neutrophils, and plasma cells.) (A, from E. Pikarsky et al., *Nature* 431:461–466, 2004. With permission from Nature.)

In the livers of these mice, TNF-α is initially produced by inflamed endothelial cells as well as infiltrating inflammatory immune cells, such as neutrophils and macrophages, in the stroma. The released TNF-α acts in a paracrine manner on nearby hepatocytes, which display receptors for TNF-α. Like PKC-α in keratinocytes, the ligand-activated TNF-α receptor of these hepatocytes funnels signals through the NF-κB pathway (see Section 6.12). As described above, NF-κB is dispatched to the nucleus, where it activates anti-apoptotic genes and genes favoring proliferation including, in this case, the TNF-α gene. The resulting TNF-α, once released by hepatocytes, attracts more inflammatory cells through *paracrine* signaling and amplifies hepatocyte NF-κB signaling through *autocrine* signaling.

When NF-κB signaling was blocked in the hepatocytes of the $mdr^{-/-}$ mice through treatment with a non-steroidal anti-inflammatory drug (see Figure S11.10A), tumor incidence was strongly suppressed. This inhibition of signaling could also be achieved through the introduction of an anti-TNF-α antibody into the $mdr^{-/-}$ mice (which blocked the paracrine signaling between inflammatory stromal cells and hepatocytes) or by expressing a nondegradable IκB in the hepatocytes (which inhibited NF-κB activation). In both cases, loss of NF-κB signaling resulted in greatly increased rates of apoptosis in the pre-neoplastic hepatocytes (see also Figure 11.36).

Indeed, prevention of apoptosis likely explains much of the tumor-promoting effect of inflammation in this mouse model. Interestingly, shutdown of NF-κB signaling in hepatocytes did not prevent the early steps of liver tumor progression—hepatitis, tumor initiation, and the development of dysplasia—but the subsequent progression of dysplastic tissue to hepatocellular carcinoma was blocked. Hence, in this experimental model, TNF-α and NF-κB are involved in promotion and not in the earlier stages of initiation.

A similar conclusion was reached in studies of a mouse model of colitis-associated colon cancer: inactivation of IKK signaling led to greatly increased rates of apoptosis in pre-cancerous enterocytes—the epithelial cells lining the colon. Without NF-κB signaling, these cells failed to express elevated levels of the potently anti-apoptotic Bcl-X_L (see Figure 9.23C) and instead produced high levels of the pro-apoptotic Bax and Bak proteins. Once again, some of the tumor-promoting effects of NF-κB could be traced to its ability to protect initiated epithelial cells from apoptosis.

These descriptions indicate that NF-κB signaling is highly active in the epithelial cells of inflamed tissues (for example, hepatocytes in the liver or enterocytes in the colon). The inflammation is created by inflammatory cells of the immune system (notably macrophages, neutrophils, eosinophils, mast cells, and lymphocytes) that are recruited into the stromal compartments of these tissues, where they release pro-inflammatory signals. Importantly, the NF-κB pathway also operates within these stromal immune cells, enabling them to release pro-inflammatory signals such as TNF-α. These interactions operating in the liver are summarized in Figure S11.10B). Moreover, in the above-cited model of colitis and colorectal cancer, shutdown of IKK signaling in the inflammatory immune cells of the intestinal stroma also led to a significant suppression of colorectal tumor formation.

Supplementary Sidebar 11.14 Evidence supporting the key role of COX-2 and PGE2 in the tumor-promoting inflammatory response

The observations that reduction of incidence of multiple cancer types through use of NSAIDs (non-steroidal anti-inflammatory drugs) requires explanation because these responses represent some of the most compelling demonstrations of the role of inflammation in cancer pathogenesis and, at the same time, appear to suggest a future strategy designed to develop drugs to prevent certain types of cancer.

The signaling pathways illustrated in Figure S11.10B provide no clue to the biochemical actions of the most commonly used NSAID, acetylsalicylic acid, that is, aspirin. Insight here requires discussion of its protein target, the enzyme cyclooxygenase-2, its mechanism-of-action, and the role of aspirin in inhibiting this enzyme. The substrates of COX-2 are two prostaglandins that are generated through

the metabolism of arachidonic acid (**Figure S11.11A**). The overall molecular structure of the COX-2 enzyme indicates a homodimeric enzyme with well-localized sites of action (Figure S11.11B). The catalytic clefts of the enzyme are obstructed by acetylation of a critical serine residue lining this cleft and triggered by hydrolysis of aspirin/acetylsalicylic acid (Figure S11.11C). (Not shown here is the action of another commonly used NSAID, ibuprofen, which also acts by inhibiting COX-2; being less selective than aspirin, ibuprofen also inhibits COX-1.)

Figure S11.11 Prostaglandin metabolism and the actions of anti-inflammatory drugs The profound effects of anti-inflammatory drugs in suppressing the incidence of a variety of commonly occurring carcinomas result from their ability to inhibit the catalytic activity of the cyclooxygenase-2 (COX-2) enzyme (sometimes called prostaglandin H_2 synthase), see Figure 11.36. COX-2 is induced in many tissues in response to inflammatory stimuli. (A) Prostaglandins derive from the metabolism of arachidonic acid, which itself is generated through the actions of phospholipase A2, which liberates it from the plasma membrane into the cytosol. The two distinct catalytic activities of COX-2 involve its participation in two sequential steps in this pathway that result in the conversion of arachidonic acid into prostaglandin H_2. The latter is metabolized to prostaglandin E_2 (PGE_2; *red*), which evokes many of the tumor-promoting, pro-inflammatory responses described here. The PGDH (15-hydroxyprostaglandin

dehydrogenase) enzyme (also termed hydroxyprostaglandin dehydrogenase, HPGD) degrades PGE_2 into 15-keto-prostaglandin E_2, which is presumed to be inactive. (B) The catalytic sites of COX-2, a homodimer, that convert arachidonic acid to prostaglandin G_2, are largely inactivated by the most commonly used anti-inflammatory drug—aspirin (acetylsalicylic acid)—which acetylates (*yellow balls* and *arrows*) serine 530 of COX-2 and leaves the salicylate moiety weakly bound in the catalytic cleft (*orange balls* and *arrows*). α-helices (*teal*), inter-helix loops (*gray*), β-pleated sheets (*light green*), heme group (*red*). (C) In more detail, the acetylation of serine 530 by aspirin obstructs the catalytic cleft and thus the enzymatic activity of COX-2, which is responsible for converting arachidonic acid to the precursor of all prostanoids, prostaglandin G_2; the latter is then converted further to prostaglandin H_2 by a second site in the COX-2 enzyme. (B and C, courtesy of R.M. Garavito.)

The biological function of celecoxib, another NSAID that inhibits COX-2, is revealed dramatically by its effects on the development of mammary carcinomas in a transgenic mouse model that drives cancer formation through the actions of a transgene-encoded polyomavirus middle T oncoprotein; this oncoprotein functions to transform cells through its ability to bind and activate, among other cellular proteins, the c-Src tyrosine kinase enzyme described in Chapter 3. As indicated, acetylsalicylic acid exposure triggers apoptosis of carcinoma cells (**Figure S11.12A**) and concomitantly inhibits their proliferation (Figure S11.12B). The modulation of the pro-inflammatory PGE_2 molecule is achieved in significant part through changes in the levels of the PGE_2-degrading enzyme termed PGDH (**Figure S11.13A and B**). Reduced levels of PGDH can result in greatly increased intracellular levels of PGE_2, which in turn can evoke a variety of dramatic biological responses, one of which is revealed here in a mouse model of the adenomatous polyposis coli (APC) syndrome described in Section 7.10 (Figure S11.13C).

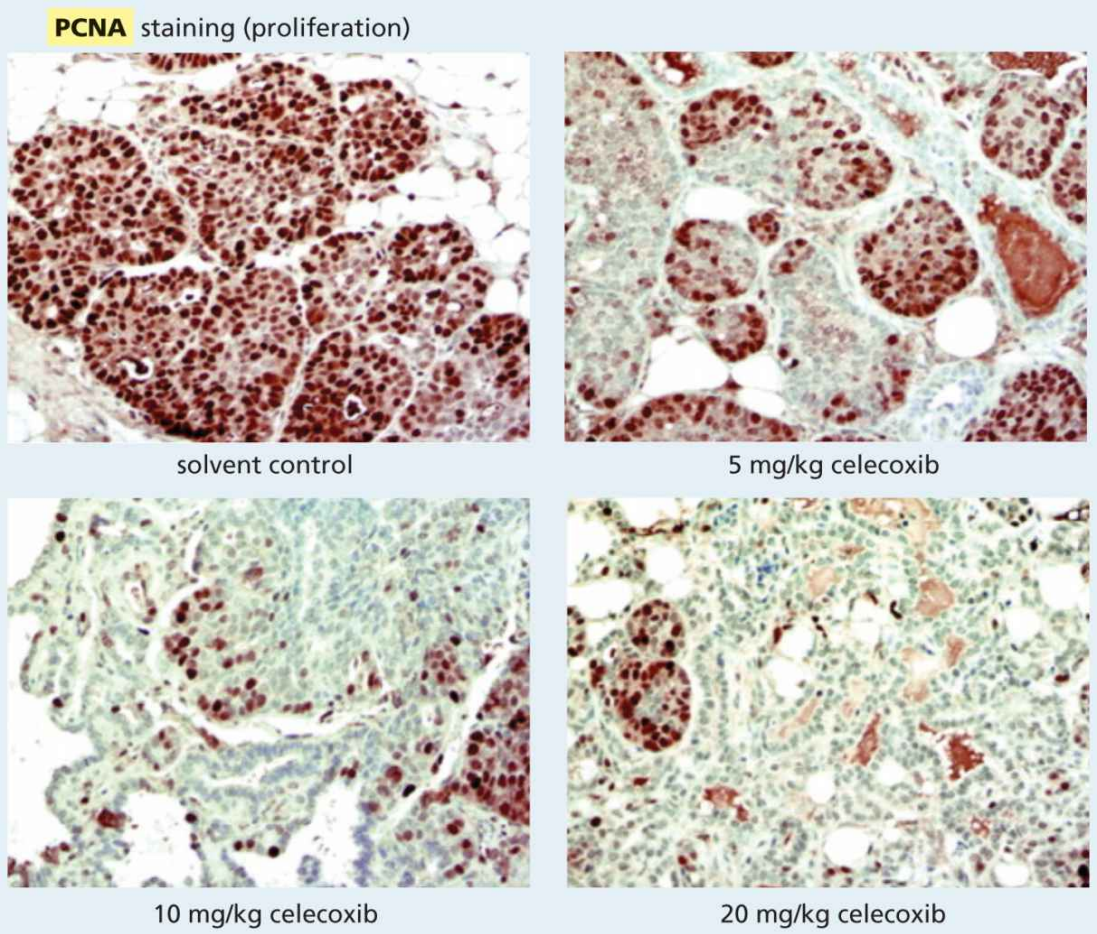
(A)



(B)

Figure S11.12 COX-2 inhibition in mammary carcinomas of tumor-prone transgenic mice In a transgenic mouse model of mammary carcinoma pathogenesis, the development of tumors is driven by the transgene-encoded polyomavirus middle T oncoprotein. Tumor formation is strongly reduced by treatment with celecoxib, another NSAID that is a potent and selective inhibitor of cyclooxygenase-2 (COX-2). It acts in two complementary ways by inducing increased apoptosis and reducing cell proliferation. (A) As indicated here, increasing doses of this drug generate progressively higher numbers of tumor cells (*light green*) that stain with the TUNEL assay (*dark brown spots*; see Figure 9.18), which marks cells in the midst of apoptosis. In this case, the proportion of tumor cells that are TUNEL-positive provides an indication of the extent of apoptosis induction. (B) Acting in a complementary fashion, increasing concentrations of celecoxib lead to decreasing cell proliferation, as revealed by staining (*dark red*) for PCNA (proliferating-cell nuclear antigen), a marker of cell cycle progression. Celecoxib doses are presented as milligrams of drug per kilogram of body weight.

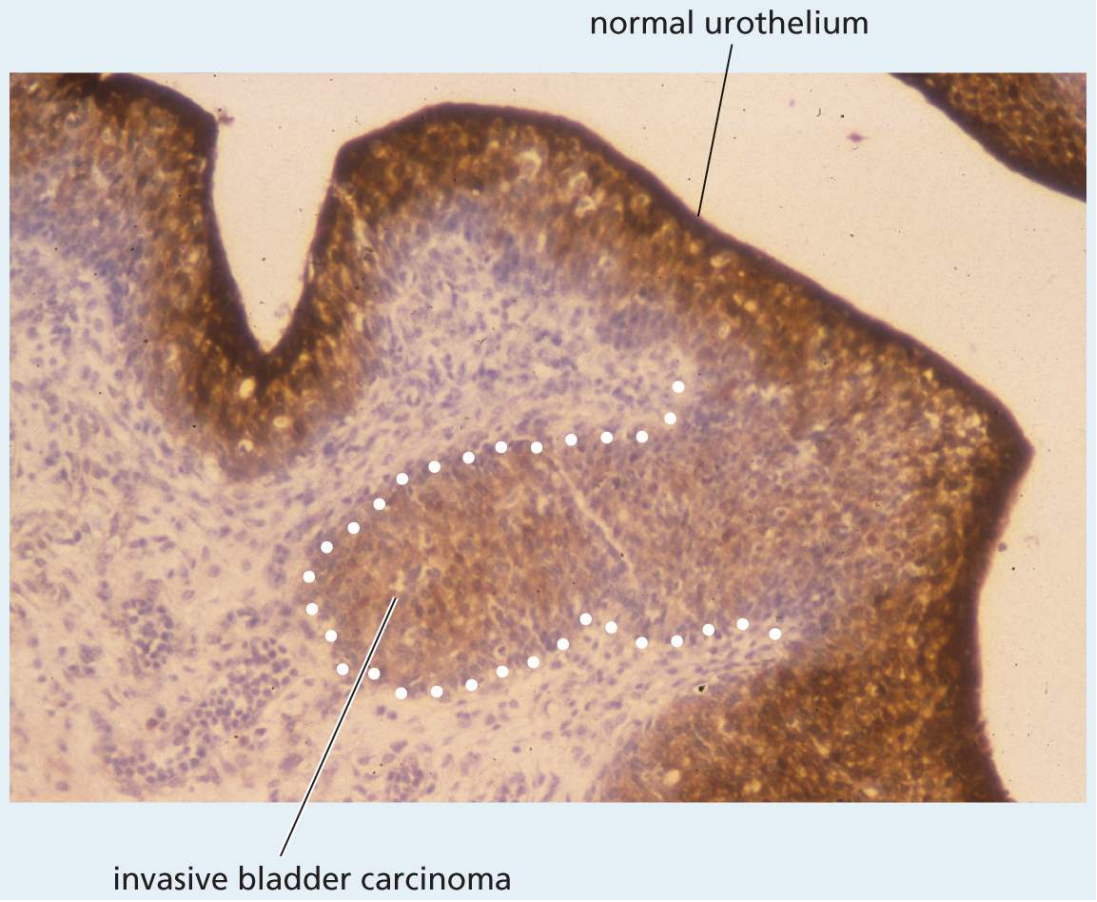
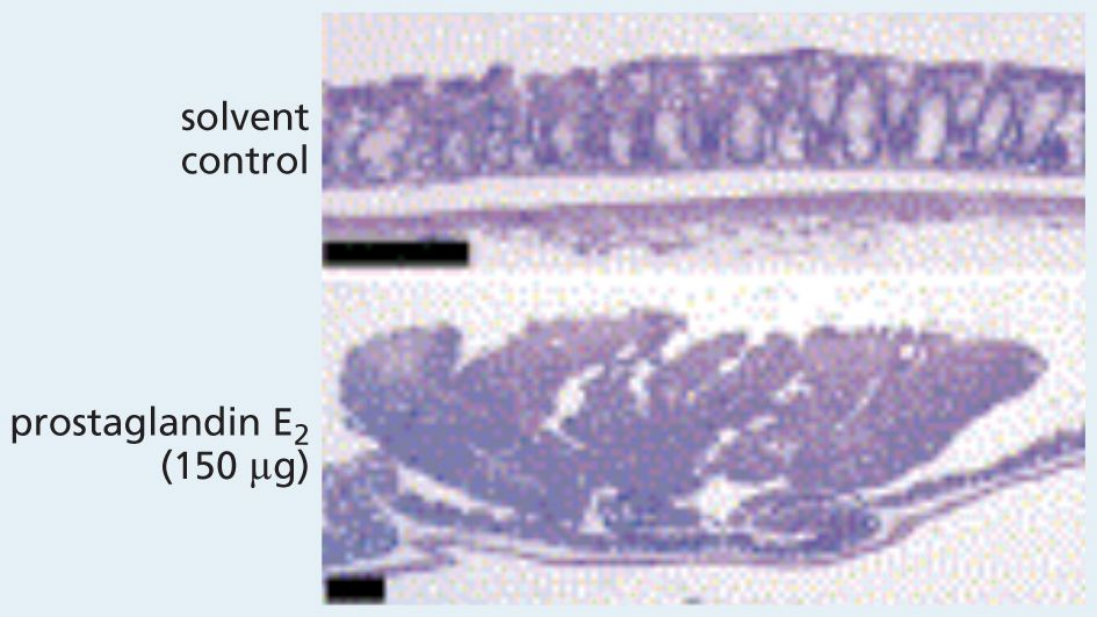
(A)



(B)



(C)

Figure S11.13 Biological effects of elevated prostaglandin E_2 levels and regulation of these levels by the PGDH PGE_2-degrading enzyme The levels of PGE_2 can be modulated in various ways, resulting in increased rates of tumor progression. (A) In general, these levels are dictated by the rates of its synthesis by COX-2 and its degradation by PGDH (see Figure S11.11A). In many carcinomas, increased COX-2 levels in the stroma and epithelium are complemented by reduced levels of the PGDH—the PGE_2-degrading enzyme—in the epithelial compartment. Indeed, PGDH expression is depressed in the majority of lung, colon, breast, and bladder carcinomas. As seen here, PGDH (*dark stain*) is strongly expressed in the normal enterocytes facing the lumen of the colon (*left*) while being undetectable in a colon carcinoma that arose nearby (*right*). (B) Similarly, the intense expression of PGDH (*dark brown*) in the normal urothelium (the epithelial lining of the bladder) contrasts with the almost-total loss of this PGE_2-degrading enzyme in a tongue of invasive carcinoma cells. (C) Increases in PGE_2 levels can be achieved experimentally by feeding this prostaglandin to mice of the *Apc* mutant strain (see Section 7.10). This causes a dramatic increase in the number of colonic polyps (*below*) compared with those seen in control *Apc* mutant mice (*above*). The size bars indicate the relative magnification of the two panels. (A, from M. Yan et al., *Proc. Natl. Acad. Sci. USA* 101:17468–17473, 2004. Glossary

incidence
: Frequency with which a condition or a disease occurs or is diagnosed in a population.

rate-limiting
: Referring to a step in a multi-step process that governs the overall rate at which the process as a whole reaches completion because this particular step is kinetically slower than all other steps.

vasculogenic mimicry
: The process that enables the neoplastic cells within a tumor to assemble into blood-carrying microvessels without these cells becoming *bona fide* endothelial cells.

Matrigel
: A preparation of ECM components, largely of basement membrane origin, that is secreted by mouse sarcoma cells and is often used as a gelatinous matrix in which to suspend cells in three-dimensional culture.

prenatal
: Occurring before birth. *See also* **natal**.

ontogeny
: The developmental history of an individual organism.

phylogeny
: The evolutionary history and development of a species.

celecoxib
: A clinically employed nonsteroidal anti-inflammatory drug that strongly inhibits the COX-2 enzyme.

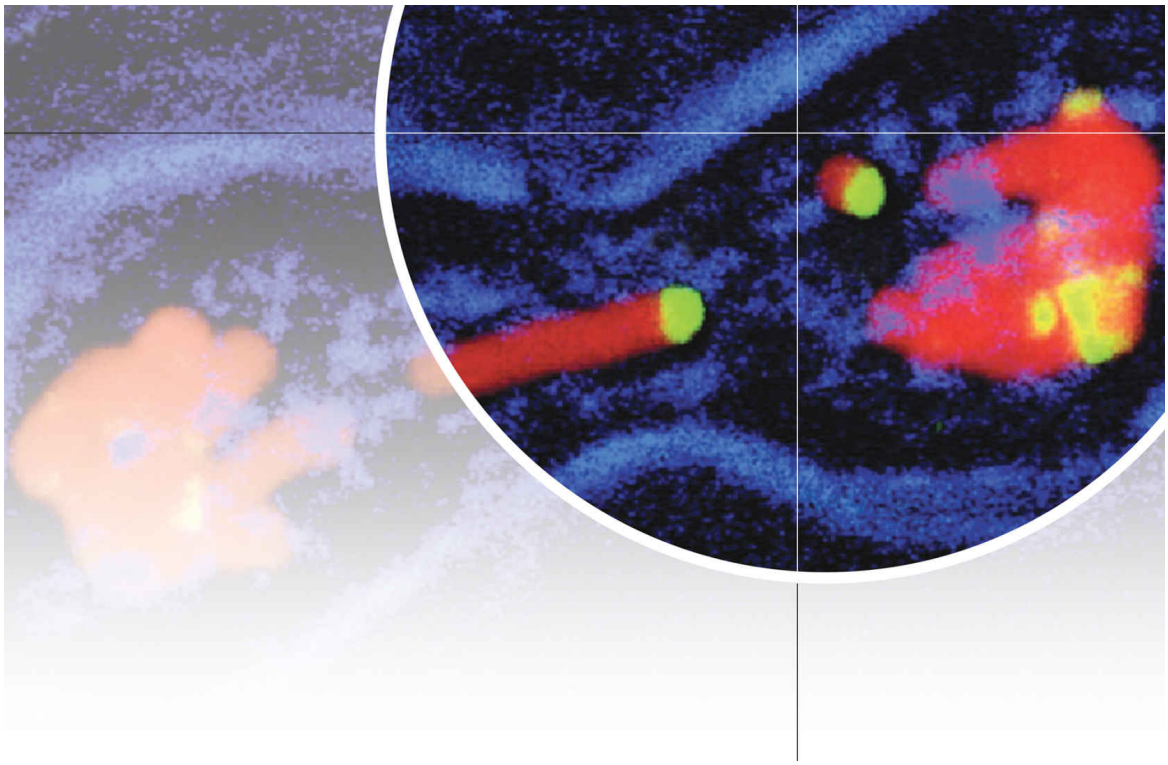
Chapter 12
Shaping and Characterizing the Cancer Genome



A fluorescence microscopy image of loose D N A fragments in a cell approaching the end of the cell division process.

> The capacity to blunder slightly is the real marvel of DNA. Without this special attribute, we would still be anaerobic bacteria and there would be no music.
>
> Lewis Thomas, biologist, 1979

The fact that human tumor formation is a complex, multi-step process reflects the multiple lines of defense against cancer that have been established within our cells, each maintained by the hard-wiring of a complex regulatory circuit. The

human body—actually, its individual cells—entrusts the maintenance of these anti-cancer defenses to its most stable, reliable constituents: DNA molecules. Over extended periods of time, DNA sequences are the most fixed, unchangeable components of cells; most of their other parts are in constant flux, being created and broken down continuously. Despite the inherent stability of DNA, however, the lifelong requirement for DNA replication provides ample opportunity for DNA damage and the accumulation of cancer-associated mutations that drive tumorigenesis.

By current estimates, an adult human has approximately 4×10^{13} cells. In some tissues, such as the brain, there is relatively little cellular turnover and thus relatively little need for cell division. However, in highly regenerative tissues such as the intestine, the skin, or the blood, our bodies are producing cells at a remarkable rate. Indeed, by one estimate we produce approximately 80 billion new cells every hour of every day. Prior to each division, the mother cell is charged with faithfully duplicating its chromosomal DNA in the S phase of the cell cycle and accurately segregating it to the daughter cells in M phase. Given that the total length of the decondensed chromosomes of a single cell is about 2 meters, every hour we make an aggregate of approximately 160 billion meters of DNA! This is enough DNA to wrap around the circumference of the Earth a staggering 4000 times.

This prodigious rate of replication is why the mechanisms that govern DNA synthesis and chromosomal segregation must function at high fidelity in order to minimize the likelihood that cells will acquire faulty genomes. Adding to this challenge is that throughout our lifetimes our cells are exposed to a series of endogenously produced mutagenic chemical species as well as mutagens of exogenous origin that can increase the mutation rate significantly. With more mutations, there is an increased chance that a proto-oncogene or tumor suppressor gene will be altered by cancer-promoting mutations. Multiple mutant alleles of these genes must be acquired before adult tumors erupt, and so the rate of formation of these alleles is a critical-rate limiting determinant of cancer formation.

In this chapter, we consider the various mutagenic processes that impinge on normal cells as well as incipient cancer cells and that ultimately shape the cancer genome. Guarding against the effects of these mutagenic events are a battery of DNA repair and genome maintenance pathways that function to restore genomic order. As we discussed in Chapter 7, loss-of-function mutations in many of the genes that function in these pathways (so-called caretaker genes) are frequently

themselves mutated in cancer cells, leading to increased mutation frequency and genomic instability.

Over the past decade, the development of high-throughput genomic sequencing technologies has enabled the extensive analysis of cancer genomes from many human cancer types. The emerging data from this new era of cancer genomics underscore the fact that the march from cellular normalcy to malignancy is typically accompanied and indeed driven by widespread genomic alterations. These broad-based cancer genome characterization efforts have provided insights into the mutational landscape of human cancer as well as the mutagenic processes that drive it.

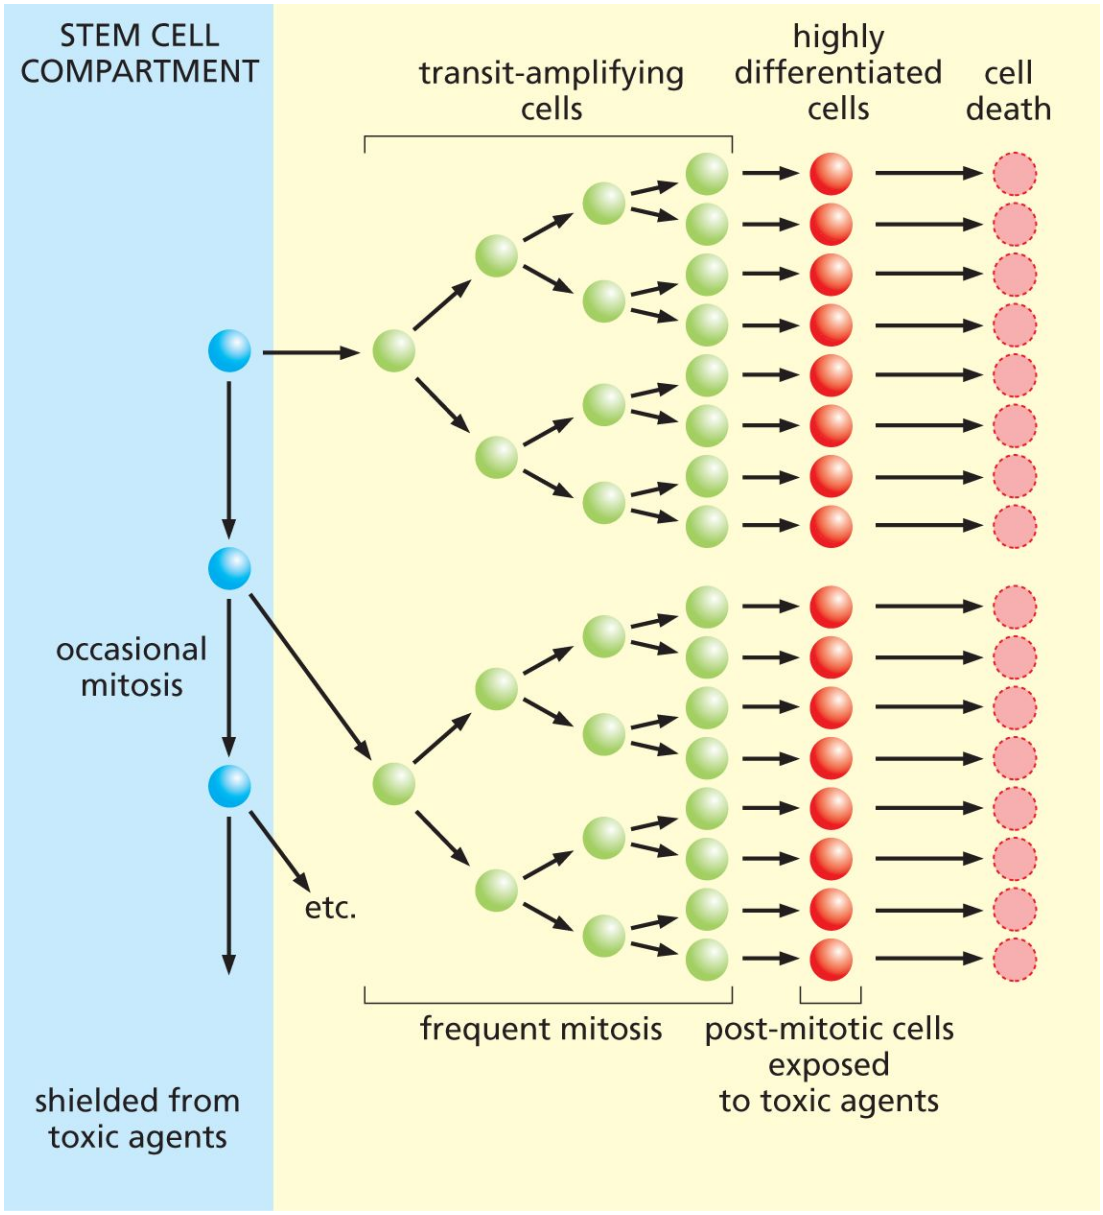
OceanofPDF.com

12.1 Tissues are organized to minimize the progressive accumulation of mutations

On several occasions throughout this book, we have described the effects of carcinogens and tumor promoters on target cells throughout the body. However, the specific biological identities of these target cells have never been spelled out. As it turns out, knowledge of the nature of these cells is critical to understanding how genome integrity is maintained and how it breaks down. To explore the topic of genome integrity, we need to delve into the organization of tissues and the types of cells that form them. Their biological behavior furnishes us with insights into the strategies that tissues and cells exploit to minimize the accumulation of genetic lesions.

As described earlier (see Section 11.7), a common scheme seems to explain the construction and maintenance of many tissues throughout the body. Within each tissue, a relatively small number of cells populate its stem cell compartment. These self-renewing cells may constitute a minute fraction of the entire cell population within a tissue, sometimes as few as 0.1 to 1% of the total. In truth, in most tissues these numbers represent nothing more than poorly informed guesses. Because stem cells are present in very small numbers, are not particularly distinctive in appearance, and are often scattered among other cell types within tissues, they can be difficult to identify and study. Consequently, much of what is described below rests on inference rather than on direct observation of stem cells and their properties.

As is the case with stem cells of tumors (see Section 11.7), the stem cells in a normal tissue are self-renewing, because at least one of the two daughters of a dividing stem cell will retain the phenotype exhibited by the mother cell prior to cell division (see Figure 11.20). In many tissues, the second daughter cell and its transit-amplifying descendants will pass through a substantial number of cell divisions before entering into a post-mitotic, highly differentiated state (see Sidebar 11.6). These actively dividing cells, which serve as intermediates between a stem cell and its differentiated descendants, generate large flocks of differentiated descendants of the second daughter cell that will be discarded sooner or later, only to be replaced by newly minted differentiated cells (**Figure 12.1**). Implicit in what follows is a simple idea: because the lineage of stem cells represents the only stable repository of genetic information within a tissue, the genomes of stem cells must be protected as much as possible from corruption.



An illustration of how the stem cell genome remains protected. A stem cell is shown undergoing occasional division, each time producing a daughter stem cell that remains within the stem cell compartment and a transit-amplifying cell that leaves it. The transit-amplifying cells multiply through frequent mitosis, eventually producing highly differentiated cells that are exposed to toxic agents post-mitosis, causing cell death. All the while, the line of stem cells continues and remains within the stem cell compartment, where it is shielded from toxic agents.

Figure 12.1 Tissue organization and protection of the stem cell genome The organization of many epithelial tissues seems to conform to the scheme shown here. Each stem cell (*blue*) divides only occasionally in an asymmetric fashion to

generate a new stem cell daughter and a transit-amplifying daughter. These stem cells are often shielded anatomically from toxic agents. The transit-amplifying cells (*green*) undergo repeated rounds of growth and division, expanding their populations exponentially. Eventually, the products of these cell divisions undergo further differentiation into post-mitotic, highly differentiated cells (*red*). The highly differentiated cells, which are often in direct contact with various toxic agents, are shed with some frequency; hence, any mutant alleles that arise in these cells will be lost, sooner or later, from the tissue. This means that the genomes of stem cells are often protected through two mechanisms: infrequent cell division and an anatomical barrier that blocks noxious, potentially mutagenic influences.

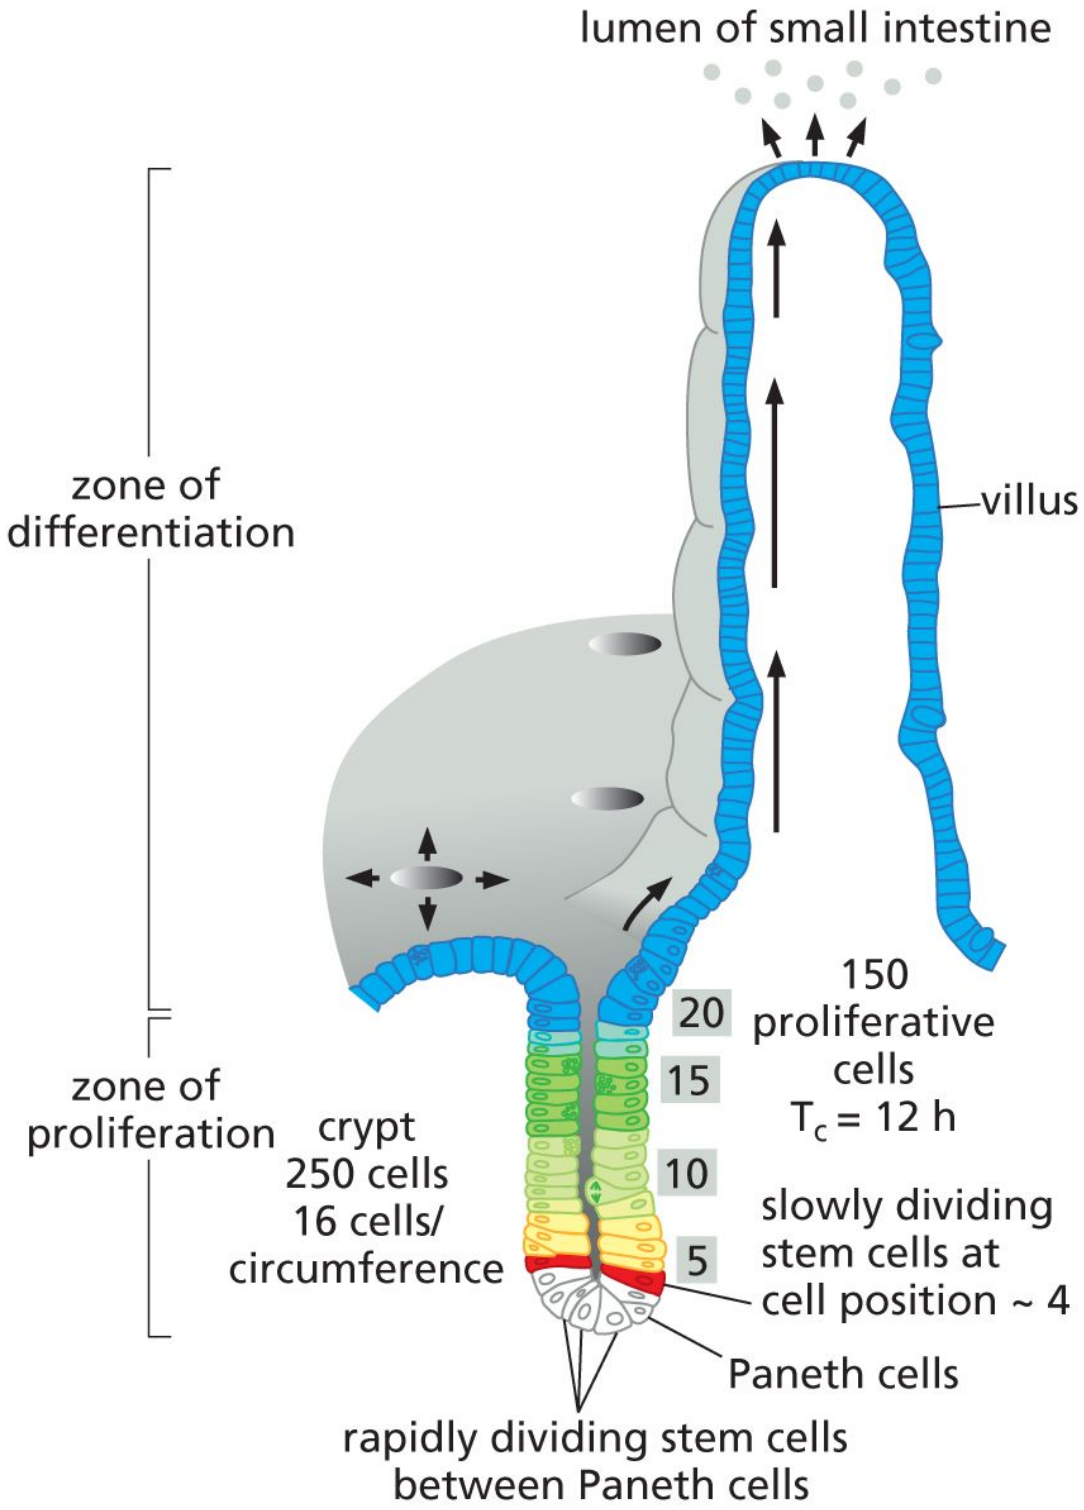
The exponential increase in the number of transit-amplifying cells prior to end-stage differentiation means that a stem cell needs to divide only on rare occasion in order to maintain a large pool of end-stage, highly differentiated cells in a tissue. In the colonic crypts, for example, it is estimated that a single stem cell division ultimately results in the formation of as many as 32 differentiated enterocytes (see Figure 7.21). Therefore, while one might think that stem cells participate in continual cycles of growth and division, the reality is usually much different: the transit-amplifying cells create the great bulk of mitotic activity in highly proliferative tissues. Because the DNA replication occurring during each cell cycle is inherently prone to making errors, this scheme reduces the risk that mutations will accumulate in the genomes of the long-lived cells within a tissue, that is, its stem cells. Conversely, although the mitotically active transit-amplifying cells may indeed accumulate mutations, their mutant descendants will be discarded sooner or later, reducing the accumulation of mutant cells in the tissue as a whole.

In many epithelial tissues, the differentiated epithelial cells are especially vulnerable to genetic damage of a different origin, because they form cell sheets that line the walls of various ducts and cavities that often contain toxic substances. In the cases of the colon and the bile duct, the epithelial cells confront fecal contents and highly corrosive bile, respectively. The cells lining the alveoli in the lungs cope every day with particulates and pollutants in the air. The keratinocytes in our skin are exposed directly to the outside world and hence are susceptible to sustaining several types of damage, including those inflicted by ultraviolet radiation and various toxic chemicals.

The differentiated end-stage cells (see Figure 12.1) in these and other tissues have, as stated, a finite lifetime and are discarded sooner or later. The epithelial cells in the colon live for 5 to 7 days before they are induced to enter apoptosis and are sloughed off into the lumen of the intestine. The keratinocytes in our skin die within 20 to 30 days of being formed and are shed continually in small flakes of dead skin (see, for example, Figure 2.5A). Once again, any genetic damage they have sustained will disappear with them. (To be sure, some cell types are shed for a different reason: they

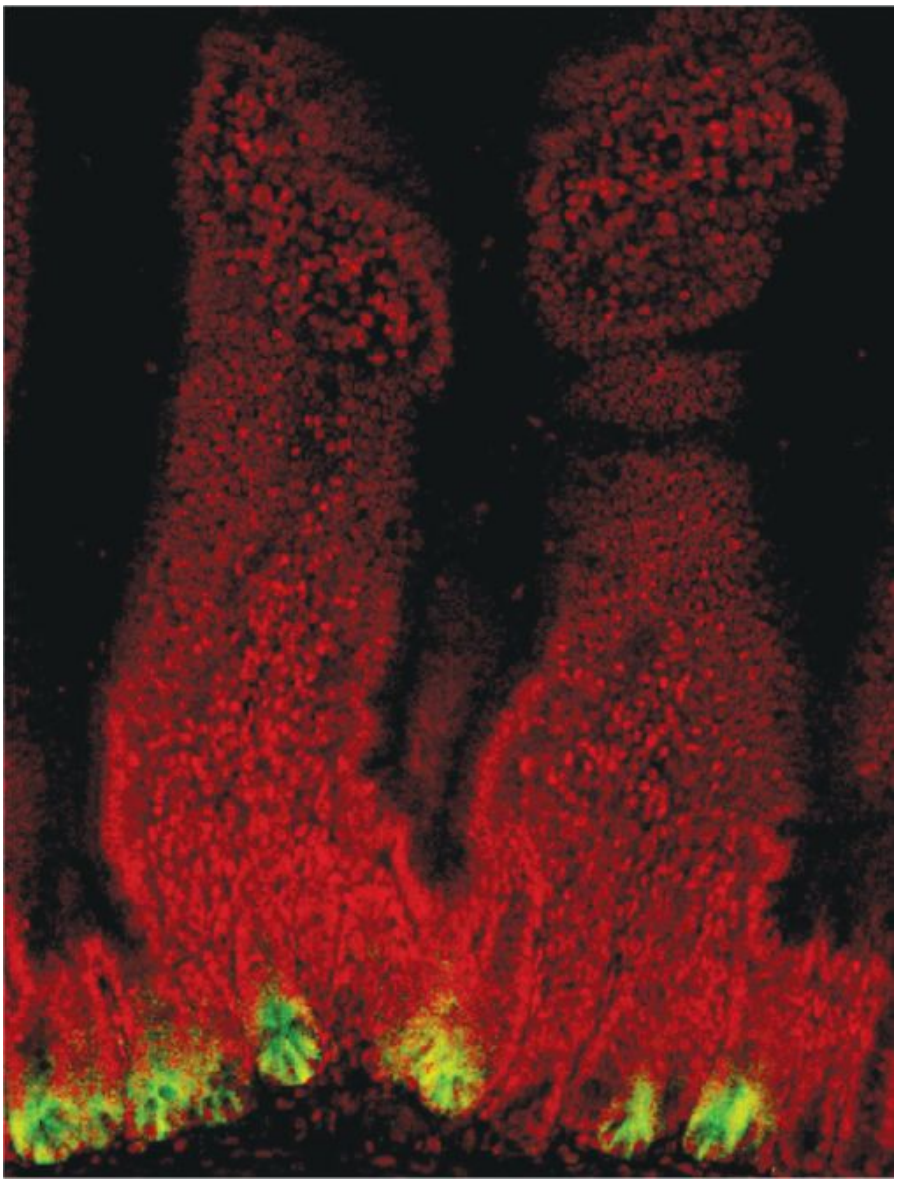
may simply age and lose their viability, being worn out from carrying out the active business of the tissue. For example, red blood cells have an average lifetime of approximately 120 days, after which they are scavenged by the spleen, broken down, and their contents recycled or excreted.)

These schemes explain why, in the context of intestinal function, loss of the ability of a tissue to discard its more differentiated cells can create the seeds of future malignancy (see Section 7.10). In fact, the genomes of stem cells in the small intestine and the colon are also protected in an entirely different biological strategy. Recall that the stem cells in the gut are embedded deep within the crypts (**Figure 12.2A and B**). There they are well out of harm's way, being shielded from the mutagenic contents of the intestinal lumen by a thick layer of mucus secreted by other cells in the crypt. This mucus, which is formed from highly glycosylated proteins termed mucins, creates a jelly-like barrier that prevents the contents of the intestinal lumen from penetrating deep into the crypt and illustrates yet another evolutionary strategy for minimizing mutations in stem cells, namely, anatomically shielding them from the actions of toxins, including carcinogens. (Indeed, mice that have been genetically deprived of the gene encoding Muc2, the most abundant gastrointestinal mucin, are prone to develop adenomas in the small intestine, many of which progress to adenocarcinomas.) This physical barrier confers further protection on the genomes of stem cells, complementing the dynamics described above, which ensures that enterocytes that may have sustained mutations are continuously flushed out of the crypts and eliminated in less than a week (Figure 12.2C).



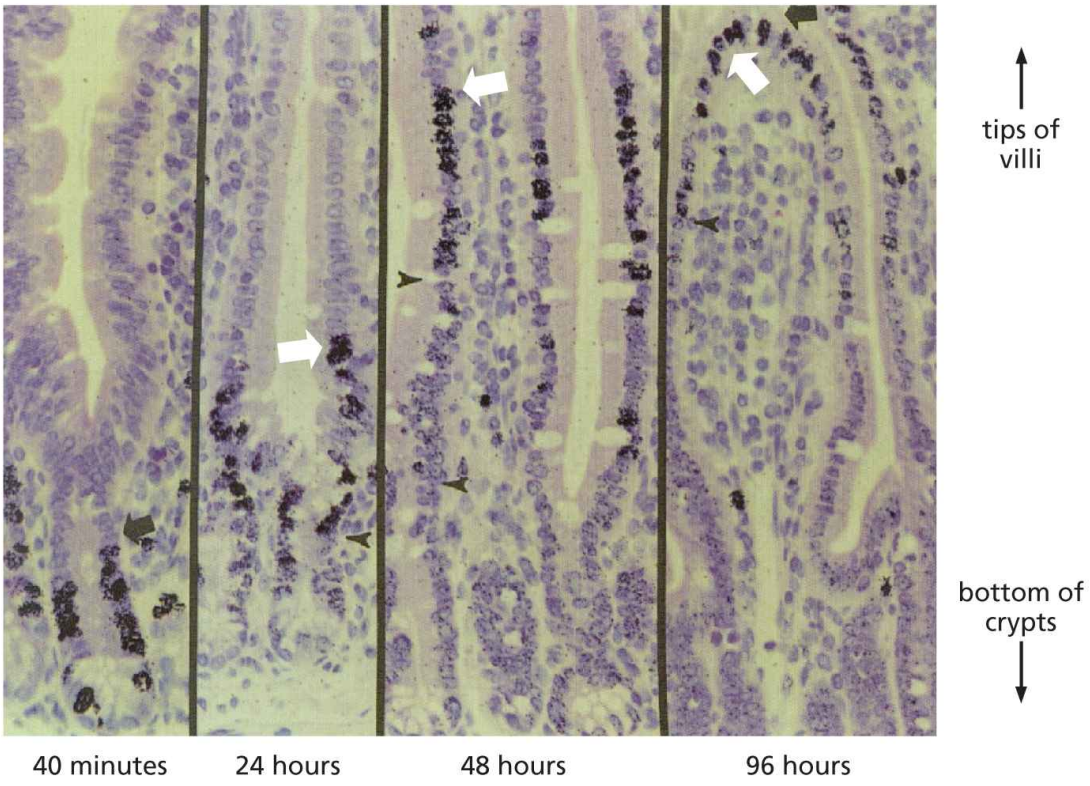
A diagram of a piece of small intestine, showing one crypt and an adjacent villus in cross section. The crypt contains about 250 cells total and is 16 cells in circumference. At the bottom are rapidly dividing stem cells between Paneth cells. At the base of the side wall, approximately at cell position 4, are

slowly dividing stem cells. Cell positions 5 through 15 are occupied by highly proliferative cells that have a doubling time of roughly 12 hours. From the bottom of the crypt to the top of these cells is called the zone of proliferation. Above that is the zone of differentiation. It includes the hollow, thin-walled villus, which rises up toward the small intestinal lumen. Cells are constantly migrating upward in the villus and being shed off the top.
(A)



A fluorescence microscopy image of villi appearing like deep red plumes of smoke rising up from a bed of yellow green flames. The spots of yellow green are clusters of stem cells.

(B)



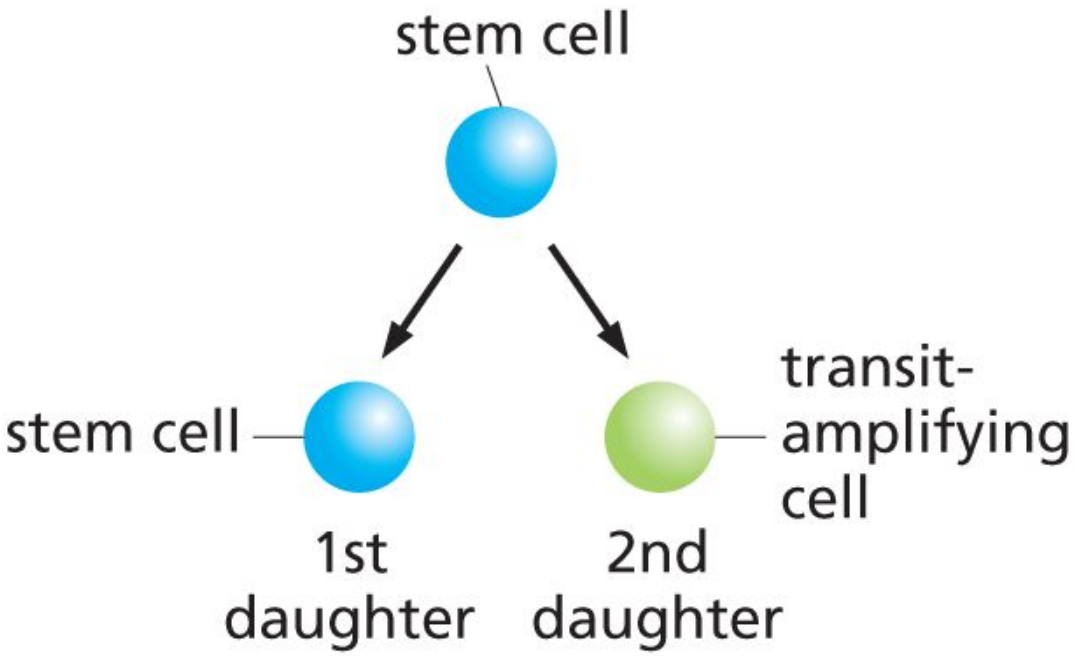
Four autoradiography images, capturing different moments in time: 40 minutes, 24 hours, 48 hours, and 96 hours. They all show villi in side view and document the transit-amplifying cells as dark grains migrating from the bottoms of villi to the tops.

(C)

Figure 12.2 Stem cells and the organization of gastrointestinal crypts (A) Boxed numbers indicate the position of individual enterocytes counting in cell diameters from the bottom of the crypt. Four to six very slowly cycling stem cells (*red*) are located 4–5 cell diameters from the bottom of the crypts. In addition, more rapidly cycling stem cells are found interspersed among the Paneth cells at the bottom of the crypts (*not shown*). Both groups of stem cells are shielded from the contents of the small intestine by their location and by mucus that prevents fluids in the intestinal lumen from entering the crypt. The stem cells spawn a large number (~150) of highly proliferative transit-amplifying cells (*yellow, green*), which divide every 12 hours or so. Their division eventually yields approximately 3500 enterocytes (*blue*), which cover the finger-like villus. The enterocytes are continuously migrating toward the tip of the villus, where they undergo apoptosis and are shed into the lumen of the small intestine (*gray*). (B) The Lgr5 protein has

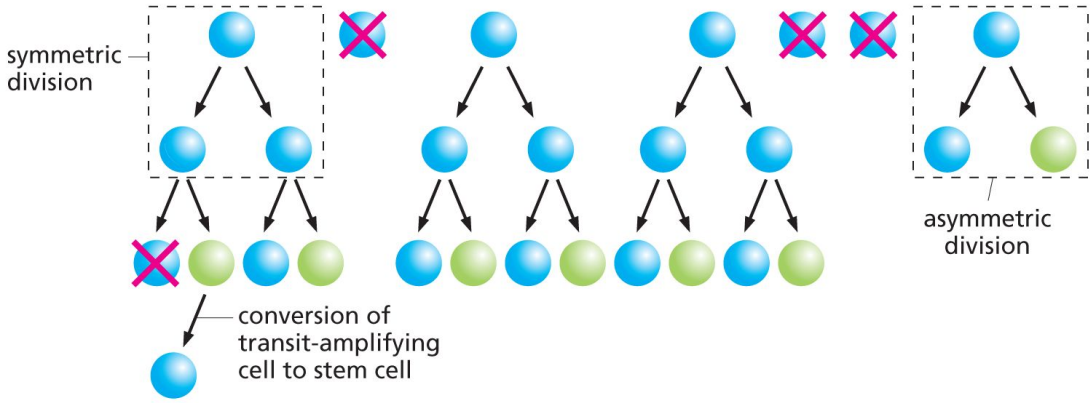
been found to be a highly useful marker for identifying stem cells in a number of tissues. Located in the bottoms of the crypts of the mouse small intestine (duodenum), these cells are labeled here by a transgene that fuses the coding region of the Lgr5 gene with a sequence encoding green fluorescent protein (GFP, *green*). Other evidence, not shown here, points to the presence of a second stem cell population located at 4 cell diameters (from the crypt bottom) that is normally relatively quiescent but becomes mitotically active in response to tissue injury that requires replacement of the $Lgr5^+$ cells. (C) The emigration of transit-amplifying cells from the crypts of the small intestine can be tracked by injecting a dose of ^{3}H-thymidine into a mouse and following the incorporation of this radiolabel into DNA by autoradiography; radioactive decay is indicated by dark silver grains. Seen here are the cells in the crypts of the duodenum of the mouse at the indicated times after injection of the ^{3}H-thymidine. Cells that multiplied only a small number of times after initial incorporation of ^{3}H-thymidine remain heavily labeled (*broad arrows*), while the great majority underwent multiple additional divisions and therefore exhibit diluted radiolabeling. After four days, virtually all cells carrying genomes that were synthesized at the beginning of the experiment have moved out of the crypts to the tips of the villi. (A, courtesy of C.S. Potten. B, courtesy of N. Barker and H. Clevers. C, from C.S. Potten, *Philos. Trans. R. Soc. Lond. B Biol. Sci.* 353:821–830, 1998. With permission from the Royal Society.)

In theory, the stem cell compartment within a tissue has an inexhaustible ability to generate differentiated progeny without ever suffering depletion. However, almost inevitably, a stem cell will be lost through one or another mishap. This gap in the ranks must be filled by other stem cells. More specifically, both daughters of a surviving stem cell will need to retain the phenotype of their mother, which therefore undergoes a symmetrical division (**Figure 12.3**). Alternatively, in certain tissues, loss of critical stem cells may trigger the dedifferentiation of transit-amplifying cells, which reverse their earlier exit from the stem cell compartment (see Figure 11.20C).



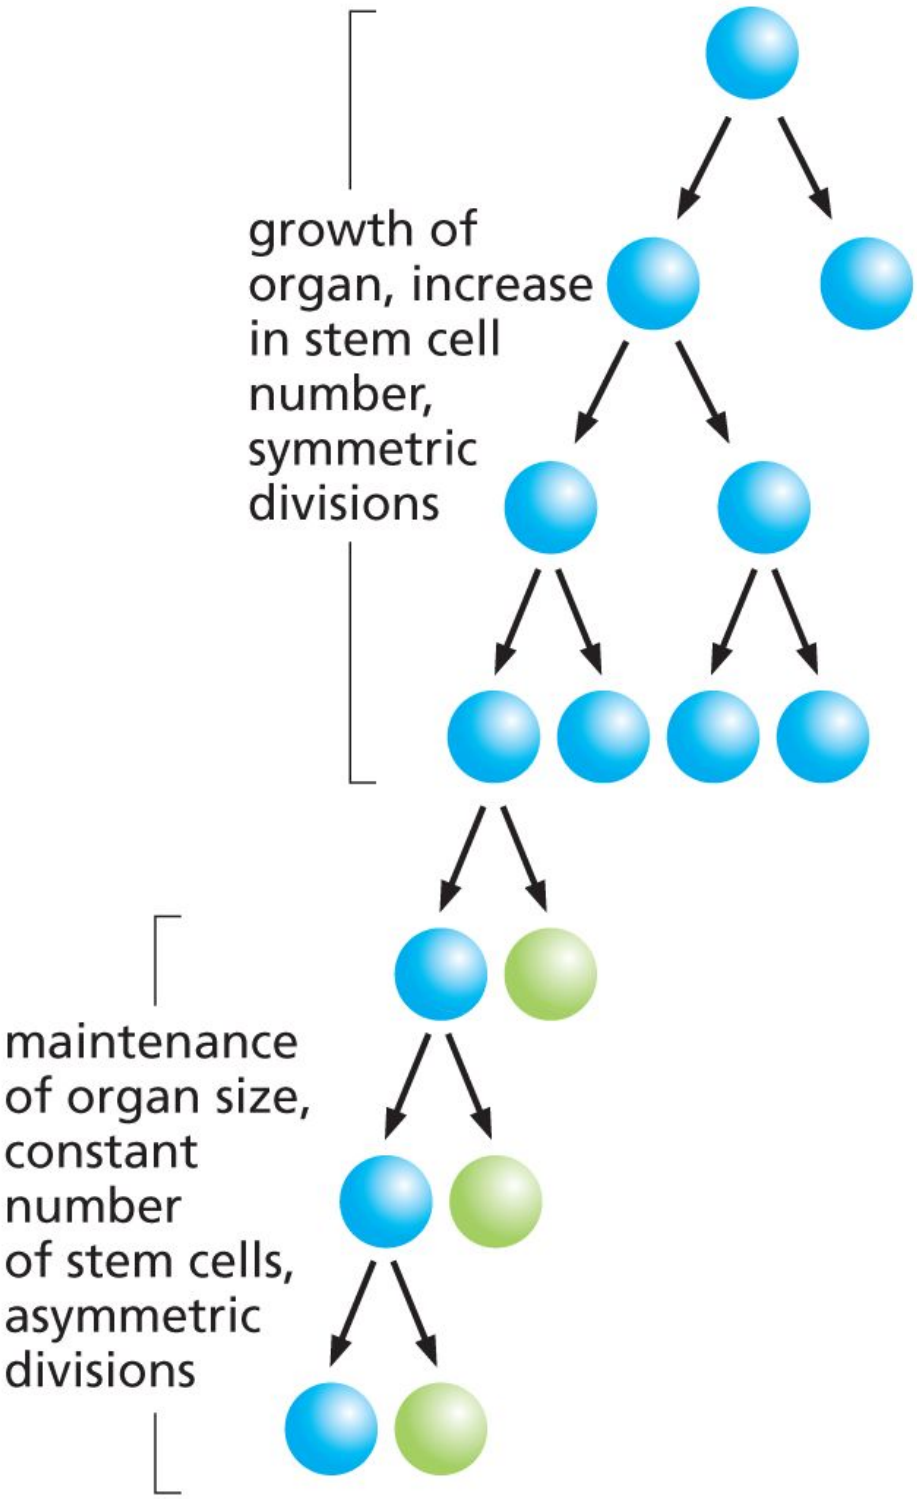
Asymmetric division of a stem cell. The first daughter cell is also a stem cell. The second daughter cell is a transit-amplifying cell.

(A)



Three generations of cells. The first consists of 7 stem cells, of which 3 die without reproducing. Of the 4 that reproduce, 1 undergoes asymmetric division to produce one stem cell and one transit-amplifying cell in the second generation, while the other 3 under symmetric division to produce 2 stem cells in the second generation, creating 7 stems cells and 1 transit-amplifying cell. All 7 stem cells of the second generation survive. 6 of the 7 stem cells in this generation divide asymmetrically to each produce one stem cell and one transit-amplifying cell in the third generation. One of the stem cells in the

third generation dies. Its sister cell, initially a transit-amplifying cell, converts into a stem cell.
(B)



A series of cell divisions, beginning with a single stem cell, divided into two phases: organ growth and size maintenance. In organ growth, cells divide symmetrically, producing more stem cells. In this example, it lasts four generations. This is followed by size maintenance, in which three generations of stem cells divide asymmetrically, producing one stem cell and one transit-amplifying cell each. The number of stem cells remains constant and the organ is maintained in size.

(C)

Figure 12.3 Asymmetric and symmetric divisions of stem cells (A) In general, during normal tissue function, it appears that a stem cell will usually divide asymmetrically, with one of its daughters remaining a stem cell (*blue*) and the other (*green*) proceeding to spawn a flock of transit-amplifying cells (*not shown*; see Figure 12.1). (B) In the event that several stem cells in a tissue are lost, some of the surviving stem cells may divide symmetrically in order to re-populate the stem cell pool. As seen here, three stem cells have been lost (*red crosses, top row*) from a pool of seven. The subsequent symmetric divisions undertaken by the surviving stem cells regenerate the original population size of the stem cell pool. Alternatively, the loss of a stem cell (*red cross, third row*) may cause its transit-amplifying sister to revert back to a stem cell (*bottom*). (C) Similarly, when an organ is growing, the number of stem cells must increase proportionately, requiring some stem cells to undergo symmetric divisions.

Glossary

compartment
: Physical or virtual functional space that contains all cells of a given type within a tissue, e.g., a stem cell compartment.

enterocyte
: Epithelial cell lining the luminal wall of the gastrointestinal tract or associated structures such as villi.

mucin
: Member of a family of heavily glycosylated glycoproteins that are secreted by luminal cells in a variety of epithelial tissues and form gel-like aggregates in order to lubricate or erect barriers to protect the luminal and underlying epithelial cell layers.

OceanofPDF.com

12.2 The properties of stem cells make them good candidates to be cells-of-origin of cancer

The properties of the intestinal cells (see Figure 12.2) also provide important clues about the identities of the cells that are common targets of carcinogenesis. Actually, we already have come across evidence that points to the central role of long-lived cells in the process of carcinogenesis. In Section 11.11, we read about experimental protocols used to induce skin cancer in mice. One such protocol involved painting a patch of skin with an initiating agent, allowing the patch to remain untouched for some months, and then painting it repeatedly with TPA, a potent skin tumor promoter. Cells that had been exposed to the initiating carcinogen “remembered” the earlier exposure one year later by undergoing proliferation and forming a skin papilloma in the presence of the promoter. In the skin, as in many other epithelial tissues, the long-lived cells are those in the stem cell compartment.

Provocatively, the number of skin papillomas and carcinomas induced by the mouse skin carcinogenesis protocol (see Figure 11.30) is not reduced if the mouse skin is treated with 5-fluorouracil (5-FU) shortly after being exposed to a mutagenic initiating agent. Because 5-FU selectively kills actively cycling cells, this indicates that the cell targeted by carcinogenic mutagens during initiation is not in the active cell cycle at the time of initiation and shortly thereafter, lending weight to the notion that the target for initiation is a cell type that divides only occasionally.

Analyses of several types of leukemia suggest that the initial targets of carcinogenesis in the hematopoietic system are also stem cells. The most dramatic example is provided by chronic myelogenous leukemia (CML). As described earlier, the Philadelphia (Ph^1) chromosome, which results from a

reciprocal chromosomal translocation that fuses the *BCR* and *ABL* genes (see Section 4.5), is observed in almost all cases of CML. Extensive evidence points to this particular translocation as the genetic lesion that initiates this disease.

A number of distinct hematopoietic cell types within a CML patient may carry the Ph^1 chromosome. Included are lymphoid cells (both B and T lymphocytes), as well as cells of the myeloid lineage (including neutrophils, granulocytes, the megakaryocyte precursors of platelets, and erythrocytes). This finding provides compelling evidence that the cell type in which the translocation is harbored is the common progenitor of all of these hematopoietic cell lineages, specifically the pluripotent stem cell that serves as the precursor for many types of hematopoietic cells (**Supplementary Sidebar 12.1**). Like a variety of other stem cells, this hematopoietic stem cell (HSC) is thought to have a very long lifetime in the hematopoietic system, more specifically in the bone marrow. In the particular case of CML, a stem cell that has suffered a critical mutation—formation of the Ph^1 chromosome—retains the option to dispatch its progeny into a number of distinct hematopoietic cell lineages. Yet other indications that stem cells are targets for tumor formation come from other types of hematopoietic disorders (**Sidebar 12.1**). Although stem cells play an important role in the origins of many cancers, current evidence supports the candidacy of other cells within tissues as also being important players in tumor initiation (**Sidebar 12.2**).

Sidebar 12.1 Blocked differentiation is a frequent theme in the development of hematopoietic malignancies

Studies of human cancer have revealed dozens of examples of malignancies in which inhibition of differentiation favors the appearance of neoplasia. Possibly the first to be defined genetically involved the avian erythroblastosis virus, a retrovirus that encodes two oncoproteins: its erbB oncogene specifies a constitutively active version of the epidermal growth factor (EGF) receptor (see Section 5.4), which drives the proliferation of erythroblasts (precursors of red blood cells), and its erbA oncogene encodes a nuclear receptor (a homolog of the thyroid hormone receptor), which

inhibits differentiation of the hyperproliferating erythroblasts created by erbB. Similarly, in human acute myelogenous leukemia (AML), a large variety of genetic lesions found in the leukemic cells have been assigned to two functional classes: those that are required to drive the proliferation of the myeloid precursor cells, and others that are required in the same cells to block subsequent differentiation.

In the megakaryoblastic leukemias (a malignancy of platelet precursor cells) encountered with some frequency in Down syndrome patients, the gene encoding the GATA1 transcription factor is frequently found to be mutated, preventing the proper maturation and differentiation of these precursors of platelets. These few examples point to the notion that the exit of cells from stem cell compartments must be impeded in order for tumorigenesis to succeed.

Not addressed by these observations are the precise identities of the cellular targets of transformation. In many cases, the target is not likely to be the pluripotent hematopoietic stem cell, but instead one of its derivatives that is already committed to one or another lineage of differentiation. Such "committed progenitors" (see **Supplementary Sidebar 12.1**) normally may have significant (but limited) self-renewal capacity and are not yet fully differentiated, and thereby can be considered stem cells. Their transformation from normal to tumor stem cells involves, among other changes, an acquisition of unlimited self-renewal capability.

Compelling observations of the role of stem cells in cancer derive from transgenic mice in which the expression of an activated *ras* oncogene is limited to either the keratinocyte stem cells in the skin (which in this case are located in hair follicles) or the keratinocytes that have begun to enter into a terminally differentiated state. When the transgene directs expression of the *ras* oncogene in the stem cells, the mice develop malignant carcinomas. In contrast, when the same oncogene is expressed in the differentiating keratinocytes, benign papillomas are formed and these tend to regress.

Sidebar 12.2 An alternative target of cancer-driving mutations

Most current evidence points clearly to stem cells as being direct targets of the mutations driving tumor initiation and progression. There is, however, an alternative mechanistic model and an alternative set of cells that may often serve as the cellular targets of cancer-forming mutations. This newer thinking comes from extensive evidence that transit-amplifying/progenitor cells can dedifferentiate under certain circumstance and thus re-enter the stem cell pool as mentioned above and as is illustrated in Figure 11.20C. Such dedifferentiation may be triggered, for example, if the pool of stem cells within a stem-cell niche has been depleted for various reasons, requiring replenishment, which can accomplished by dedifferentiation. This notion was explored briefly in Sidebar 11.7. In fact, there are several reasons that transit-amplifying cells are more attractive candidates for sustaining mutations than are stem cells, simply because there are usually far more of them in a tissue, increasing proportionately the chance that a mutation will hit their compartment rather than that of the stem cell. In addition, the transit-amplifying cells, because of their high rate of proliferation, often generate the lion's share of the mitotic activity; if errors in cell proliferation cause mutational events, they are more likely to target these cells, rather than stem cells. Importantly, by dedifferentiating, a mutant transit-amplifying cell can introduce a mutant allele back into the stem cell pool, thereby ensuring the perpetuation of its recently acquired mutation back in the stem cell niche. Indeed, it may be that many of the reported experimental demonstrations of stem cells as direct targets of oncogenic mutations may have ignored the bidirectional interconversions between stem cells and transit-amplifying cells and thus the possibility of this alternative source of cancer-associated mutant genomes. In many tissues, these two alternative mechanisms of cancer-driving mutagenesis remain unresolved experimentally.

12.3 Apoptosis, drug pumps, and DNA replication quality control mechanisms offer tissues a way to minimize the accumulation of mutant preneoplastic cells

The important role played by normal stem cells as targets for transformation requires that the genomes of these cells must be protected by whatever biological and biochemical strategies these cells and the tissues around them can muster. We have already come across two such strategies: the relatively infrequent replication of stem cell DNA and the placement of stem cells in anatomically protected sites. Still, these mechanisms do not seem to suffice, so organisms have developed yet other strategies.

One protective mechanism is suggested by the responses of stem cells in the crypts to massive genetic damage. In the intestinal crypts of the mouse, stem cells that have suffered genetic damage inflicted by X-rays will rapidly initiate apoptosis rather than halt their proliferation and attempt to repair the damage. The motive here seems to be associated with the less-than-perfect nature of DNA repair. As we will learn later, the DNA repair apparatus is highly efficient but hardly perfect, and therefore a residue of unrepaired or incorrectly repaired lesions may remain in the chromosomal DNA. If the DNA replication machinery encounters such lesions, damaged DNA sequences may be copied and passed on as mutations to daughter cells, including those that will themselves become stem cells. So, rather than risk this outcome, stem cells in the mouse crypts are primed to activate apoptosis in response to DNA damage.

Yet another mechanism is suggested by a commonly used technique for separating stem cells from the bulk of cells in a tissue via fluorescence-activated cell sorting (FACS; see **Supplementary Sidebar 11.5**). Stem cells efficiently pump out certain fluorescent dye molecules, whereas these cells' differentiated derivatives do so much less actively. As a consequence, after exposure of cell populations to such dyes, the stem cells fluoresce much more weakly than all other cells in these populations. The active excretion of these fluorescent dye molecules results from the actions of a plasma membrane protein termed Mdr1 (multi-drug resistance 1), which was discovered because many cancer cells exploit it to pump out, and therefore acquire resistance to, chemotherapeutic drug molecules (see Figure 17.26). The unusually high levels of Mdr1 expressed by many types of stem cells seem to represent a strategy that

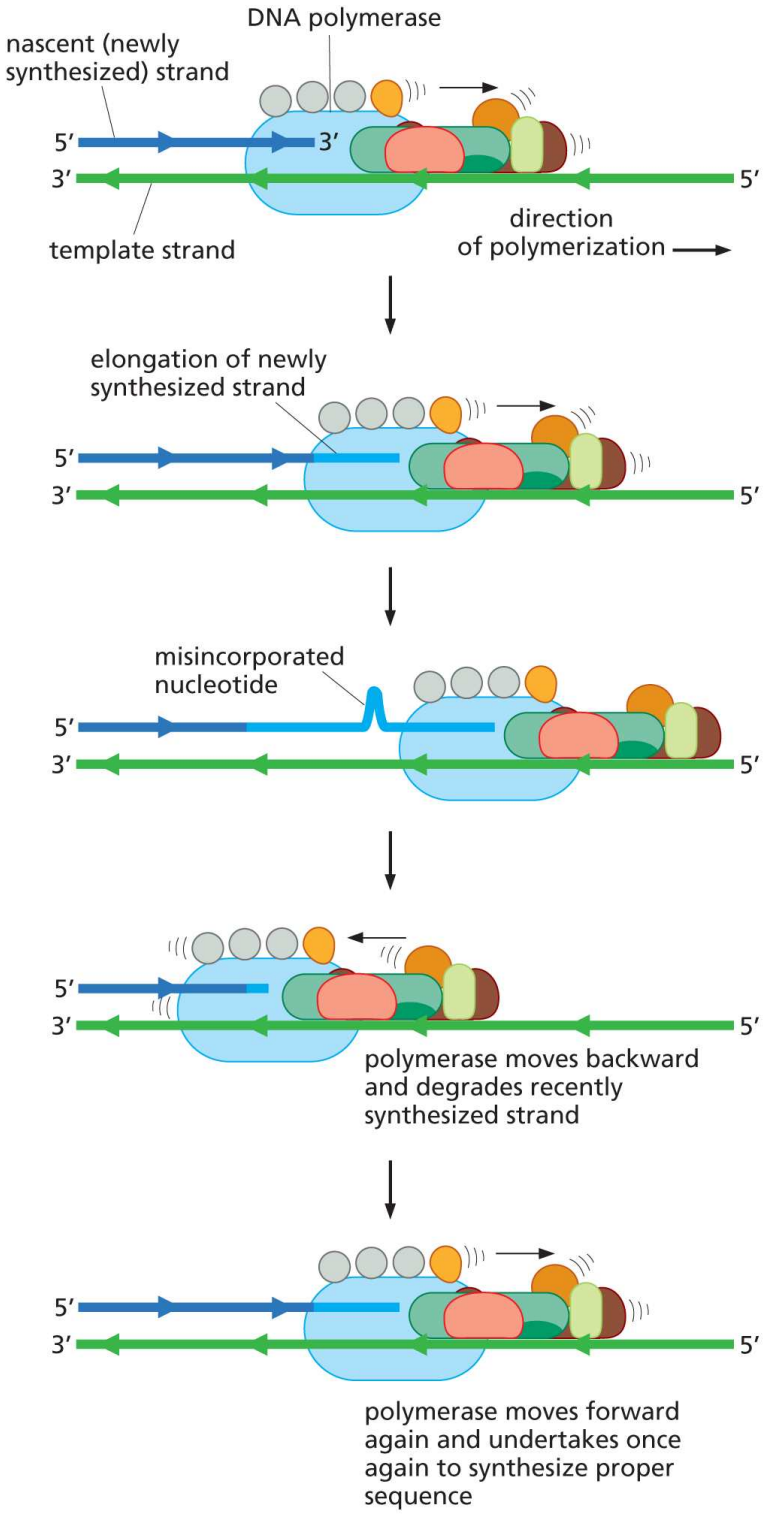
they use to protect their genomes from potentially mutagenic compounds that may have entered them from outside.

The design of stem cell compartments and the behavior of individual stem cells illustrate several biological strategies used by tissues to reduce the burden of accumulated somatic mutations. Importantly, these strategies represent only the first line of defense against genomic damage. The next line of defense, which is relevant to all cells in the body, is a biochemical one that depends on the ability of their various expressed proteins to recognize and repair damaged DNA molecules.

In fact, DNA molecules are under constant attack by a variety of agents and processes. For the sake of simplicity, we can place these mutagenic processes in three categories. First, the replication of DNA sequences by DNA polymerases during the S phase of the cell cycle is subject to a low but nonetheless significant level of error. Included among these errors are those generated when chemically altered nucleotide precursors are inadvertently incorporated into DNA in place of their normal counterparts. Second, even in the absence of misincorporation of such altered nucleotides, those that have already been incorporated into DNA molecules undergo chemical changes spontaneously; these changes often alter the base sequence and thus the information content of the DNA. Finally, DNA molecules may be attacked by various mutagenic agents, including those molecules generated endogenously by normal cell metabolism as well as agents of exogenous origin—chemical species and physical mutagens (X-rays and UV rays) that enter the body from outside. We will return to the latter two processes in the next sections.

The molecular machinery that is responsible for replicating almost all chromosomal DNA sequences has a remarkably low rate of error. The basic replication machinery in the cell nucleus is powered by the actions of three polymerases, pol-α, pol-δ, and pol-ε. (In all, at least 14 distinct DNA polymerase genes have been cataloged in the human genome; as will be apparent later, most of these are not involved in DNA replication per se but rather in the repair of damaged DNA molecules.)

A cell has two major strategies for detecting and removing the miscopied nucleotides arising during DNA replication. The first strategy rests with the DNA polymerases themselves, which are structurally complex assemblies composed of a number of distinct protein subunits. While they are advancing down single-strand DNA templates and extending nascent DNA strands in a 5′-to-3′ direction, DNA polymerases, such as pol-δ, continuously look backward, scanning the stretch of DNA that they have just polymerized; such monitoring is often called proofreading. Should a polymerase detect a copying error, it will use its associated 3′-to-5′ exonuclease activity to move backward and digest the DNA segment that it has just synthesized and then copy this segment once again, with the hope of a better outcome the second time (**Figure 12.4**).

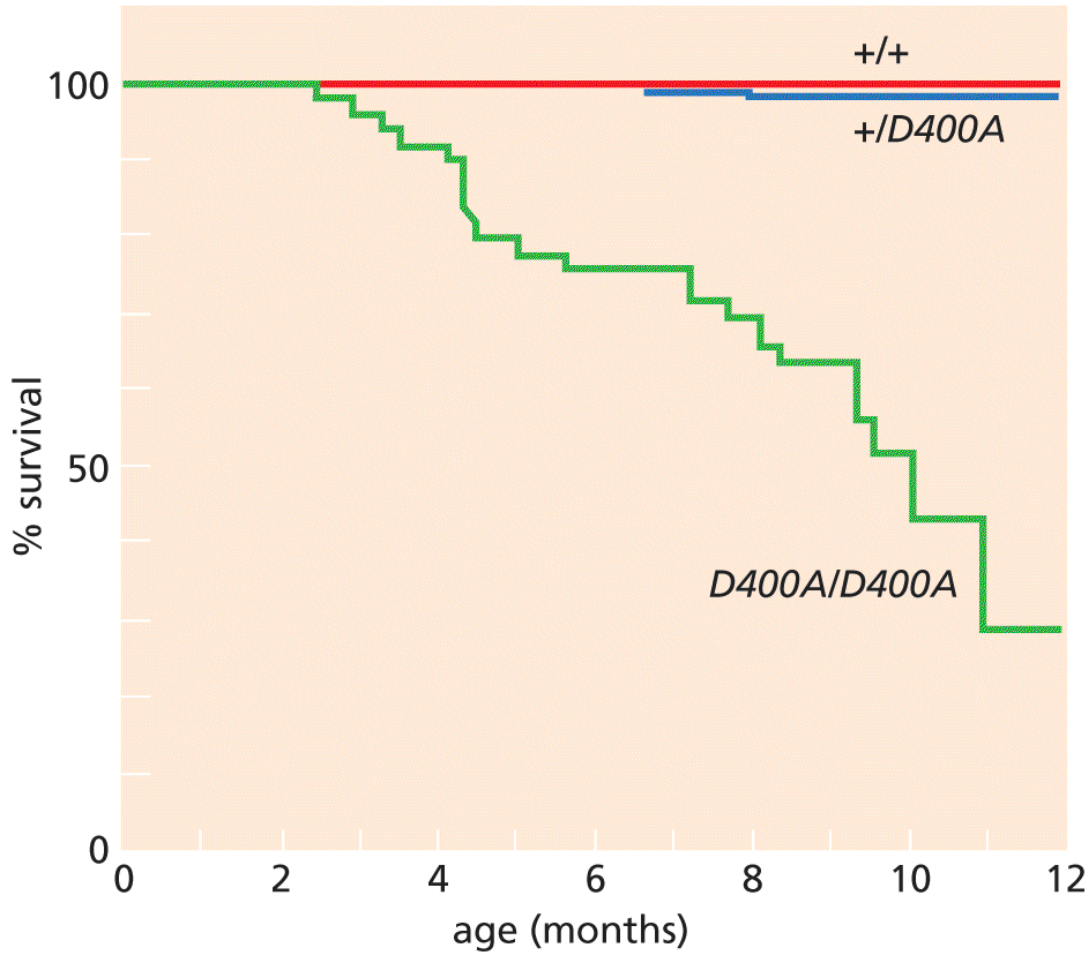


A five-step diagram depicting proofreading during D N A polymerization. In step 1, D N A polymerase is reading a template strand in the 3 prime to 5 prime direction and synthesizing a new strand in the 5 prime to 3 prime direction. In step 2, the newly synthesized strand is being elongated. In step 3, the newly added

segment has a misinterpreted nucleotide, resulting in a loop that does not properly attach to the template strand. In step 4, the polymerase moves backward and degrades the recently synthesized strand. In step 5, the polymerase moves forward again and undertakes once again to synthesize the proper sequence.

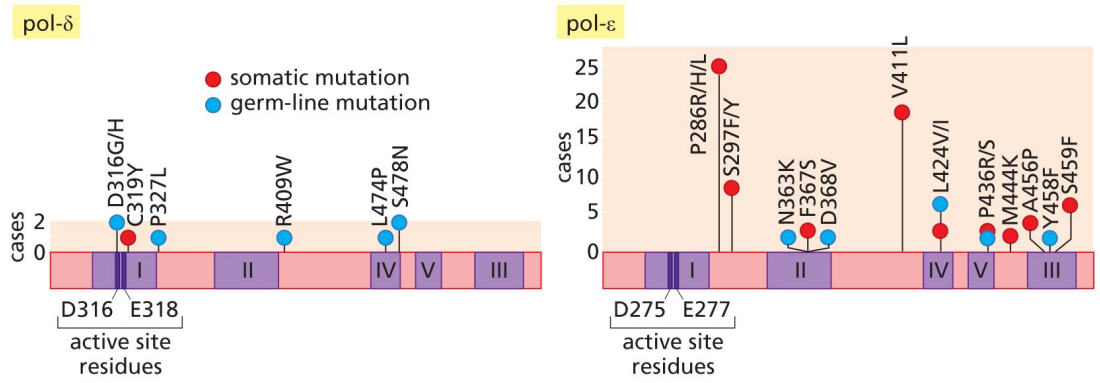
Figure 12.4 Proofreading by DNA polymerases A number of DNA polymerases have a proofreading ability that allows them to minimize the number of bases that are misincorporated and retained in the recently synthesized DNA strand. Thus, as a DNA polymerase extends a nascent strand (*dark blue*) in a 5′-to-3′ direction (moving rightward), it will use the existing 3′-OH of the nascent strand as the primer for further elongation (*light blue*). However, if a base has been misincorporated (*third drawing*), the DNA polymerase, which is continuously looking backward to check whether it has incorporated the correct bases in the growing DNA strand, can degrade in a 3′-to-5′ (leftward) direction the recently elongated strand (*fourth drawing*) and undertake once again to synthesize this stretch of nascent strand (*bottom drawing*).

The importance of this proofreading mechanism for the prevention of cancer has been illustrated dramatically by the creation of a mouse strain whose germ-line pol-δ–encoding gene has been subtly altered (by a point mutation encoding a single amino acid substitution). The resulting mutant pol-δ retains its ability to carry out lagging-strand DNA synthesis at the replication fork but has lost its 3′-to-5′ exonuclease activity; this loss eliminates its proofreading function. In a cohort of mice carrying the mutant *PolD* allele in a homozygous configuration, nearly half developed tumors by one year of age, whereas no tumors developed in a group consisting of twice as many heterozygous mice (**Figure 12.5A**). As discussed in Section 12.8, humans with germ-line mutations affecting the proofreading domains of pol-δ or pol-ε (responsible for leading-strand synthesis at the replication fork) are cancer prone (Figure 12.5B). Somatic mutations affecting the proofreading domains of these polymerases are observed in certain human cancers as well (see Figure 12.5B).



A line graph showing percent survival as a function of time. 100 percent of homozygous wild-type mice survived to age 12 months. Some heterozygous wild-type slash D400A mutation mice died, starting at 6 months, but over 95 percent survived to 12 months. Homozygous mutant mice began to die before 3 months, and continued dying steadily. Only about 30 percent survived to 12 months.

(A)



Two schematic of genes. The polymerase delta gene schematic shows five sites of germ-line mutations, one or two cases each, and one site of a single case of a somatic mutation. The polymerase epsilon gene schematic shows five sites of germ-line mutations, one occurring in 5 cases, and nine sites of somatic mutations, including one occurring in 25 cases and another occurring in 18 cases.

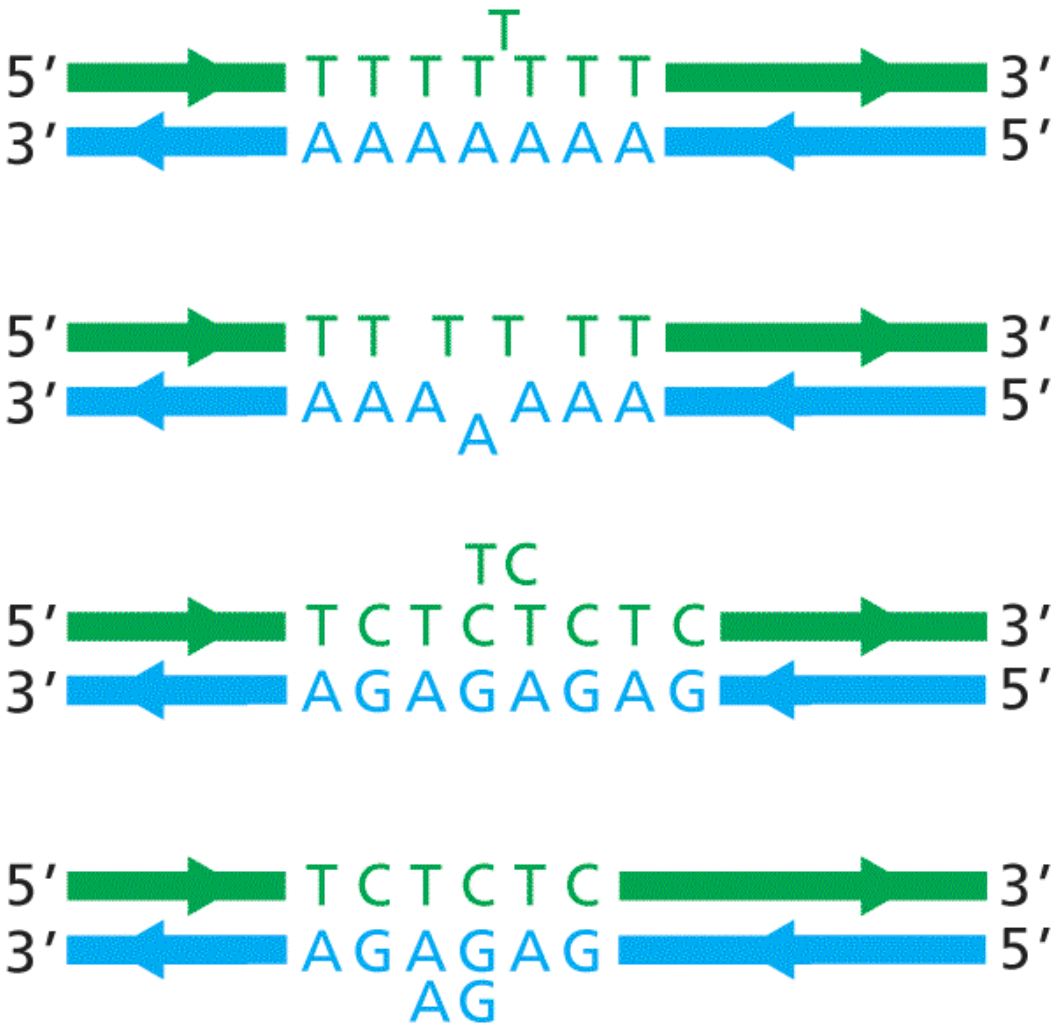
(B)

Figure 12.5 Mutations inproofreading domains of DNA polymerases promote cancer (A) A point mutation was introduced into the germ-line copy of the mouse gene encoding DNA polymerase δ (pol-δ), the mammalian DNA polymerase that is responsible for most lagging-strand synthesis. This mutation, termed D400A, alters the amino acid sequence in the proofreading domain of the polymerase by specifying the replacement of an aspartic acid by an alanine at residue position 400 of the polymerase molecule; the synthetic activity of the polymerase is unaffected by this mutation. Shown here is the fate of 53 wild-type mice (+/+), 97 heterozygotes (+/D400A), and 49 homozygous mutants (D400A/D400A). Deaths of the mutant homozygotes were all a result of malignancies; these included lymphomas, squamous cell carcinomas of the skin, lung carcinomas, and several other types of cancer that occurred less frequently. Two of the heterozygotes died from causes that were unrelated to cancer, whereas the homozygous wild-type mice all survived to the age of one year. (The cooperating partner of pol-δ, called pol-ε, carries out leading-strand synthesis and proofreading; when it is similarly mutated, mice develop largely carcinomas of the small intestine.) (B) Mutations in the human pol-δ and pol-ε genes occur both in the germline in individuals with inherited cancer predispositions and somatically in certain cancer types. The exonuclease domains of both polymerases are shown with the five conserved exonuclease motifs marked by Roman numerals (I–V) along with key active site residues. Residues found mutated in the germ line (denoted by *blue circles*) or somatically (*red circles*) are indicated. In each of the indicated point mutations, the letter indicating the wild-type amino acid precedes the codon number and the

altered residue follows it. As indicated by the number of reported cases shown, pol-ε mutations are more common. Germ line and somatic mutations in the proofreading domains of these polymerases are associated with colon and endometrial cancers as well as other cancers at lower frequency. Tumors harboring these mutations exhibit “ultra-mutated” genomes with more than 100 mutations detected per megabase of DNA sequenced. (A, from R.E. Goldsby et al., *Nat. Med.* 7:638–639, 2001. B, from E. Rayner et al., *Nat. Rev. Cancer* 16: 71–81, 2016. Both with permission from Nature.)

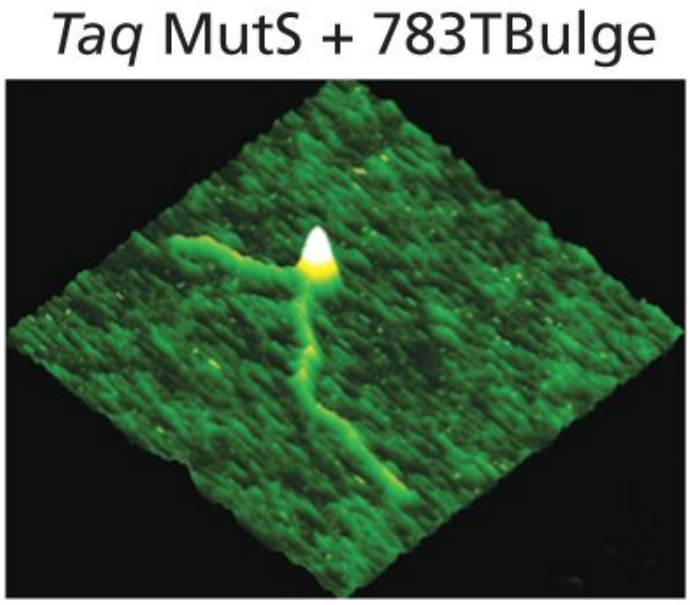
These observations demonstrate that the maintenance of wild-type genomic sequences, in this case by two DNA polymerases, represents a critical line of defense against the onset of cancer. Moreover, for us, these observations are the first of many indications that the mutations leading to cancer may arise through endogenous processes associated with normal cellular proliferation rather than being triggered exclusively by exposure to exogenous carcinogenic agents.

Augmenting the DNA polymerases and their proofreading activities is a complex set of mismatch repair (MMR) enzymes. These enzymes monitor recently synthesized DNA in order to detect miscopied DNA sequences that have been overlooked by the proofreading mechanisms of the DNA polymerases described above. The actions of the MMR system become especially critical in regions of the DNA that carry repeated sequences. These sequence blocks include simple mononucleotide repeats (such as AAAAAAA), dinucleotide repeats (such as AGAGAGAG), and repeats of greater sequence complexity. In instances of strand slippage, which occurs in the replication fork when the parental and nascent strands slip out of proper alignment, DNA polymerases appear to occasionally “stutter” while copying these repeats, resulting in incorporation of longer or shorter versions of the repeats into the newly formed daughter strands (**Figure 12.6**). Thus, the sequence AAAAAAA, that is, A_7, might well cause a polymerase to synthesize a T_6 or T_8 sequence in the complementary strand. The resulting insertions or deletions may elude detection by the proofreading components of the DNA polymerases, making them prime targets for recognition and repair by the MMR machinery.



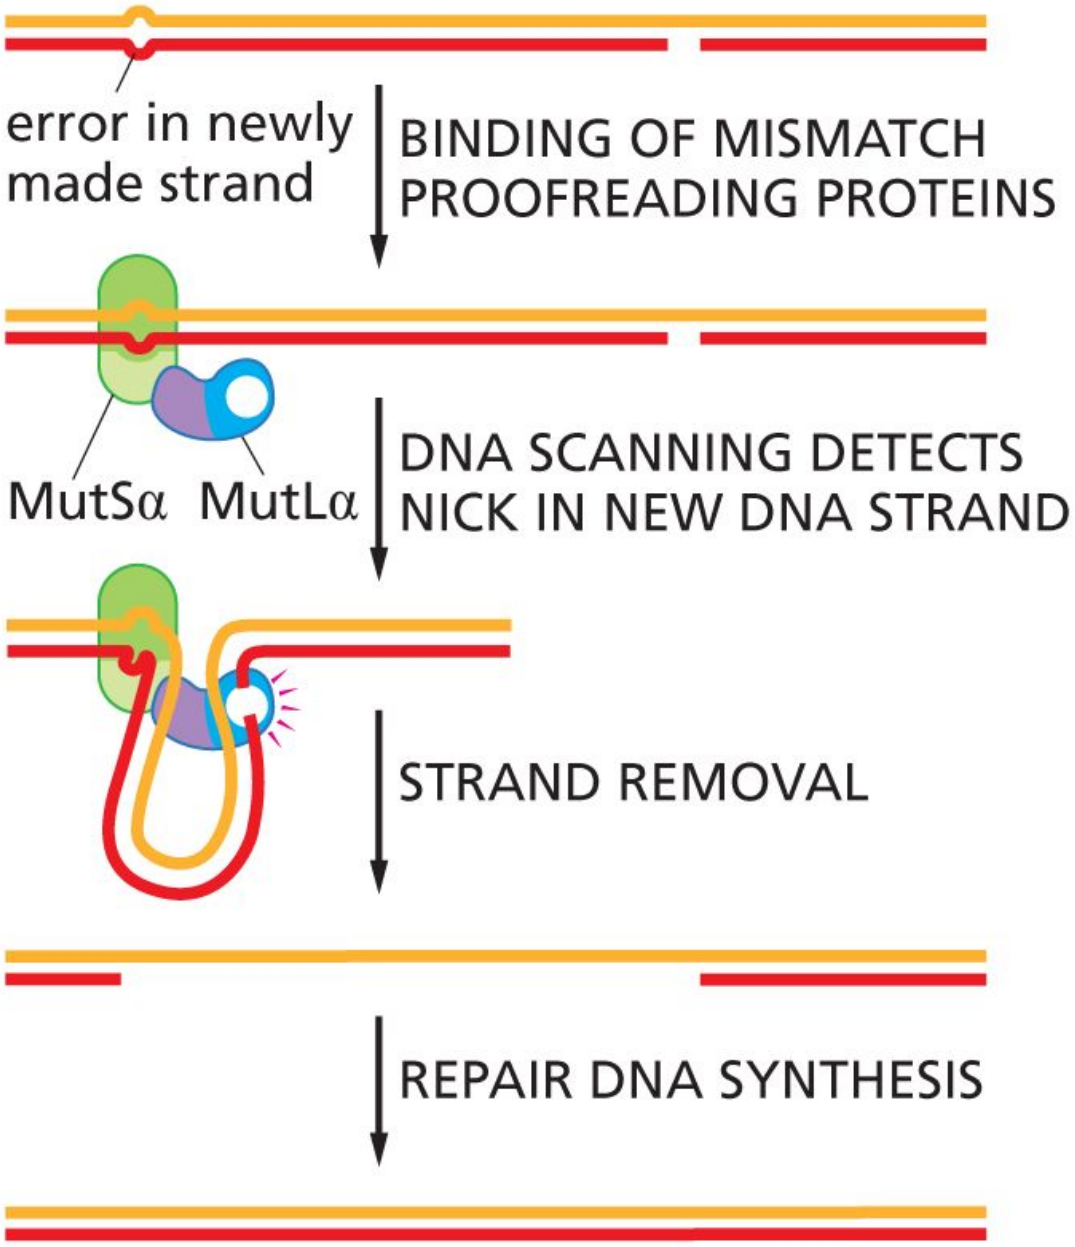
Illustrations of four copying errors. First, a string of 7 ayze may get copied as a string of 8 tees, with an extra tee that forms an unattached loop. Second, a string of 7 ayze may get copied as a string of 6 tees, leaving one extra “A” in the template strand as an unattached loop. The third and fourth examples are similar, but the sequence to be copied is alternating ayze and jeeze, and the errors involve either an extra tee see or an extra see gee.

(A)



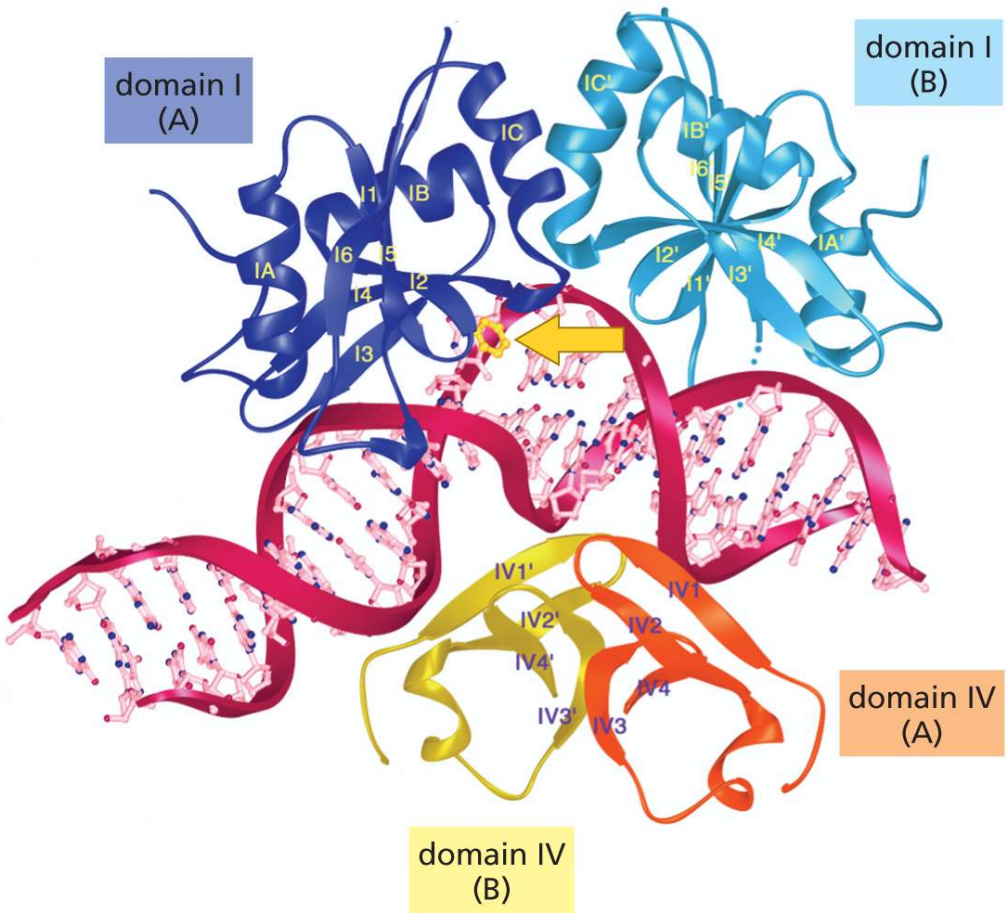
A micrograph showing a segment of double-stranded D N A from which a white toothlike spur appears to jut upward.

(B)



A five-step diagram. Step 1 shows an error in a newly made double strand, where an error has produced a location where the two strands do not attach. Also visible, to the right, is a short break in the newly made strand. After BINDING OF the MISMATCH site by the PROOFREADING PROTEIN M u t S alpha, the associated protein M u t L alpha removes the strand segment from the break back to the mismatch site. A new strand segment is then synthesized to repair this stretch of the D N A.

(C)



A partial ribbon diagram of an M u t S protein. Subunits A and B, each with a domain 1 and a domain 4, overlie each other in an X shape across a section of misformed double stranded D N A.

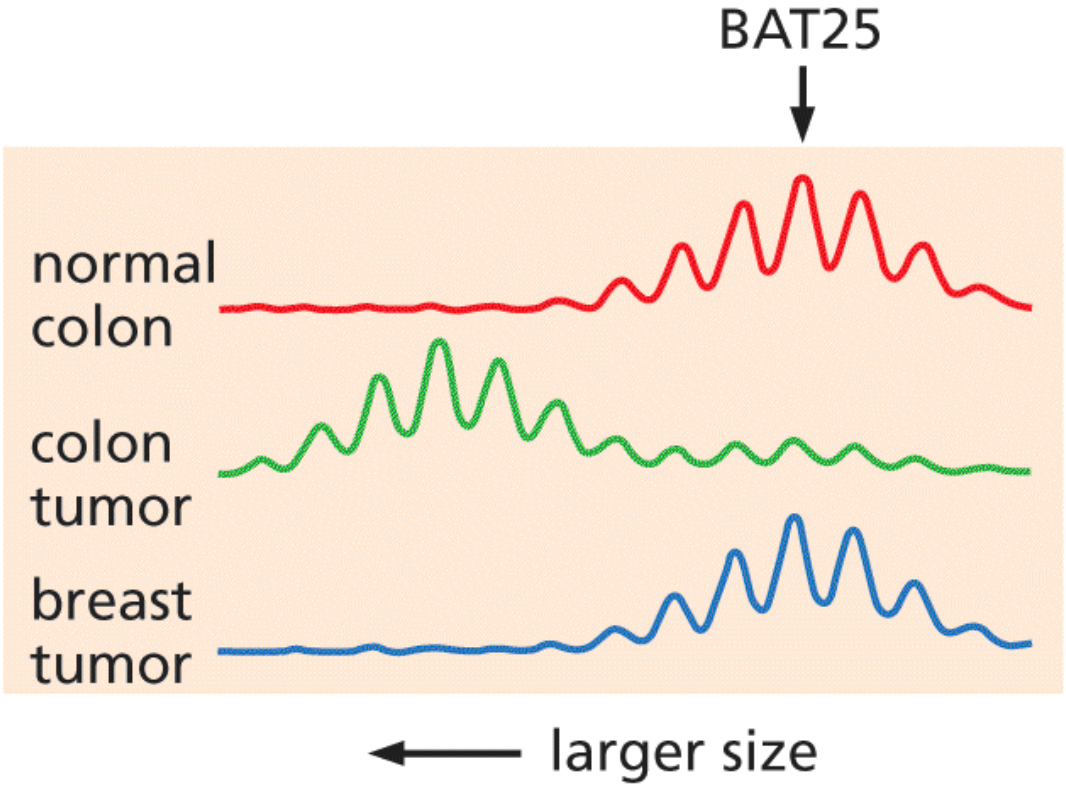
(D)

Figure 12.6 DNA polymerase errors and mismatch repair (A) The DNA polymerases, notably pol-δ, occasionally "stutter," or skip a base when copying a repeating sequence of DNA (e.g., a microsatellite sequence) in the template strand (*blue*). As a consequence, the newly synthesized strand (*green*) either may acquire an extra base that increases the length of the repeating sequence or may lack a base (*top two images*). Identical dynamics may cause similar changes in microsatellite sequences where the repeat unit is a TC dinucleotide segment (*bottom two images*), or a more complex repeating sequence (*not shown*). (B) Mismatch repair (MMR) proteins recognize and repair the mistakes made by DNA polymerases, including misincorporated bases and inaccurate replication of microsatellite sequences. Here, use of atomic-force microscopy reveals the behavior of the MutS MMR protein, a bacterial homolog (from *Thermus aquaticus*) of a number of mammalian MMR proteins. MutS is seen binding to a

DNA fragment into which a mismatch has been introduced at a specific nucleotide site. MutS kinks the DNA double helix as it scans for and ultimately finds regions of mismatch (793T Bulge), where it binds in a stable fashion, seen here as a white pyramid. (C) In eukaryotic cells, two components of the MMR apparatus, MutSα and MutLα, collaborate to initiate repair of mismatched DNA. After MutSα (a heterodimer of MSH6 and MSH2) scans the DNA and locates a mismatch, MutLα (a heterodimer of MLH1 and PMS2) scans the DNA for single-strand nicks, which identify the strand that has recently been synthesized (*red*). In addition, the under-methylation of the recently synthesized strand may aid in this identification (*not shown*). MutLα then triggers degradation of this strand back through the detected mismatch, allowing for repair DNA synthesis to follow. (D) Part of the structure of the *T. aquaticus* MutS homodimeric protein in complex with a mismatched helix (*red*) . In addition, is shown. Domains I and IV of subunit A are in *dark blue* and *orange*, and the corresponding domains of subunit B are in *light blue* and *yellow.* An arrow (*yellow*) indicates where phenylalanine residue 39 of domain I of subunit A is associated with an unpaired thymidine in one of the two DNA strands. Defects in the human homolog of this protein play a critical role in triggering hereditary non-polyposis colon cancer (HNPCC), as discussed in Section 12.8. (B, from H. Wang et al., *Proc. Natl. Acad. Sci. USA* 100:14822–14827, 2003. With permission from National Academy of Sciences, U.S.A. C, adapted from B. Alberts et al., Molecular Biology of the Cell, 7th ed. New York: W.W. Norton, 2022, D, from G. Obmolova et al., *Nature* 407:703–710, 2000. With permission from Nature.)

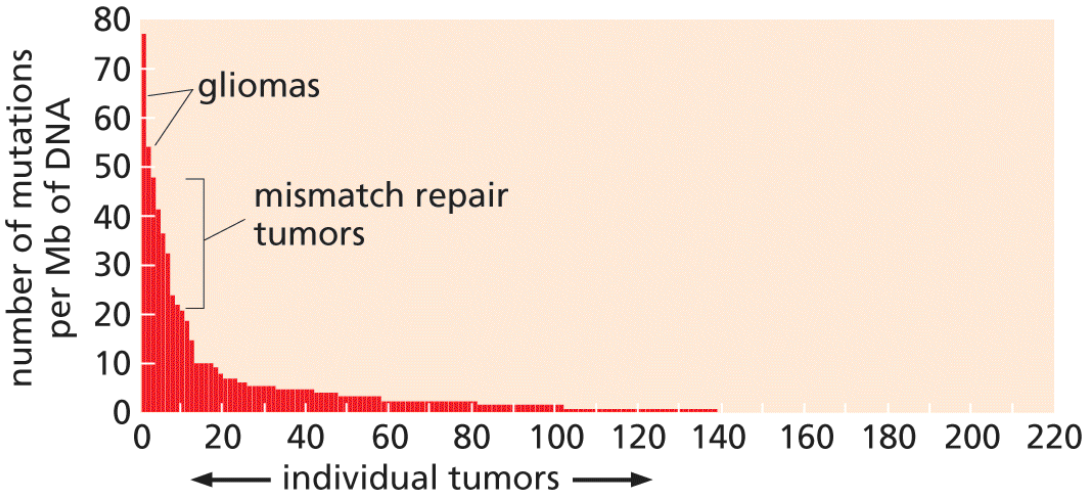
For historical reasons, highly repeated sequences in the genome, often carrying 100 or more nucleotides per repeat unit, have been called "satellite" sequences. Because the simple, far shorter sequences discussed here are also found in many places in the genome, they have been named microsatellites. A defective mismatch repair system that fails to detect and remove stuttering mistakes made by DNA polymerases when copying a microsatellite will result in the expansion or shrinkage of its sequences in progeny cells. This creates the genetic condition known as microsatellite instability (MIN; **Figure 12.7A**), which may ultimately involve changes in thousands of microsatellite sequences scattered throughout a cell genome. Importantly, as illustrated in Figure 12.7B, defects in MMR yield base substitutions even more frequently than expansions and contractions of microsatellite sequences; indeed, the genome is showered with point mutations in an MMR-defective cancer cell. These more subtle alterations may also be detected and erased by mismatch repair proteins, which are highly sensitive to bulges and loops in the double helix caused by inappropriately incorporated nucleotides. Importantly, the mismatch repair machinery must be able to distinguish the recently synthesized DNA strand from the complementary "parental" strand that served as the template during DNA synthesis; in making this distinction, the

MMR apparatus is able to direct its attention to removing and then repairing the recently synthesized and therefore defective DNA strand (see Figure 12.6C). Like the proofreading function described above, mismatch repair involves the excision of the nucleotides that have created the mismatch and a new attempt at synthesis of this strand.



The results of comparing the length of the D N A sequence B A T 25 in breast and colon tumor tissue samples to a sample of normal colon tissue from the same patient. The measurement readout takes the form of a squiggly bell curve. The readout for the breast tumor sample is normal, indicating that there has been no change in the B A T 25 sequence. By contrast, the readout for the colon tumor sample is shifted left, indicating an expansion-type error in the sequence.

(A)



A histogram with number of mutations per megabase of D N A on the vertical axis and individual tumors, numbered 1 through 210, on the horizontal axis. The tumors are ordered by decreasing number of mutations. Tumors 1 and 2, both gliomas, both had more than 50 mutations per megabase. Tumors 3 through 8, all mismatch repair tumors, had between 20 and 50 mutations per megabase. The 72 tumors starting at number 138 had no mutations at all.

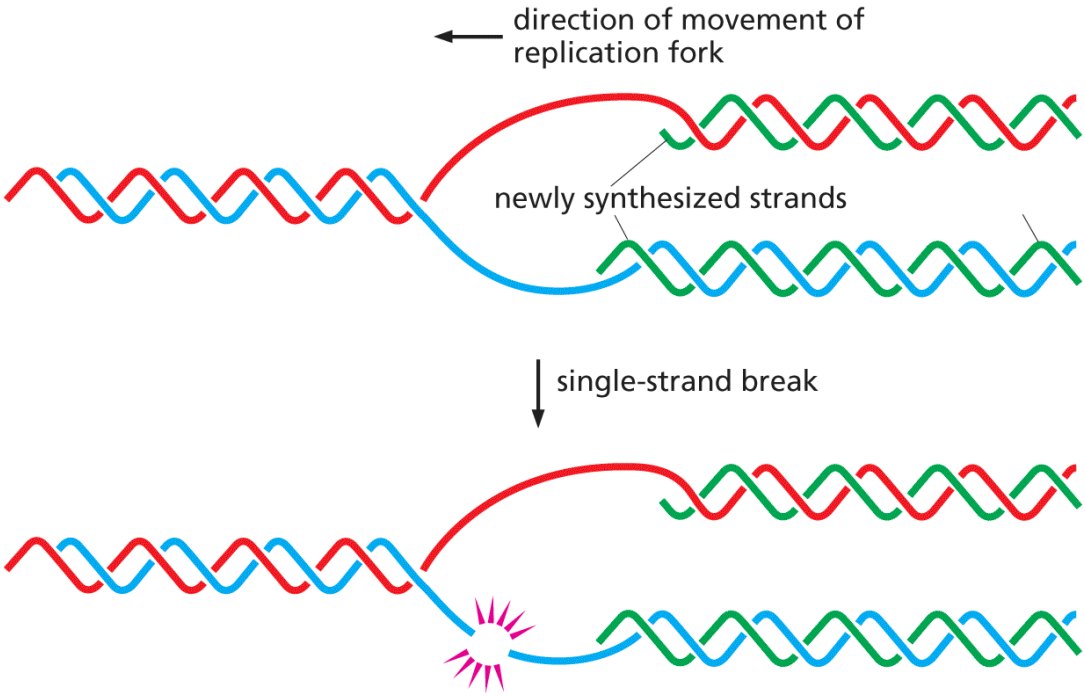
(B)

Figure 12.7 Detection of microsatellite instability Defects in mismatch repair (MMR) are responsible for the accumulation of a variety of mutations in the genome. (A) The most obvious type of these mutations is microsatellite instability (MIN), which causes an expansion or contraction of the size of a microsatellite repeat sequence. In the analysis shown here, the size of a mononucleotide repeat is analyzed in a woman suffering from HNPCC (hereditary non-polyposis colon cancer) and presenting in the clinic with both a colorectal and a breast carcinoma; analysis was performed using PCR (polymerase chain reaction). The BAT25 sequence, which is located on human Chromosome 4q12, consists of the sequence TTTTxTxTTTTxT7xxT25, where “x” indicates a nucleotide other than T. As a result of errors made by the polymerase used in the PCR reaction, the products of the PCR reactions show a Gaussian distribution of lengths grouped around the actual length of the genomic DNA segment being amplified. This analysis reveals a clear increase in size of the microsatellite repeat in the colon carcinoma (*leftward shift*), whereas the breast tumor exhibits a microsatellite repeat that is precisely the same as normal, control DNA. (This observation strongly suggests that the breast carcinoma, unlike the colon carcinoma, is unlikely to have been caused by MIN.) (B) The coding exons of 518 kinase-encoding genes in the genomes of 210 human tumors of diverse type were sequenced, revealing 1007 somatic mutations in all. As is apparent, the density of mutations (number per

megabase) of all types varied dramatically, with one-third of the tumor genomes showing no mutations at all (*rightward*). Two classes of tumors showed especially high densities of mutations in their genomes. Gliomas/glioblastomas, which had previously been exposed during the course of treatment to high doses of temozolomide, a mutagenic chemotherapeutic agent, exhibited an unusually high density of mutations. In addition, the genomes of a group of five MMR-deficient tumors showed an almost-equivalent density of mutations, consisting largely of base substitutions (14–40 per megabase) plus insertions/deletions of microsatellite repeats (5–12 per megabase). (A, from A. Müller et al., *Cancer Res*. 62:1014–1019, 2002. With permission from American Association for Cancer Research. B, from C. Greenman et al., *Nature* 446:153–158, 2007. With permission from Nature.)

Working together, these various error-correcting mechanisms yield extremely low rates of miscopied bases that survive to become mutant DNA sequences. To begin, DNA polymerases make copying mistakes in only about 1 out of 10^5 polymerized nucleotides. The $3' \rightarrow 5'$ proofreading by the polymerases overlooks only about 1 out of every 10^2 nucleotides initially miscopied by the polymerase, thereby reducing the error rate to about 1 in 10^7 nucleotides. After the DNA polymerase has passed through a stretch of DNA followed by polymerase-associated proofreading, the mismatch repair proteins check the recently synthesized DNA strand a second time. The mismatch repair enzymes fail to correct only about 1 miscopied base out of 100 that have escaped the proofreading actions of the DNA polymerase. Together, this yields a stunningly low mutation rate of only about 1 nucleotide per 10^9 that have been synthesized during DNA replication, yielding only several miscopied bases per haploid genome following each cycle of cell growth and division. As we will see, defects in these error-correcting mechanisms can lead to both familial and sporadic human cancers.

Finally, DNA replication holds yet other dangers for the genome. Some measurements indicate that as many 10 double-strand (ds) DNA breaks occur per cell genome each time a cell passes through S phase. These breaks appear to occur near replication forks, ostensibly because the single-strand DNA at the unwound but not-yet-replicated portion of the parental DNA is susceptible to inadvertent breakage (**Figure 12.8**). Cells have well-developed mechanisms for dealing with such dsDNA breaks, as we will see later. Failure to repair such breaks properly can lead to disastrous consequences, including chromosomal breaks and translocations.



An illustration of a break at the replication fork during the replication of double-strand D N A. In the upper part of the figure, the original double strand of D N A is on the left, and two parallel double strands are on the right, each containing one strand from the original D N A and one newly synthesized strand. Replication is proceeding from right to left. In the lower part of the figure, a single-strand break has occurred in one of the two original D N A strands, at a point where it has been unwound from its partner strand but synthesis of the new strand has not yet occurred.

Figure 12.8 Double-strand DNA breaks at replication forks During DNA replication, the DNA molecules are especially vulnerable to breakage in the single-stranded portions near the replication fork that have not yet undergone replication. Such breaks often occur because of the chemical alteration of a base (discussed later in this chapter) that causes the DNA polymerase to stall, being unable to recognize this altered base; polymerase stalling results in a region of single-stranded DNA that may persist for an extended period of time before it is finally protected by successful replication and thus formation of a complementary strand. The breakage of such a single-stranded region (sometimes termed a “collapsed” replication fork) is functionally equivalent to a double-strand break occurring in an already-formed double helix, in that the break leaves two helices unconnected by either strand.

OceanofPDF.com

Glossary

proofreading
: Process by which a DNA polymerase scans the deoxyribonucleotide segment that it has just synthesized in order to ensure that the sequence of this segment was properly synthesized and thus is precisely complementary to that of the template strand. *See also* **mismatch repair**.

mismatch repair
: Class of DNA repair processes that depend on proofreading a recently synthesized segment of DNA and removing any misincorporated bases that may have escaped previous correction by DNA polymerase-associated proofreading functions. Defects in mismatch repair lead to microsatellite instability. *See also* **microsatellite instability**, **proofreading.**

satellite
: Highly repetitive sequences present in genomic DNA. These sequences often have a different composition of bases compared to that of the bulk of the genomic DNA and thus form separate “satellite” bands that can be resolved upon isopycnic density centrifugation. *See also* **isopycnic**, **microsatellite**.

microsatellite
: A DNA relatively short oligonucleotide segment of simple sequence that resides within a cell genome and is repeated hundreds, even thousands of times in this genome, often at sites scattered though this genome. *See also* **satellite**.

microsatellite instability
: A condition caused by mutations in genes involved in DNA mismatch repair that is manifested when microsatellite sequences undergo frequent expansion or shrinkage in length. *See also* **microsatellite**, **mismatch repair**.

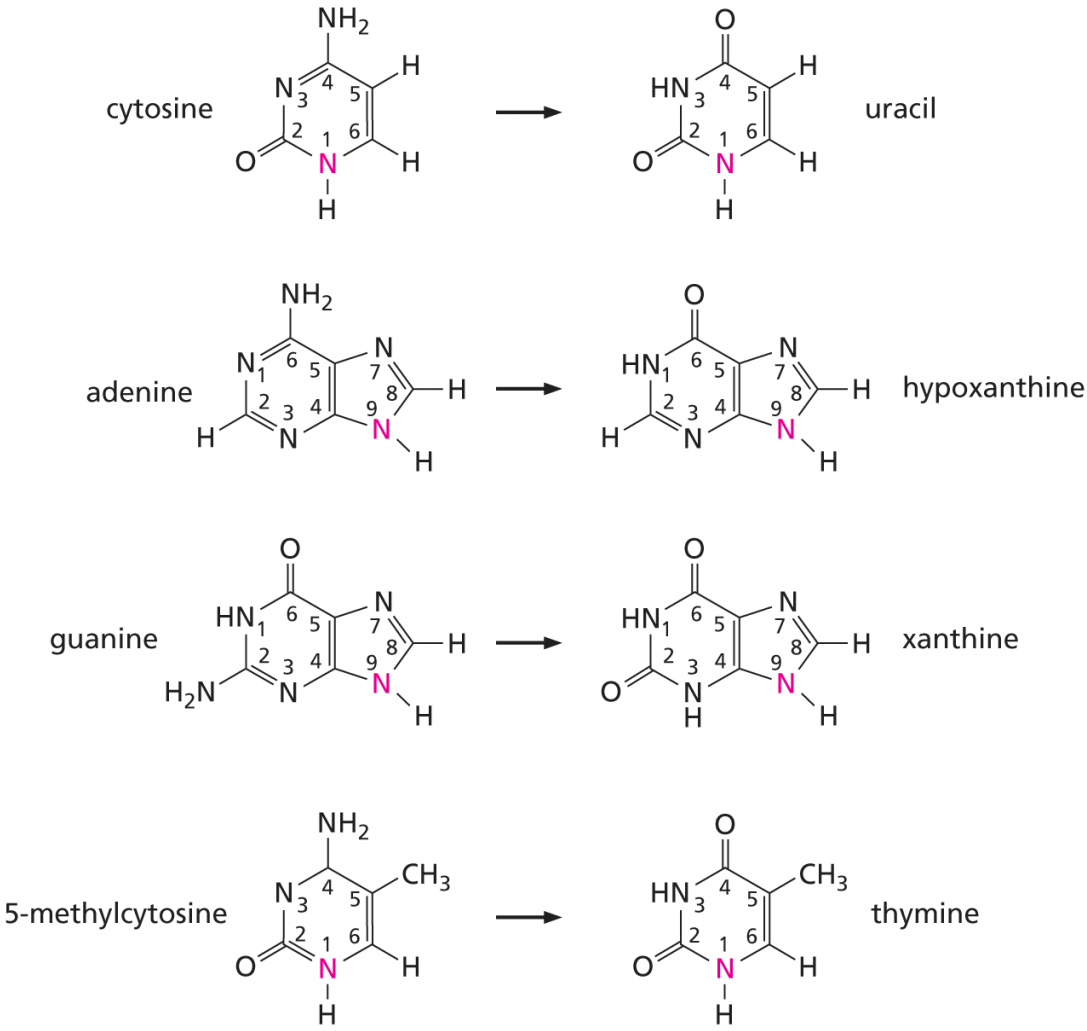
12.4 Cell genomes are under constant attack from endogenous biochemical processes

Most accounts of the origins of contemporary cancer research contain a strong emphasis on the actions of carcinogenic agents that enter the body through various routes, attack DNA molecules within cells, and create mutant cell genomes that occasionally cause the formation of cancer cells (see Section 11.11). Unrecognized by these models are the mutagens and mutagenic mechanisms of endogenous origin. In recent decades, however, analytical techniques of greatly improved sensitivity have allowed researchers to detect altered bases and nucleotides in the DNA of normal cells that have not been exposed to exogenous mutagens. The results of these analyses have caused a profound shift in thinking about the origins of most of the mutant genes present in the genomes of human cells, because they have shown that endogenous biochemical processes usually make far greater contributions to genome mutation than do exogenous mutagens. Because mutagenic events, independent of their origin, are potentially carcinogenic, there has been a rethinking of the cause of many human cancers.

An important contributor of these endogenous mutational processes is deamination, in which the amine groups that protrude from cytosine, adenine, and guanine rings of the bases are lost. This deamination leads respectively to uracil, hypoxanthine, and xanthine (**Figure 12.9**). The uracil, for instance, may be read as a thymine during subsequent DNA replication, thereby causing a C-to-T (C>T) point mutation, known as a transition mutation, in which one pyrimidine replaces another. The bases generated by deamination are all foreign to normal DNA, and consequently can be recognized as such and removed by specialized DNA repair enzymes. However, any such altered bases that escape detection and removal represent potential sources of point mutations.

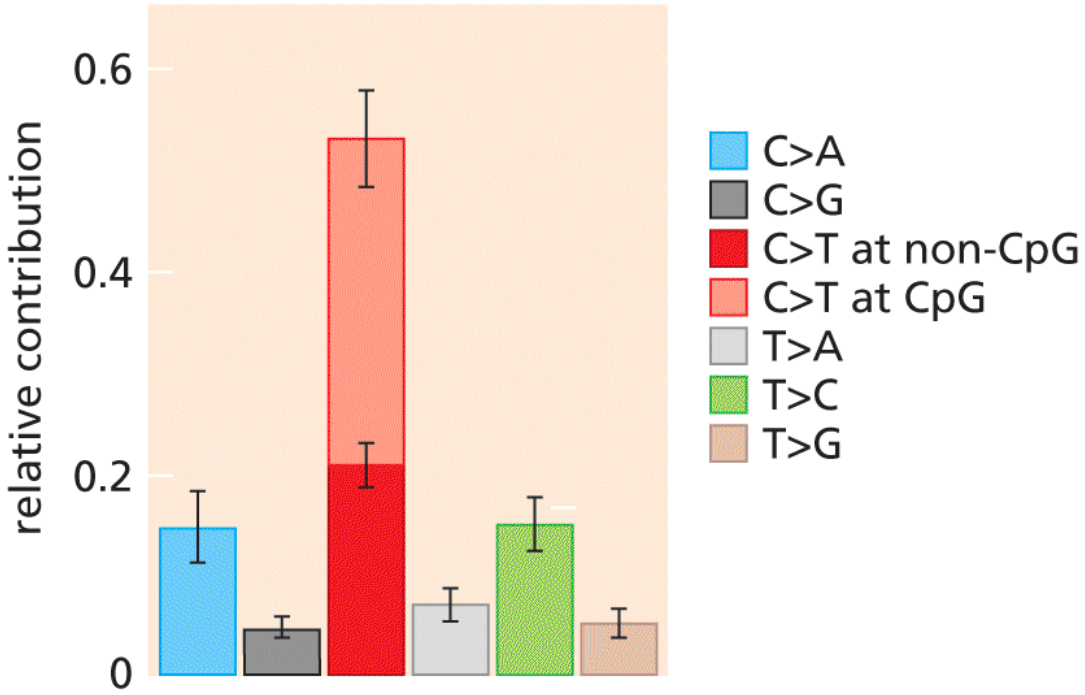


Base deamination. In deamination, an amino group on a carbon in a carbon-nitrogen ring is replaced with a double-bonded oxygen, and an adjacent nitrogen in the ring loses a bond and gains a hydrogen. This process turns cytosine into uracil, adenine into hypoxanthine, guanine into xanthine, and 5-methyl cytosine into thymine.

Figure 12.9 Base deamination The deamination reactions affecting purine and pyrimidine bases, which occur spontaneously at various rates at neutral pH, lead to changes in nucleotide sequences unless they are repaired. The deamination of 5-methylcytosine yields thymine (*bottom*); because this base is naturally present in DNA, the repair machinery does not always recognized it as being aberrant, explaining the frequent mutations at sites bearing this methylated base. (In each case, the nitrogen atom in red participates in the formation of a glycosidic bond with the 1-carbon of deoxyribose.) (Adapted from B. Alberts et al., Molecular Biology of the Cell, 7th ed. New York: W.W. Norton, 2022.)

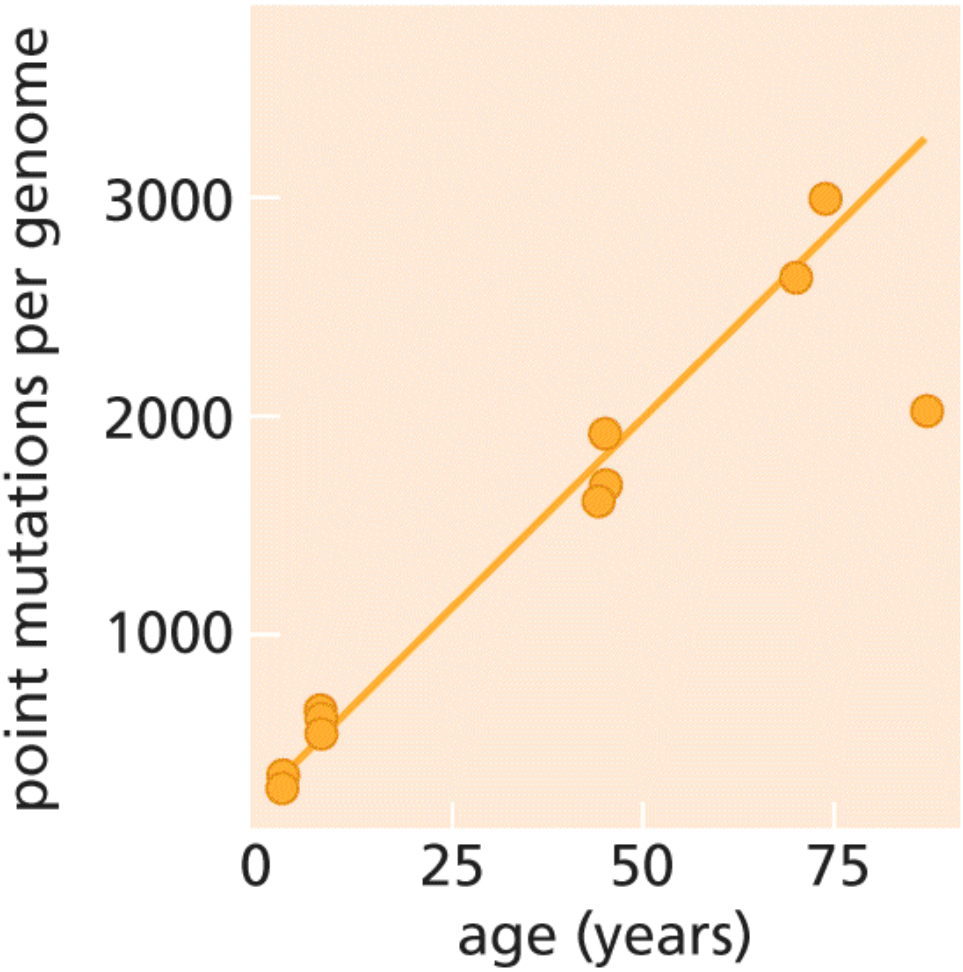
The rate of spontaneous deamination of the 5-methylcytosine base—the methylated form of the cytosine in CpG dinucleotides that we encountered earlier (see Section 7.7)—is even higher, yielding thymine (see Figure 12.9). This creates a significant problem for the DNA repair apparatus, because thymine (unlike the other three products of deamination described above) is a component of normal DNA, and the T:G base pair may therefore escape detection, survive, and ultimately serve as template during a subsequent cycle of DNA replication, leading to a C>T point mutation.

In fact, this deamination of 5-methylcytosine represents a major source of point mutations in human DNA, including in cancer genomes as well as the genomes of otherwise-normal cells as individuals age. As discussed in greater detail in Section 12.13, with the advent of high-throughput DNA sequencing methods, it is now possible to obtain comprehensive DNA sequence information from any number of genomic sources. These analyses have clearly demonstrated that the mutation of CpG sequences to TpG is the highest frequency, spontaneous mutational event in the genomes of many cell types in the human body, including different types of stem cells (**Figure 12.10A**). These mutations accumulate progressively in our tissues as we age (Figure 12.10B). Because most of them do not have any phenotypic consequences for the cell and thus for the tissue around them, these mutations are tolerated and simply serve as markers of the proliferative history of a stem cell over extended periods of time. Indeed, the accumulation of these mutations can be read out as a type of molecular clock of organismal aging. Likewise, CpG>TpG transition mutations are found frequently in cancer cell genomes, reflecting in part the mutations that preexisted in the cell-of-origin of a tumor and in part the ongoing methyl-cytosine deamination events occurring during the course of multi-step tumorigenesis. In cancers that are not the product of environmental exposure to highly mutagenic carcinogens (for example, smoking-associated lung cancers or UV-induced melanomas of the skin; see Section 12.13), these CpG>TpG mutations rank among the most common types of genetic change.



A bar graph comparing the relative contributions of different base substitution mutations. C to G, T to A, and T to G are all relatively rare. C to A and T to C are more common but the relative contribution of each is still less than 20 percent. By far the most common are C to T, with a relative contribution of about 55 percent, of which over half occur in C p G sequences.

(A)



A scatterplot correlating point mutations per genome with age in years, for about a dozen human donors. All points lie very close to a trendline that runs from the origin up to about 3000 mutations at age 75, except for one outlier donor who had only about 2000 mutations at age 90.

(B)

Figure 12.10 Age-associated accumulation of somatic point mutations in human intestinal stem cells Single normal human stem cells were isolated from the small intestines of individuals of different ages, expanded as organoid cultures, and then subjected to whole-genome sequencing (see Section 12.13) to determine the pattern and frequency of mutations as a function of age. Normal blood samples were sequenced from the same individuals for reference. (A) The relative contribution of genome-wide mutations of the pyrimidine bases of base pairs to the three alternative bases is shown for all samples according to the color scheme in the key. Note that C>T mutations occur at the highest frequency, with the majority of these occurring at CpG dinucleotide sequences. This pattern is

explained by high frequency of spontaneous deamination of 5-methylcytosine at CpG sites, leading to thymine (see Figure 12.09). (B) Correlation of the number of somatic point mutations in each stem cell sample as a function of the age of the donor. Each data point represents a single small intestinal stem cell sample. The accumulation of CpG to TpG mutations can be considered a type of mutational clock that correlates with organismal age. (From F. Blokzijl et al. *Nature* 538:260–264, 2016. With permission from Nature.)

The spontaneous breakage of the chemical bond linking a purine or pyrimidine base to its deoxyribose sugar in DNA, termed depurination and depyrimidination, respectively, also occurs remarkably frequently. By some estimates as many as 10,000 purine bases are lost by depurination each day in a mammalian cell. Depyrimidination occurs at a 20- to 100-fold lower rate, but still results in as many as 500 cytosine and thymine bases lost per cell per day. Estimates of the steady-state level of base-free nucleotides present in a single human genome range from 4000 to 50,000. If not effectively repaired, these events can also lead to mutation.

The intracellular environment holds yet other dangers for the chromosomal DNA. The greatest of these comes from the processes of oxidation, which may inflict far more damage on DNA than the reactions mentioned above. Most important here are the reactions that occur in the mitochondria and generate a variety of intermediates as oxygen is progressively reduced to water:

$$O_2 + e^- \rightarrow O_2^{\cdot -} + e^- \rightarrow H_2O_2 + e^- \rightarrow {}^{\cdot}OH + e^- \rightarrow H_2O$$

superoxide ion | hydrogen peroxide | hydroxyl radical

Some of these incompletely reduced intermediates—the so-called reactive oxygen species (ROS)—may leak out of the mitochondria into the cytosol and thence into the rest of the cell. Among them are the superoxide ion, hydrogen peroxide, and the hydroxyl radical—the intermediates in the reactions listed above. (By one estimate, in normal cells 1–2% of oxygen molecules consumed by mitochondria end up as ROS; these levels may increase after mitochondria become more leaky following cell transformation.) Other oxidants arise as by-products of various oxygen-utilizing enzymes, including those in peroxisomes (cytoplasmic organelles that are involved in the oxidative breakdown of various cellular constituents, notably lipids); yet others are formed by the spontaneous oxidation of lipids, which results in their peroxidation. Inflammation also provides an important source of the oxidants that favor mutagenesis and therefore carcinogenesis (**Sidebar 12.3**).

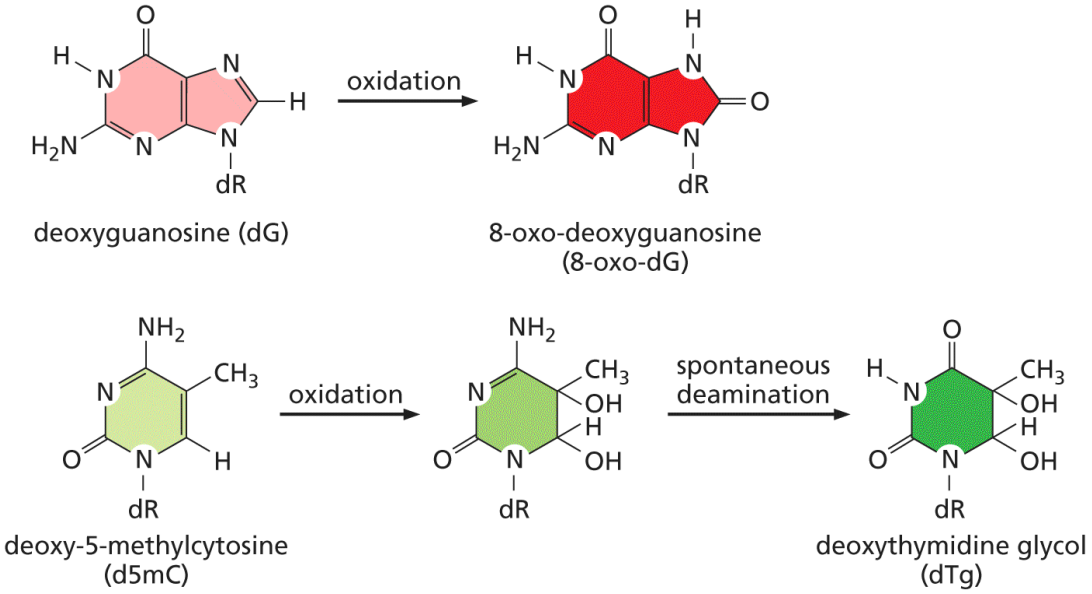
Sidebar 12.3 Inflammation can have both mitogenic and mutagenic consequences

Chronic inflammation of tissues is often provoked by infectious agents, such as hepatitis B and C virus infections of the liver, *Helicobacter* infection of the gastric epithelium, and human papillomavirus (HPV) infection of the cervical epithelium (see Sections 11.13 and 11.16). These infections often lead to cell death and resulting compensatory proliferation of the surviving cells—a type of tumor promotion discussed in the previous chapter.

In addition, infected cells attract the attentions of a variety of cells from the innate and adaptive immune systems, as discussed in Chapter 15. Among them are macrophages and neutrophils that are dispatched to sites of infection; there they create localized inflammatory responses, which may be accompanied by mutagenic consequences. For example, phagocytes kill infected cells in part by releasing bursts of a powerful mix of oxidants, including nitric oxide (NO), superoxide ion ($O_2^{\cdot -}$), hydrogen peroxide (H_2O_2), and hypochlorite (OCl^-). Such highly reactive chemical species are deployed to kill the intended target cells but, in addition, may cause collateral damage by leaving behind survivors whose genomes they have also damaged. Like the by-products of normal oxidative metabolism, these oxidants act as mutagens on the genomes of nearby bystander cells through their ability to generate chemically modified bases via nitration, oxidation, deamination, and halogenation. Indeed, the DNAs of inflamed and neoplastic tissues have been found to carry substantially increased concentrations of 8-oxo-dG (see Figure 12.11), one of the primary products of DNA oxidation. (As examples, the total daily excretion of oxidized bases by smokers can be as much as 50% higher than by nonsmokers, ostensibly from the chronic inflammation in their lungs, and the urine of those suffering a chronic flatworm infection in Thailand has even higher concentrations of 8-oxo-dG.) The increased mutation rate resulting from base oxidation helps to explain why chronic inflammation in many tissues favors tumor progression.

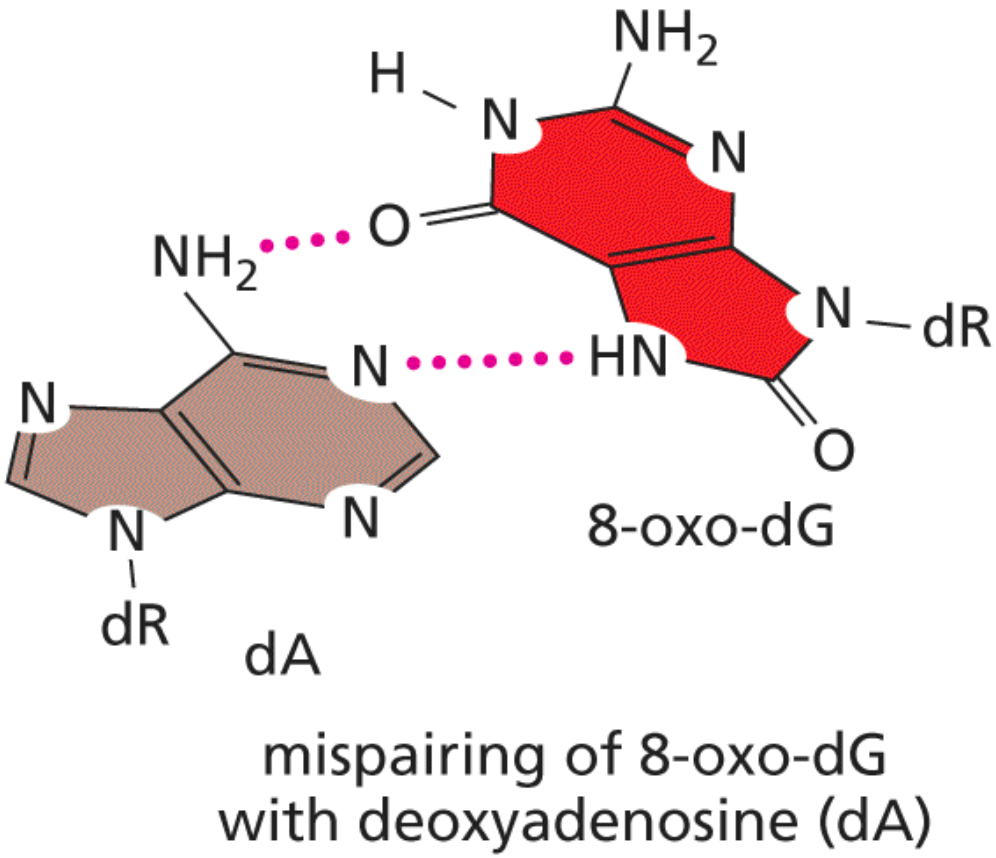
The highly reactive molecules produced by these various processes proceed, usually within seconds, to form covalent bonds with many other molecular species in the cell. Among the many targets of ROS attack are the bases within DNA, including both purines and pyrimidines (**Figure 12.11A**). In addition, reactive oxygen species can induce single- and double-stranded DNA breaks, apurinic and apyrimidinic sites (together known as abasic sites), in which bases are cleaved from deoxyribose, as well as DNA–protein cross-links. As described below, many of the resulting altered bases are recognized by specialized components of the DNA repair machinery that proceed to excise them from the DNA. Some of the excised bases, including thymine glycol, which derives from deoxythymidine glycol, and 8-oxoguanine, which derives from 8-oxo-deoxyguanosine (8-oxo-dG), can be detected and quantified in the urine of

mammals, providing some indication of the rate at which they are produced throughout the body (**Supplementary Sidebar 12.2**).



The acquisition of a single double-bonded oxygen turns deoxyguanosine into 8-oxo-deoxyguanosine. The acquisition of two single-bonded oxygens, followed by spontaneous deamination, turns deoxy-5-methylcytosine into deoxythymidine glycol.

(A)



8-oxo-deoxyguanosine mis-paired with deoxyadenosine.

(B)

Figure 12.11 Oxidation of bases in the DNA The oxidation of DNA bases, which often results from the actions of reactive oxygen species (ROS), can be mutagenic in the absence of subsequent DNA repair reactions. (A) Two frequent oxidation reactions involve deoxyguanosine (dG), which is oxidized to 8-oxo-deoxyguanosine (8-oxo-dG), and deoxy-5-methylcytosine (d5mC), the nucleotide that is present in methylated CpG sequences. Upon oxidation, the latter initially forms an unstable base that rapidly deaminates, yielding deoxythymidine glycol (dTg). (B) The 8-oxo-dG, which arises from the oxidation of dG, can mispair with deoxyadenosine (dA) rather than form a normal base pair with deoxycytosine (dC). Hence, if 8-oxo-dG is not removed from a double helix, the DNA replication machinery may inappropriately incorporate a dA rather than a dC opposite it, resulting in a C>A point mutation. The notation “dR” signifies deoxyribose in all cases. The purines are shown in various shades of red and brown, and the pyrimidines are shown in various shades of green.

Some experiments have shown that the yield of these compounds is directly proportional to the rate of oxidative metabolism in various species. The formation of 8-oxo-dG creates a danger of mutation, as one conformation of this altered base can readily pair with A. This mispairing of bases during DNA replication can lead, in turn, to the replacement of a G:C base pair, via G:A pairing, to a T:A base pair (see Figure 12.11B). Such a G → T replacement of a purine by a pyrimidine (or the opposite) is often termed a transversion. Taken together, the continuing hail of damage from oxidation, depurination, deamination, and methylation, which together may alter as many as 100,000 bases per cell genome each day, greatly exceeds the amount of damage created by exogenous mutagenic agents in almost all tissues.

OceanofPDF.com

Glossary

transition
: Point mutation in which one purine base replaces another, or in which one pyrimidine base replaces another. *See also* **transversion**.

depurination
: Breakage of the glycosidic bond that links purine bases to the deoxyribose or ribose of DNA or RNA, respectively.

depyrimidination
: Breakage of the glycosidic bond that links pyrimidine bases to the deoxyribose or ribose of DNA or RNA, respectively.

peroxisome
: A cytoplasmic vesicular organelle that is involved in the oxidation of various substrates, notably lipids.

phagocyte
: , (adj. **phagocytic**) Cell of the immune system—e.g., a macrophage or dendritic cell—that is specialized to engulf and destroy other cells, cellular fragments, and other debris.

apurinic
: Referring to the product of depurination, in which the glycosidic bond linking a deoxyribose or ribose to a purine base is broken, leaving behind only the deoxyribose or ribose in the DNA or RNA, respectively. *See also* **depurination**.

apyrimidinic
: Referring to the product of depyrimidination, in which the glycosidic bond linking a deoxyribose or ribose to a pyrimidine base is broken, leaving behind only the deoxyribose or ribose in the DNA or RNA, respectively. *See also* **depyrimidination**.

abasic
: Referring to a nucleotide that has lost its purine or pyrimidine base. *See also* **apurinic**; **apyrimidinic**.

transversion
: Point mutation in which a purine base replaces a pyrimidine or vice versa. *See also* **transition**.

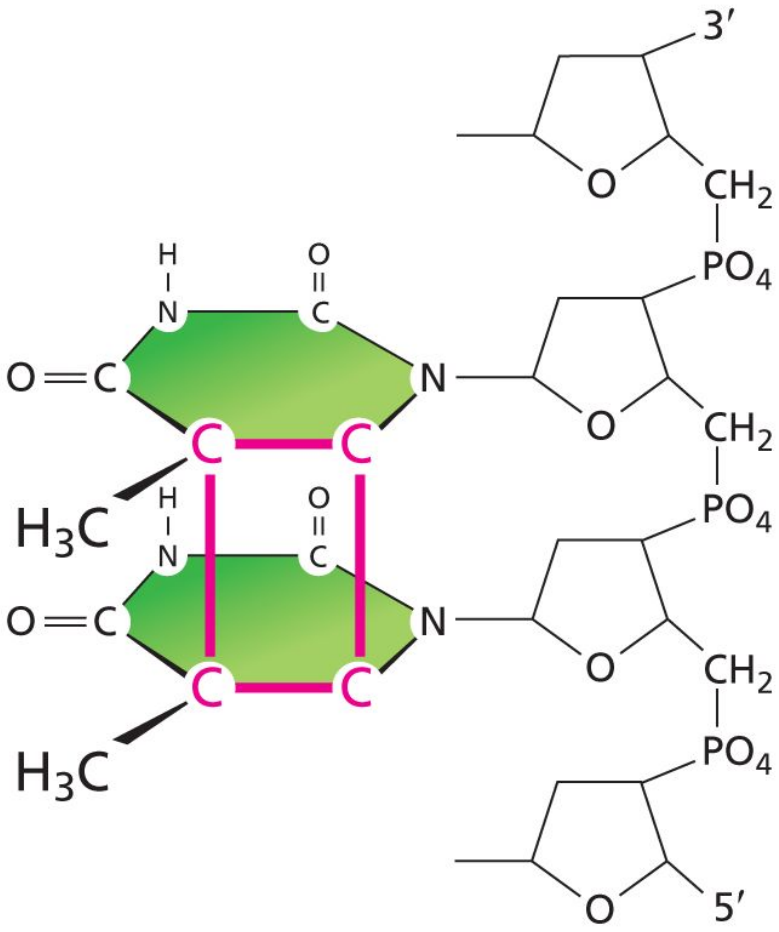
12.5 Cell genomes are under occasional attack from exogenous mutagens and their metabolites

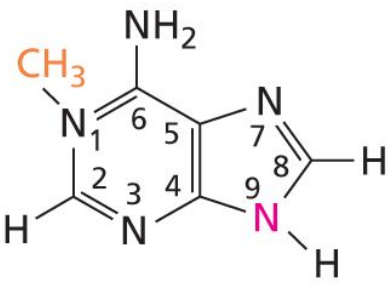
As we have discussed repeatedly in Chapter 11, cellular genomes are also damaged by exogenous carcinogens, including various types of radiation as well as molecules that enter the body via the food we eat and the air we breathe. Among the best studied of the exogenous carcinogens are X-rays, often termed ionizing radiation because of the ionized, chemically reactive molecules that this form of electromagnetic energy creates within cells. As much as 80% of the energy deposited in cells by X-rays is thought to be expended in stripping electrons from water molecules. The resulting free radicals proceed to generate ROS that create single- and double-strand breaks in the DNA double helix. As discussed later, these double-strand breaks (DSBs) are often difficult to repair and may, on occasion, generate breaks in a chromosome that are visible microscopically during metaphase.

Ultraviolet (UV) radiation from the sun is a far more common source of environmental radiation than X-rays. Living organisms have had to contend with UV radiation since life first formed on this planet some 3.5 billion years ago. Once oxygen accumulated to high levels in the atmosphere about 0.6 billion years ago, the ozone formed from atmospheric oxygen provided a protective shield that significantly attenuated the flux of UV radiation striking the Earth's surface. Nonetheless, a significant amount of UV still succeeds in penetrating the ozone shield and reaching the biosphere.

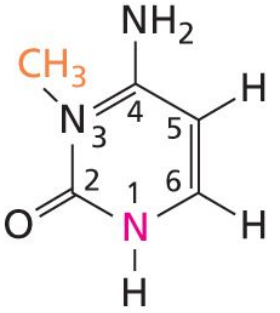
Should UV photons strike a DNA molecule in one of our skin cells, a frequent outcome is the formation of pyrimidine dimers—that is, covalent bonds form between two adjacent pyrimidines in the same strand of DNA. In principle, these can form between two adjacent C's, two adjacent T's, or a C and an adjacent T. In mammals, where the percentages of A's, C's, G's, and T's are similar, more than 60% of the pyrimidine dimers are TT and perhaps 30% are CT dimers, with the remaining dipyrimidines being CC dimers. As seen in **Figure 12.12A**, a pair of covalent bonds forms between adjacent pyrimidines, resulting in the creation of a 4-carbon (cyclobutane) ring. Another, less common class of DNA photoproducts, termed pyrimidine (6–4) pyrimidinone, also involves covalent linkage between two adjacent pyrimidines (Figure 12.12B). Once formed, pyrimidine dimers are very stable and can persist for extended periods unless DNA repair enzymes recognize and remove them.



(C)



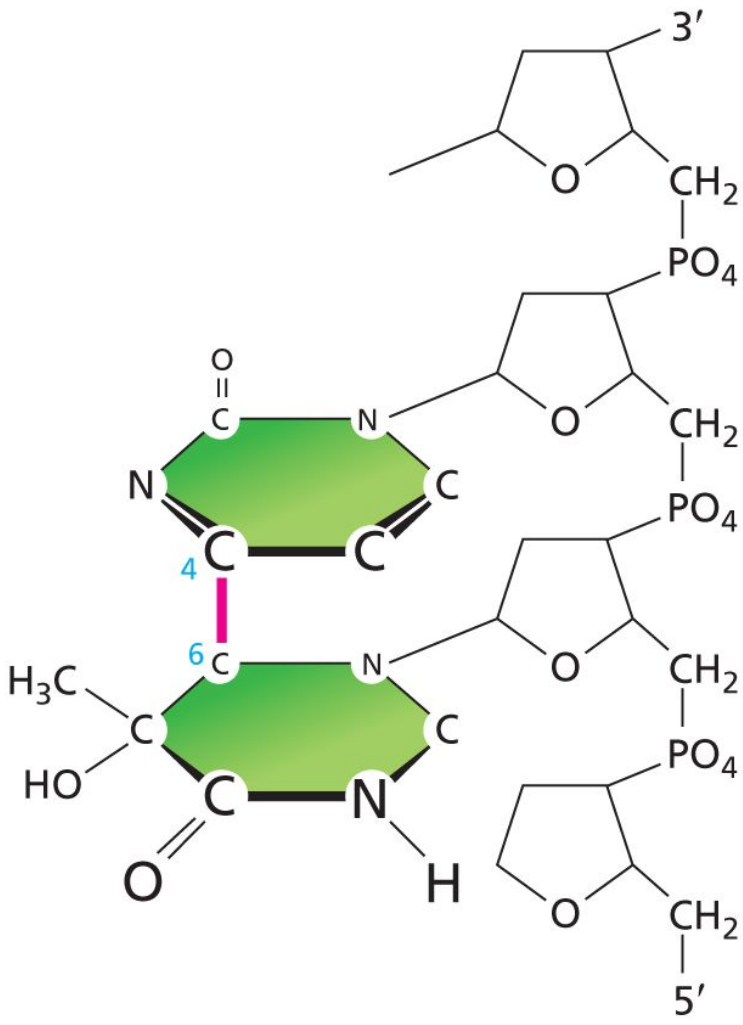
1-methyladenine

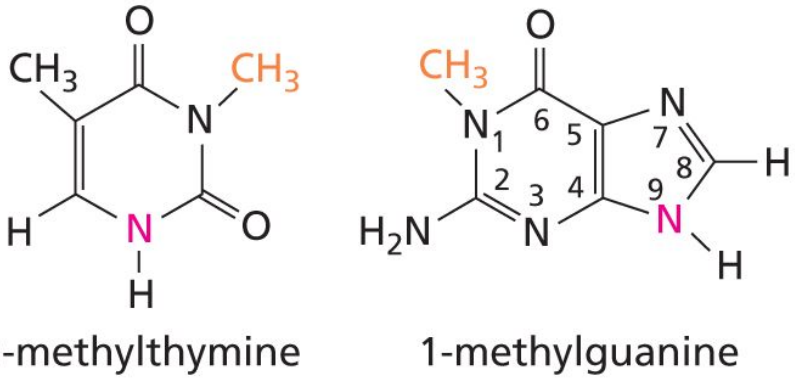


3-methylcytosine

Two hexagonal carbon-nitrogen rings are joined by covalent cross-links from adjacent carbons on one ring to corresponding adjacent carbons on the other ring. The four carbons can be considered a cyclobutane ring, which is highlighted.

(A)



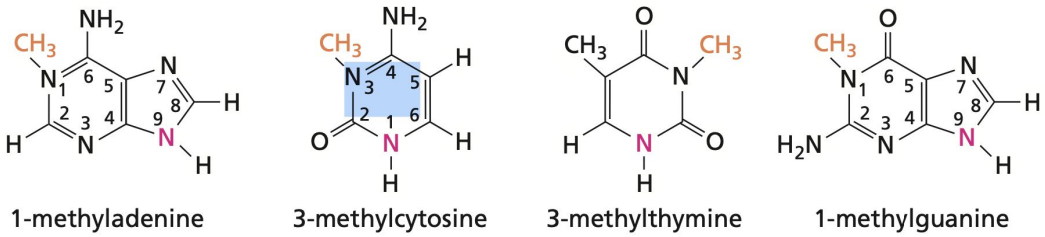


3-methylthymine 1-methylguanine

Two hexagonal carbon-nitrogen rings are joined by a single covalent cross-link between carbons.

(B)

(C)



The four familiar D N A bases, but each with an added methyl group: 1-methyladenine, 3-methylcytosine, 3-methylthymine, and 1-methylguanine.

(C)

Figure 12.12 Products of UV irradiation and alkylation of DNA Ultraviolet (UV) radiation produces covalent cross-links between adjacent pyrimidine bases in the DNA. These structures are relatively stable chemically and must be removed by transcription-coupled repair and global genomic repair (described in Section 12.7). (A) When purified DNA is irradiated with 254-nm photons, 71% of the photoproducts are cyclobutane pyrimidine dimers (CPD). The cyclobutane ring of a CPD is highlighted in *red*. (B) About 24% of the photoproducts generated from this irradiation are pyrimidine (6–4) pyrimidinone (6–4 PP). The covalent bond linking the 6-position of one pyrimidine to the 4-position of the adjacent pyrimidine is highlighted in *red*. (C) Alkylating agents of exogenous origin can covalently alter DNA bases by the attachment of alkyl groups, such as the methyl groups (*orange*) shown here. Many of these methyl groups may also be generated endogenously by the inadvertent actions of S-adenosyl methionine, which carries a highly reactive methyl that plays a key role in many normal biosynthetic reactions. The nitrogens that form glycosidic linkages with deoxyribose are shown in *pink*.

The pattern of mutations observed in genome sequencing studies of melanomas of the skin, as well as basal and squamous skin cancers, demonstrates dramatically that these pyrimidine dimers are mutagenic. In these cancers, the genomes are littered with dipyrimidine substitutions. Although the TT dimer is the one most frequently formed by UV radiation, it is only weakly mutagenic because various DNA repair and replication enzymes, to be discussed in Section 12.7, are able to deal with it effectively. The efficient repair of TT dimers explains why CC>TT substitutions, which arise from CC (rather than TT) dimers, are the most common sources of UV

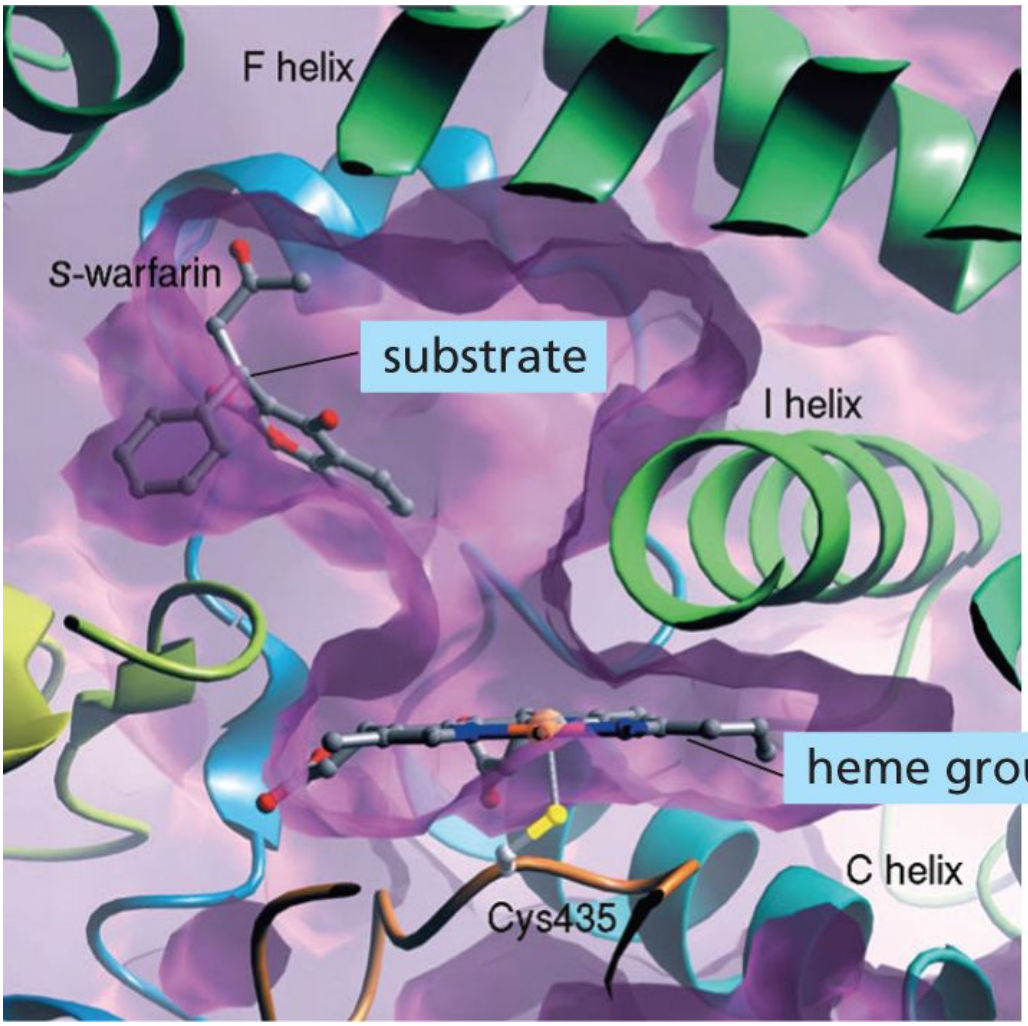
light mutagenesis found in UV-induced cancers. UV photons characteristically cause this mutation, providing further support for the notion that UV rays are directly mutagenic and carcinogenic for the human skin. Interestingly, melanomas that arise in non-sun exposed areas of the body (for example, the soles of the feet) do not show this signature of UV exposure. Other evidence for a direct mutagenic role of UV radiation comes from the observed incidence of squamous cell skin carcinomas in the human population, which doubles with each 10-degree decline in latitude, reaching its peak at the equator where cumulative UV exposure is highest.

A variety of chemical species can enter the body from outside, undergo chemical modification (see Figure 2.21), and then proceed to react with the macromolecules within cells, among them the DNA. Many of these modified chemical species are electrophilic, that is, they seek out and attack electron-rich regions of target molecules. Among the most potent mutagens are alkylating agents, chemicals that are capable of attaching alkyl groups covalently to the DNA bases (see Figure 12.12C).

The alkylation of a base may destabilize its covalent bond to deoxyribose, resulting in the loss of the purine or pyrimidine base from the DNA. Alternatively, the DNA polymerase machinery may misread the alkylated bases during DNA replication. Because of their potent mutagenicity, alkylating agents are often used experimentally to induce various types of tumors in laboratory animals.

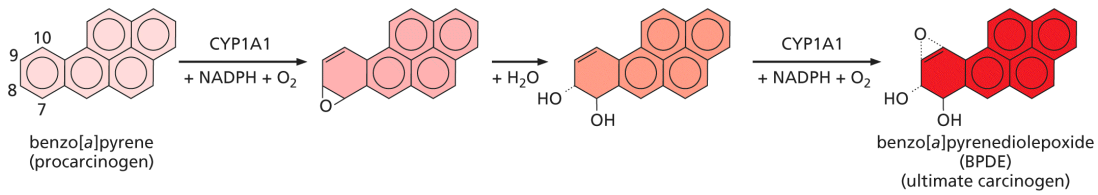
A number of potent mutagens are formed when ingested or inhaled compounds become altered by cellular metabolic processes (see Section 2.9). Take, as an example, benzo[*a*]pyrene (BP), a potent carcinogen that falls in the class of polycyclic aromatic hydrocarbons (PAHs), that is, molecules carrying multiple benzene rings fused together in various combinations (see **Supplementary Sidebar 2.7**). Experiments conducted in Britain in the late 1920s indicated that this compound is a prominent carcinogen found amid the complex mixture of compounds in coal tar.

An elaborate array of cytochrome P450 enzymes (CYPs) are dispatched by cells largely in the liver to oxidize xenobiotic compounds, such as these polycyclic hydrocarbons. (The genes for 57 distinct P450s have been uncovered in the human genome.) The intended function of these enzymes is the detoxification of foreign chemical species, converting them by oxidation into molecules that are soluble and can be readily excreted (**Figure 12.13A**). However, an inadvertent outcome of this detoxification is often the creation of chemical species that are highly reactive with the DNA and are therefore actively mutagenic (Figure 12.13B). As a consequence, chemically inert, unreactive procarcinogens are converted into highly reactive ultimate carcinogens that can attack DNA molecules directly through their ability to form covalent bonds with various bases (see Section 2.9). The chemical entity formed after reaction of a carcinogen with a DNA base is often termed a DNA adduct (**Figure 12.14**).



A diagram of multiple molecules, with ribbon diagrams of an F helix, an I helix, and a C helix, plus ball and stick models of a heme group and the substrate S warfarin.

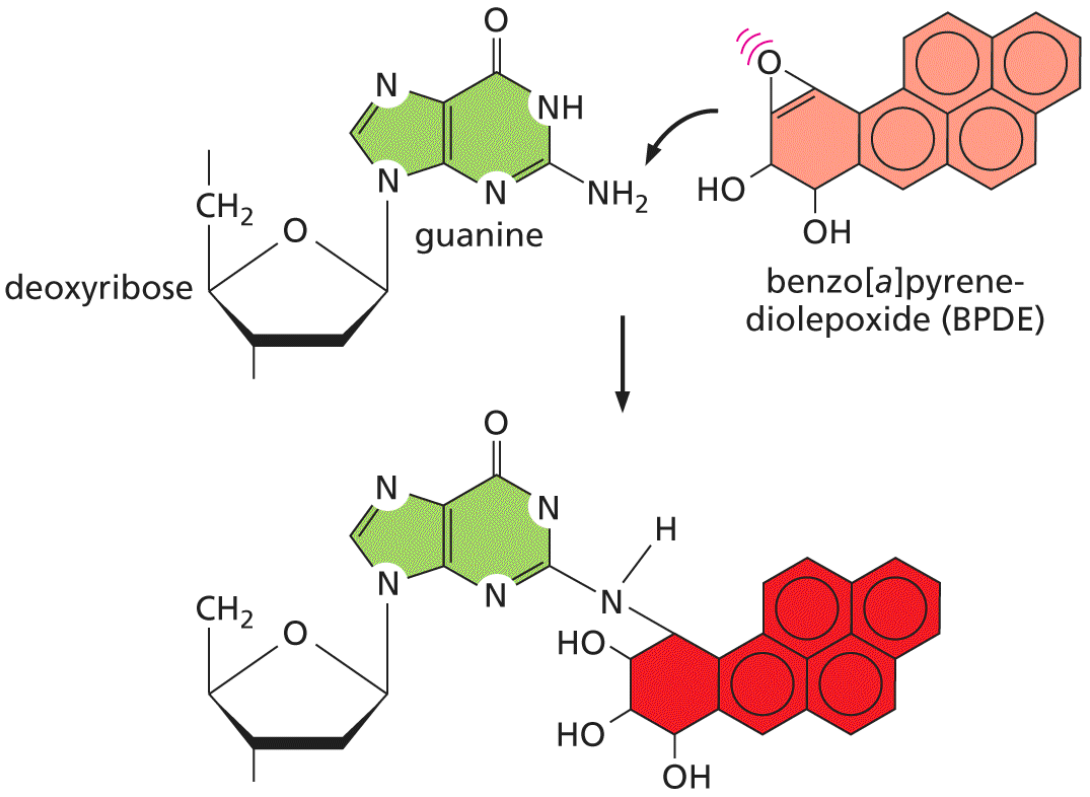
(A)



A multi-step chemical reaction involving a sequence of molecules each consisting of multiple interlocking carbon rings. The addition of C Y P 1 A 1, N A D P H and oxygen converts benzo [a] pyrene, a procarcinogen, into an intermediate molecule, which the addition of water converts into another

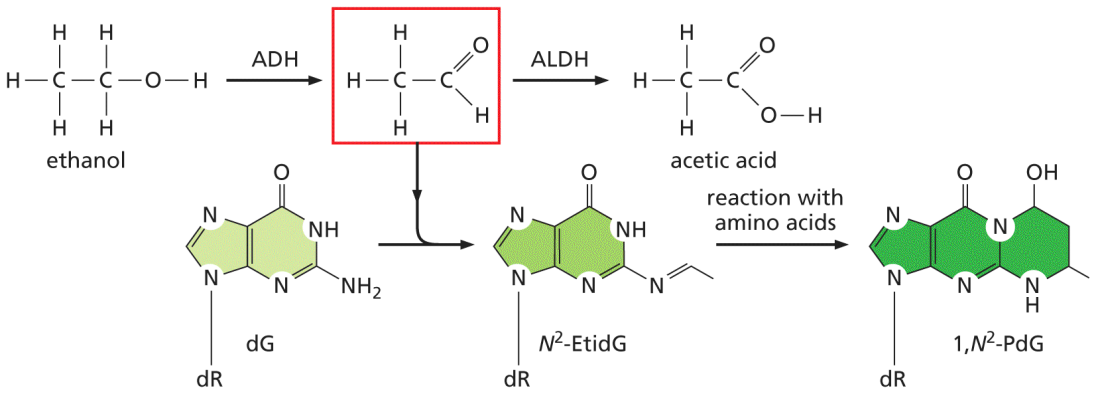
intermediate molecule, which a second addition of C Y P 1 A 1, N A D P H and oxygen converts into benzo [a] pyrenediolepoxide, an ultimate carcinogen.
(B)

Figure 12.13 Actions of cytochromes on procarcinogens (A) Cytochrome P450s (CYPs) are involved in the biosynthesis of a variety of metabolites such as steroid hormones, cholesterol, and bile acids as well as in the degradation of compounds such as fatty acids and steroids. In addition, they aid in the oxidation and associated detoxification of xenobiotics (compounds originating outside the body), such as drugs and carcinogens. The substrate-binding cavity of human CYP2C9, shown here, carries a molecule of a xenobiotic substrate, in this case warfarin (used both as an anticoagulant drug and as a rat poison). The heme ring detoxifies the warfarin by oxidizing it. The large substrate-binding cavities of CYPs allow them to accommodate a wide range of substrates, most of which are quite hydrophobic. (B) Among the xenobiotic compounds entering the body are a variety of polycyclic aromatic hydrocarbons (PAHs) that derive from tobacco smoke, broiled foods, and polluted environments. A common PAH is benzo[*a*]pyrene (BP, *far left*), which, following two successive oxidation reactions mediated by cytochrome P450 enzymes (largely CYP1A1), is converted to benzo[*a*]pyrenediolepoxide (BPDE; *far right*). This highly reactive molecule is termed an ultimate carcinogen (Section 2.9) because, unlike its BP precursor, it is able to directly attack and form covalent adducts with DNA bases, which may then generate oncogenic mutations. Importantly, exposure of a cell to PAHs increases synthesis of CYP1A1, thereby accelerating these reactions. (A, from P.A. Williams et al., *Nature* 424:464–468, 2003. With permission from Nature. B, from E.C. Miller, *Cancer Res*. 38:1479–1496, 1978. With permission from American Association for Cancer Research.)



A benzo[a]pyrene-diolepoxide, or B P D E, attaches to a guanine base by displacing one of the hydrogens on guanine's amino group.

(A)



Ethanol is shown being converted into acetaldehyde by alcohol dehydrogenase, or A D H. Eventually that will be converted into acetic acid by aldehyde dehydrogenase, or A L D H, but in the meantime the acetaldehyde is available to convert deoxyguanosine, or d G, into N2-ethylidene-d G. This, in reaction with amino acids, produces 1,N2-propano-2 prime-deoxyguanosine.

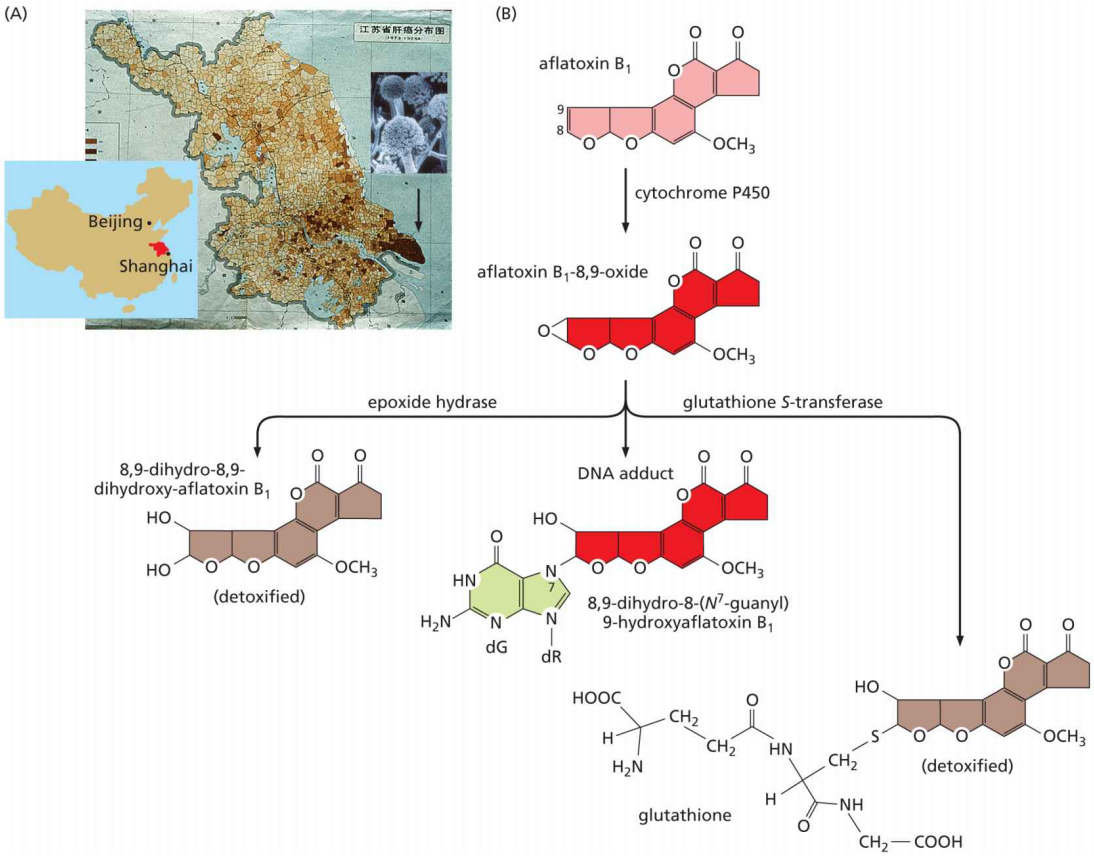
(B)

Figure 12.14 DNA adducts (A) The chemically reactive epoxide group of benzo[*a*]pyrenediolepoxide (BPDE; see Figure 12.13B) can attack a number of chemical sites in DNA, including the extracyclic amine of guanine (shown here), as well as the two ring nitrogens and the O^6 of this base. Because the cell may remove these various adducts with different efficiencies, the O^6 adduct of benzo[*a*]pyrene (BP) may be more potently mutagenic than the more frequently formed adduct shown here. Even though polycyclic aromatic hydrocarbons and BP have been studied for more than half a century, their precise contributions to human cancer development remain a matter of debate. (B) Ethanol, which is consumed in large quantities by many people, is converted by alcohol dehydrogenase (ADH) to acetaldehyde (*red box*), which has been classified as a mutagen because of its reactivity with DNA. The most abundant DNA adduct resulting from the reaction of acetaldehyde with deoxyguanosine (dG) is N^2-ethylidene-dG (N^2-EtidG), a relatively weak mutagen. A more complex adduct that is quite mutagenic is 1,N^2-propano-2′-deoxyguanosine (1,N^2-PdG), which forms from the reaction of N^2-EtidG with amino acids. Heavy drinkers with inborn alleles leading to either highly active ADH or slow acetaldehyde breakdown (via aldehyde dehydrogenase, ALDH) exhibit an especially elevated risk of developing oral and esophageal carcinomas.

In most cases, chemically reactive, ultimate carcinogens attack other molecules almost immediately after being formed. Consequently, they have lifetimes as free molecules that are measured in seconds, and consequently many of the genetic lesions they create arise in the same cells where these molecules underwent initial metabolic activation. For example, BP (benzo[*a*]pyrene), which is a prominent carcinogenic component of tobacco smoke, is often activated in the first cells that it enters—the epithelial cells (pneumocytes) in the lungs of smokers. Once formed, the activated derivative, benzo[*a*]pyrenediolepoxide (BPDE), proceeds directly to form adducts with the guanosine residues in the DNA of these epithelial cells (see Figure 12.14A). Likewise, the immediate downstream product of ethanol metabolism, acetaldehyde, is highly reactive with deoxyguanosine, forming several distinct DNA adducts that are much smaller than the bulky adduct generated by BP (see Figure 12.14B).

Among the most potent exogenous carcinogens is aflatoxin B1 (AFB1; see Figure 2.21B), which is produced by molds belonging to the *Aspergillus* genus. These molds grow on improperly stored peanuts, nuts, corn, and grains. As cited in Section 11.13, people living in areas where AFB1 exposure is high run a 3-fold elevated risk of hepatocellular carcinoma (HCC), whereas those carrying a chronic hepatitis B viral

infection have a 7-fold increased risk of this disease. Individuals with both risk factors run a 60-fold increased risk of contracting liver cancer (**Figure 12.15A**).



A two-part figure describing the role of Aflatoxin in liver carcinogenesis. Part A is a map of China's Jiangsu province, which lies northwest of the city of Shanghai. Within the province, a peninsula directly north of Shanghai is colored a uniform dark brown. As distance from the peninsula increases, the coloration of county-sized geographic areas becomes progressively lighter, with a few scattered dark spots. Also appearing on the map is an electron micrograph of fungal spores. Part B is a diagram of how the carcinogenic properties of aflatoxin B1 may be altered. Cytochrome P 4 50 turns aflatoxin B1 into aflatoxin B1-8,9-oxide. This can be detoxified either by converting it into 8,9-dihydro-8,9-dihydroxy-aflatoxin B1 by means of epoxide hydrase or by binding it to glutathione using glutathione S-transferase. If aflatoxin B1-8,9-oxide binds to the guanosine in D N A, however, it becomes the highly toxic 8,9-dihydro-8-(N7-guanyl) 9-hydroxyaflatoxin B1.

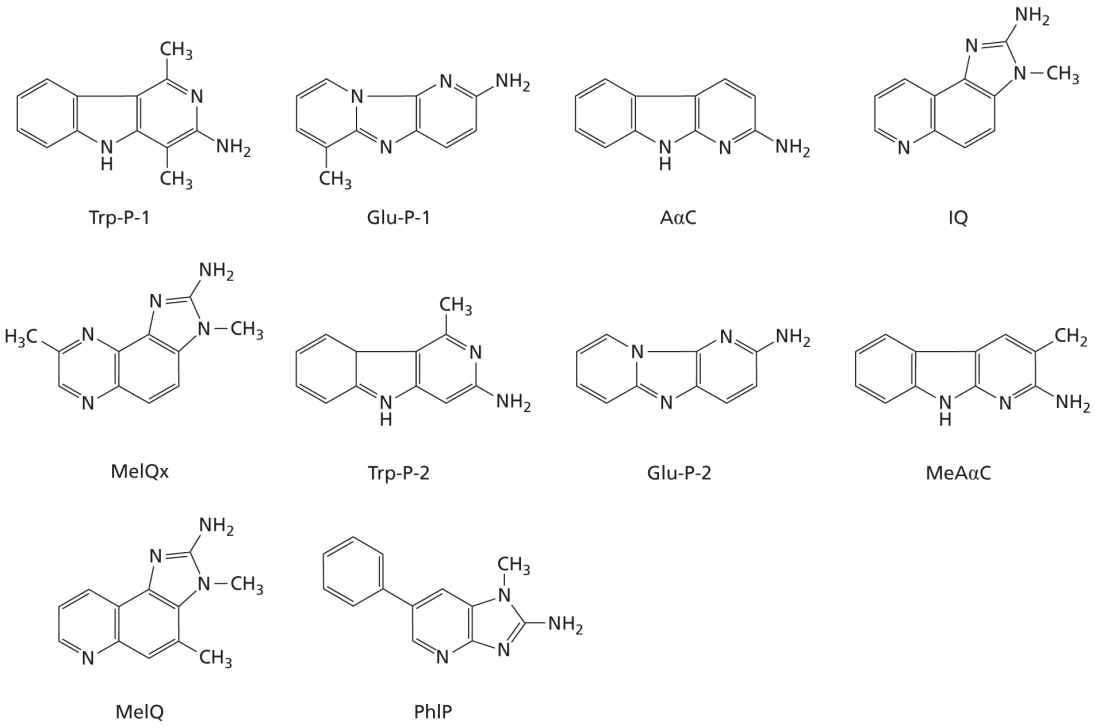
Figure 12.15 Aflatoxin and liver carcinogenesis (A) The fungal toxin aflatoxin B_1 (AFB1) is made by molds, largely *Aspergillus flavus* (*inset*), that grow on peanuts and grains that have been stored improperly, notably in areas of high rainfall and humidity; it is one of the most potently mutagenic substances known

(see Figure 2.21B). Within the Jiangsu province of eastern China, the incidence of hepatocellular carcinoma (HCC) cases (*brown dots*) is 8-fold higher in the very humid southeastern Qidong peninsula (*arrow*) than in the northwestern parts of the province. The incidence of hepatitis B virus (HBV) infection—a critical co-carcinogen in HCC pathogenesis (see Section 11.13)—is relatively constant across the province. (B) Activation of AFB1 (*pink*) by cytochrome P450s results in formation of the highly reactive 8,9-oxide form (*red*). This form may be detoxified through several side reactions (*bottom left, right*), or it can react directly with DNA, forming a covalent adduct with the N^7 atom of guanosine (*light green*) that is highly mutagenic. Indeed, the liver carcinomas of individuals living in areas of high AFB1 exposure often carry mutant p53 alleles with a characteristic G-to-T transversion in codon 249—precisely the type of mutation that would be expected from the known reactivity of AFB1. (A, from T.W. Kensler et al., *Nat. Rev. Cancer* 3:321–329, 2003. With permission from Nature. Inset, courtesy of CABI.org, UK. B, from J.D. Groopman and L.G. Cain, in C.S. Cooper and P.L. Grover, eds., Interactions of Fungal and Plant Toxins with DNA in Chemical Carcinogenesis and Mutagenesis. Berlin: Springer-Verlag, 1990. With permission from Springer.)

Once AFB1 is activated by CYPs in the liver, the resulting metabolite can attack guanine and form a DNA adduct by becoming covalently linked to this base (see Figure 12.15B). AFB1 causes a characteristic G>T mutation in DNA. Such point mutations, where the sequence AGG has been converted to AGT, are found at codon 249 of the *p53* tumor suppressor gene in about half of the hepatocellular carcinomas occurring in individuals exposed to this carcinogen. These characteristic changes in the DNA provide compelling evidence of the direct interaction of this mutagenic carcinogen with bases in the DNA. (These conclusions are important, because in the absence of such evidence, it becomes possible that a carcinogenic agent is actually functioning as a non-mutagenic tumor promoter rather than an “initiating carcinogen”; see Section 11.11).

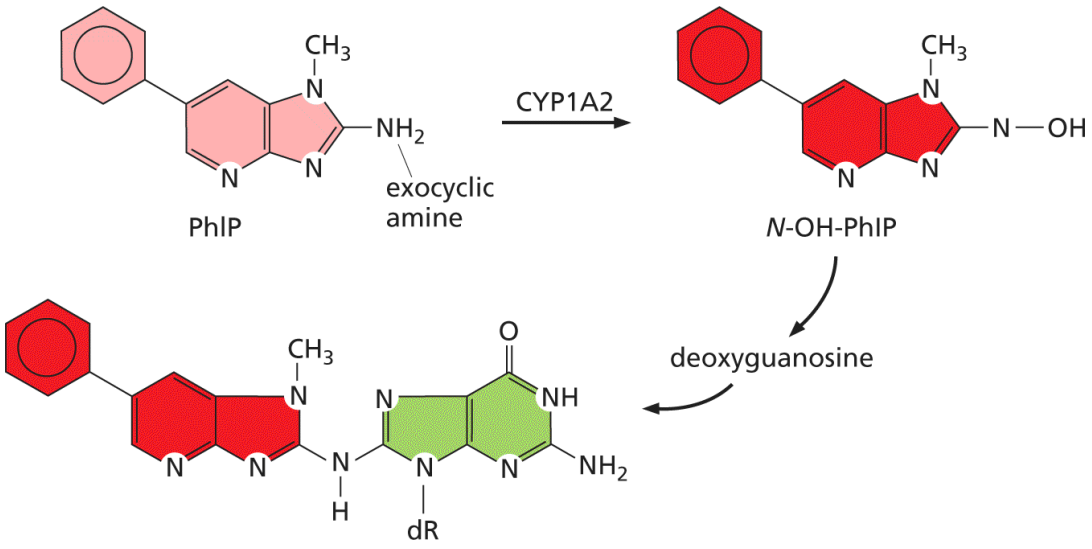
Another widely studied example of carcinogens of exogenous origin involves the heterocyclic amines (HCAs), a class of molecules that are formed in large amounts when meats of various sorts are cooked at high temperatures (**Figure 12.16A**). These compounds arise through the chemical reactions that take place between naturally occurring molecular species in cells, notably creatine, glucose phosphates, dipeptides, and free amino acids. The HCAs are undoubtedly carcinogenic. For example, the most abundant of these compounds in meats cooked at high temperature—2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP)—is capable of inducing colon and breast carcinomas in rats and lymphomas in mice. PhIP is recognized as being the principal HCA in the human diet. Nonetheless, these and other observations still do not prove that these chemical species are actual causal agents of significant numbers of

human tumors, and alternative mechanistic models of meat-induced carcinogenesis have been proposed (**Supplementary Sidebar 12.3**).



The ten Heterocyclic amines. Six of these have the same basic structure, namely: At the center is a five-ring containing four carbons and a nitrogen. The two carbons on the left are also part of a six-carbon ring, while the two carbons on the right of the five-ring are also part of a six ring that contains five carbons and one nitrogen. The six amines with this structure are labeled T r p-P-1, Glue P 1, A alpha C, T r p-P-2, Glue P-2, and M e A alpha C. They differ in the assortment of methyl and amino groups attached to the rings at various points. Three amines have a different basic structure, namely: At the center is a six-carbon ring. The two carbons on the left are also part of a six-ring containing one or two nitrogens, while the two carbons on the upper right of the middle six-ring are also part of a five-ring that contains three carbons and two nitrogens. The three amines with this structure are labeled I Q, Mel Q x, and Mel Q. Again, they differ in their assortment of attached methyl and amino groups. Finally, one Heterocyclic amine has a unique basic structure, namely: at the center is a six-ring containing one carbon. The two carbons on the right are also part of a five-ring that contains three carbons and two nitrogens. One carbon on the left of the central six-ring has an attached phenyl group. This amine is labeled P h l P.

(A)



P h l P is converted by C Y P1A2 into N-O H-P h I P, which then combines with deoxyguanosine to form a mutagenic adduct.

(B)

Figure 12.16 Heterocyclic amines (A) The 10 heterocyclic amines (HCAs) shown here are the most common HCAs to which humans are exposed. This class of compounds derives its name from being composed of multiple fused rings, which are generally formed from both carbon and nitrogen and bear one or more exocyclic amine groups protruding from the ring structure. HCAs arise through cooking foods, notably red meats, at high temperature. PhIP has been estimated to constitute two-thirds of the total dietary intake of HCAs among Americans. (B) The oxidation of the exocyclic amine of PhIP (2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine; *pink*) by CYP1A2, a cytochrome P450, leads to the highly reactive compound *N*-OH-PhIP (*red*). It can react with the 8-C of deoxyguanosine (*green*) to form a mutagenic adduct (*lower left*). (A, from T. Sugimura, *Carcinogenesis* 21:387–395, 2000. With permission from Oxford University Press. B, adapted from M. Nagao and T. Sugimura, eds., Food-Borne Carcinogens. New York: John Wiley & Sons, 2000.)

Once heterocyclic amines have entered into cells, CYPs are employed by the cells to oxidize these molecules. Some CYPs will oxidize the rings of heterocyclic amines, whereas others will oxidize the exocyclic amine groups, that is, those that protrude from the rings. Ring oxidation by CYPs leads to successful detoxification; amine group oxidation, however, leads to the formation of highly reactive compounds that can readily form covalent bonds with proteins and DNA (Figure 12.16B). Although these and other chemical conversions of HCAs are largely achieved in the liver, the

resulting reactive molecules often survive long enough to pass via the circulation into other organs where they may exercise their mutagenic activity. These various examples, only a few among many that could be cited here, illustrate how the detoxifying enzymes in our tissues, often present in high concentration in liver cells, yield genotoxic compounds rather than the end products intended by evolution—harmless, readily excretable chemical species. This discussion also raises questions about exposure to potentially mutagenic synthetic compounds and their role in human carcinogenesis (**Sidebar 12.4**).

Sidebar 12.4 Do synthetic chemicals contribute to human cancer burden?

The discussions of xenobiotic activation and inactivation lead inevitably to another question: What are the origins and the actual daily burdens of these compounds that our various tissues must routinely contend with? And among the xenobiotics, do synthetic carcinogens, such as the much-feared pesticides, contribute substantially to this burden?

Bruce Ames, of the Ames test (see Figure 2.21), has estimated that, by eating naturally occurring foodstuffs, humans are exposed on a daily basis to between 5000 and 10,000 distinct natural chemical compounds and their metabolic breakdown products. Included among these are about 2000 mg of burnt material (the products of cooking food at high temperatures) and 1500 mg of naturally occurring pesticides (manufactured by plants to protect themselves against insect predators). In contrast, the average daily exposure to all synthetic pesticide residues contaminating the food chain is about 0.1 mg.

About half of the naturally occurring plant pesticides are found to be carcinogenic when tested in laboratory rodents using standard protocols. Because (1) synthetic pesticides are as likely to register as carcinogens in rodent tests as are randomly chosen compounds of natural (that is, plant) origin, because (2) plant-derived compounds, such as those in the vegetables we eat, are generally presumed to be safe, and because (3) concentrations of synthetic pollutants in the food chain are many orders of magnitude below the natural (and equivalently carcinogenic) plant compounds, it is questionable whether synthetic pesticides are ever responsible for significant numbers of human cancers in Western populations. It may well be that the contributions of xenobiotic chemical species to human cancer formation (with the exception of tobacco combustion products and the products of cooking food at high temperature) are limited largely to those chemicals that are encountered repeatedly and at very high concentrations in certain occupations, such as agricultural workers who handle large quantities of pesticides routinely.

As discussed in Section 12.13, the patterns of mutations documented in cancer cell genomes by DNA sequencing analyses often provide clues about the identity of the responsible mutagenic agent, because many of the mutagenic processes described above leave behind characteristic mutational signatures, such as the dipyrimidine mutations associated with UV radiation.

Glossary

ionizing radiation
: A type of high-energy radiation that has enough energy to remove an electron from an atom or molecule, causing it to become ionized.

electrophilic
: Referring to a molecule that seeks out and reacts with electron-rich substrates or molecular partners.

alkylating
: Capable of attaching covalently an alkyl group or similarly structured organic chemical group to a substrate such as a DNA base, usually resulting in the replacement of a proton in the substrate with the organic group, thereby forming a covalent bond.

xenobiotic
: (n., adj.) A chemical species that originates outside of the body of an organism and is foreign to its normal metabolism.

procarcinogen
: A chemical compound that is relatively nonreactive chemically, but can be converted into a highly reactive carcinogen, usually through metabolic processes. *See also* **ultimate carcinogen**.

ultimate carcinogen
: A chemical compound that is able to directly contribute to the induction of cancer without further chemical modification, usually by direct chemical interaction with DNA, thereby altering the chemical structure of the latter. *See also* **procarcinogen**.

adduct
: Product of covalently linking a chemically reactive molecule to a targeted substrate molecule, such as the addition of a reactive mutagenic molecule to a base in the DNA.

pneumocyte
: Epithelial cell lining the alveoli of the lungs that is responsible for gas exchange with the blood and the secretion of surfactant protein.

heterocyclic amine
: Any of various carcinogenic amines formed when creatine or creatinine reacts with free amino acids and sugars in meat cooked at high temperatures.

exocyclic
: Referring to a chemical group that protrudes from the ring moiety of a molecule such as a DNA base.

cytochrome P450 enzymes
: A family of enzymes that function to oxidize steroids, fatty acids, and xenobiotics, and thereby aid in the clearance of various compounds.

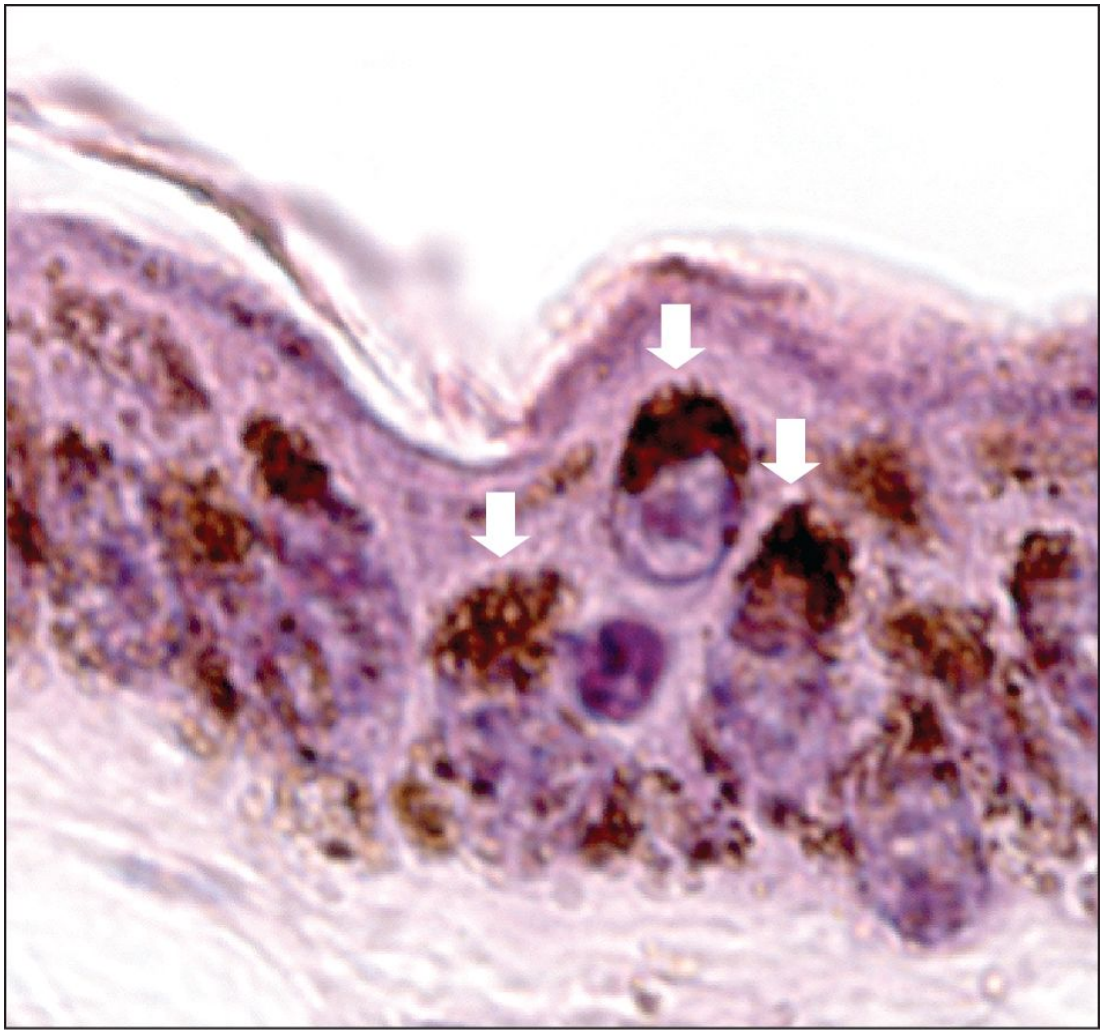
12.6 Cells deploy a variety of defenses to protect DNA molecules from attack by mutagens

The most effective way for a cell to defend its genome from disruption by mutagenic agents is to *physically* shield its DNA molecules from direct attack. In the case of ultraviolet rays from the sun, these penetrate poorly into the body's tissues, leaving the cells of the skin and pigmented cells in the retina as the only vulnerable targets of mutation. The skin shields itself from UV radiation using the melanin pigment that is transferred by melanocytes to keratinocytes located in the basal region of the epidermis (the epithelial layer of the skin; **Figure 12.17**).



A stained sample of human skin tissue, seen in cross section. White arrows indicate nuclei with dark protective caps on the side facing the skin surface.

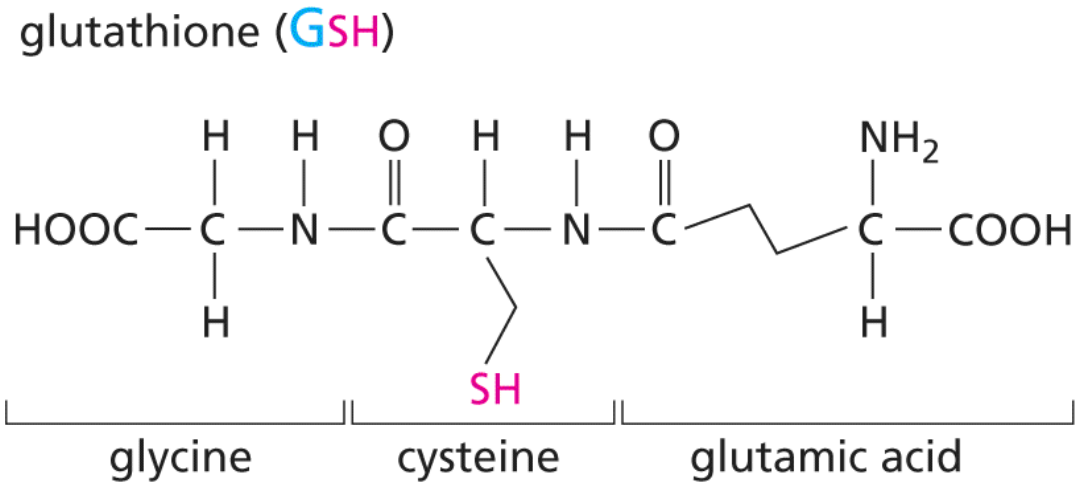
Figure 12.17 Physical shielding of keratinocyte nuclei from ultraviolet radiation The main protection that keratinocytes in the skin have from ultraviolet (UV) radiation, notably UVB photons, derives from the melanosomes—vesicles carrying melanin pigment that have been transferred from melanocytes into keratinocytes in the basal layers of the epidermis. As seen here, once the melanosomes are acquired by the keratinocytes, they are assembled into tiny sun umbrellas (sometimes called supranuclear caps) that sit above keratinocyte nuclei (*arrows*) and shield them from visible and, more importantly, UVB radiation. Keratinocyte nuclei that lack these umbrellas sustain as much as fourfold more UV-induced DNA damage than those that carry them. Moreover, redheads, who produce little or no black eumelanin pigment in their hair and skin (but do make the red/yellow pheomelanin), have an almost fourfold increased risk of developing melanoma relative to those with dark brown or black hair. (Courtesy of D.E. Fisher.)

Skin color in humans is determined by the types and amounts of melanin that are donated by the melanocytes to the keratinocytes. The role of this pigmentation in cancer pathogenesis is highlighted by the oft-cited case of skin cancers in Australia. There, a high flux of UV radiation (because of proximity to the equator) and a lightly pigmented population (deriving until recently largely from the British Isles) combine to create the world's highest incidence of these diseases. In Africa, in contrast, the darkly pigmented human populations living at similar latitudes rarely experience skin cancers. In the case of X-rays and cosmic radiation, by contrast, no effective physical shielding can be erected by the body because these types of radiation can penetrate easily through all biological substances.

These options for protection against physical carcinogens contrast with the large number of mechanisms that cells can deploy to intercept *chemical* carcinogens before they have had the opportunity to damage the cellular genome. The ambushing of ROS and free radicals is the job of a variety of enzymes, including superoxide dismutase and catalase; they collaborate to detoxify an ROS into unreactive forms of oxygen. The ROS may also be intercepted by a series of free-radical scavengers, including vitamin C, α-tocopherol (vitamin E), bilirubin, and urate. These molecules react chemically with the ROS, thereby detoxifying them.

Yet another important line of defense is erected by enzymes of the class termed glutathione ***S***-transferases (GSTs), which function to covalently link electrophilic compounds, and thus many carcinogens, with glutathione, thereby detoxifying these compounds and preparing them for further metabolism and excretion (**Figure 12.18A**

and B). Significantly, as many as 90% of human prostate adenocarcinomas exhibit a shutdown of glutathione *S*-transferase-π (GST-π) expression as a result of methylation of the promoter of the *GSTP* gene (Figure 12.18C; see Section 7.7). Frequent inactivation of this gene has been reported as well in a number of other human carcinomas. This loss of GST-π expression, which often occurs relatively early in tumor progression, suggests that premalignant prostate tumor cells acquire a distinct advantage by inactivating this gene, thereby increasing the mutability of their genomes. Thus, without this enzyme to defuse certain carcinogens, the genomes of these prostate epithelial cells are attacked more often by actively mutagenic carcinogens; the resulting increased rate of mutagenesis likely accelerates the forward march of tumor progression. Another connection between GSTs and other genes involved in carcinogen metabolism and cancer is discussed in **Supplementary Sidebar 12.4**.



The chemical structure of glutathione. It consists of three amino acids chained together in a row: glycine, cysteine, and glutamic acid.

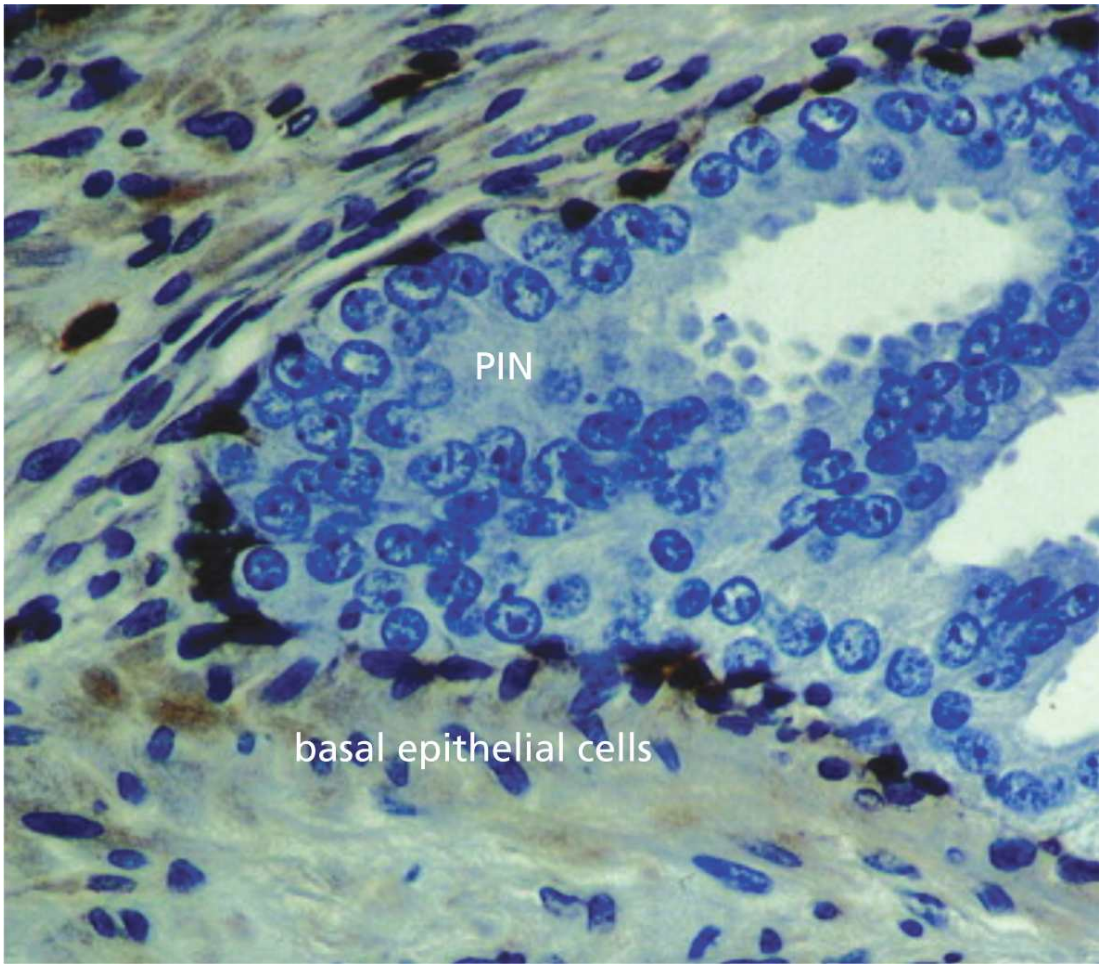
(B)



A histology image of a prostatic intraepithelial neoplasia, or P I N, surrounded by basal epithelial cells. The nuclei in the P I N are larger and rounder than those in the epithelial cells.

(C)

Figure 12.18 Glutathione *S*-transferase and its loss from tumors (A) Glutathione (GSH) is an unusual tripeptide in which a glutamic acid is attached to the amino group of cysteine via the carboxyl side chain of the glutamic acid. (B) Glutathione *S*-transferase (GST) enzymes use the sulfhydryl (SH; *pink*) group of glutathione's cysteine residue to detoxify a number of reactive compounds before the latter are able to react with cellular target molecules, such as DNA. Shown here is a typical reaction mediated by a GST in which the SH group of glutathione is used to disrupt the highly reactive epoxide group of a compound that has suffered oxidation (where R can be any of a variety of chemical groups). (C) As many as 90% of prostate carcinomas show the loss of expression of an important glutathione *S*-transferase, GST-π; this deprives the tumor cells of the means to detoxify many electrophilic mutagens. In many of these cases, loss of GST-π

expression is traceable to methylation of the GSTP1 promoter. In the premalignant PIN (prostatic intraepithelial neoplasia) lesion—a benign precursor of prostate carcinoma—shown here, use of an antibody reactive with GST-π demonstrates the presence of GST-π in the basal epithelial cells (*dark brown, left side*) but the loss of all GST-π expression in the luminal epithelial cells forming the PIN (*light blue, right side*). The luminal epithelial cells are revealed by DAPI, a stain that is specific for DNA (*blue*). (C, from C. Jeronimo et al., *Cancer Epidemiol. Biomarkers Prev*. 11:445–450, 2002. Glossary

melanin
: A brown-black or red-brown pigment that is synthesized by melanocytes and, in the skin, transferred to basal keratinocytes, thereby creating pigmentation of the skin; alternatively, pigment is transferred to cells within the iris of the eye.

melanocyte
: Cell of neural crest origin that creates pigmentation of the skin and iris.

superoxide dismutase
: An enzyme that catalyzes the conversion of 2 superoxide molecules into one diatomic oxygen molecule (O_2) and one hydrogen peroxide (H_2O_2) molecule. *See also* **superoxide**.

catalase
: An enzyme that catalyzes the reaction by which hydrogen peroxide is decomposed to water and oxygen.

glutathione-
: *S* -**transferase** A family of enzymes that catalyze the conjugation of the reduced form of glutathione (GSH) to xenobiotic compounds for the purpose of detoxification.

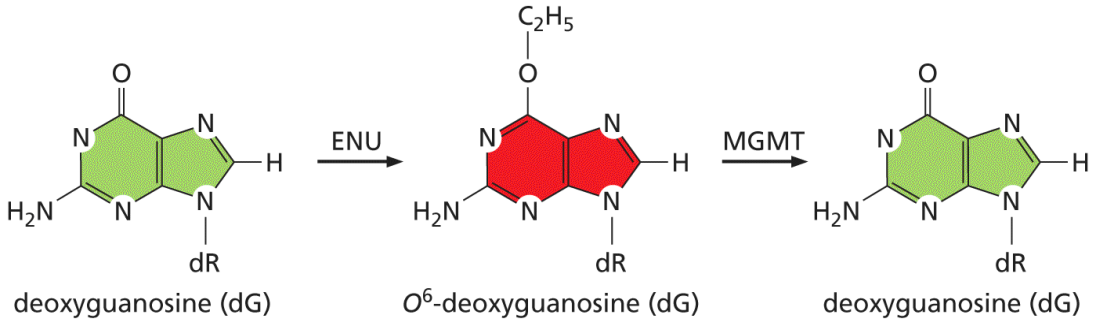
12.7 Repair enzymes fix DNA that has been altered by mutagens

If genotoxic chemicals are not intercepted before they attack DNA, mammalian cells have a backup strategy for minimizing the genetic damage caused by these potential carcinogens. An elaborate DNA repair system exists to continuously monitor the integrity of the genome, to remove inappropriate bases or nucleotides created by chemical or physical attack, and to replace them with the bases/nucleotides that occupied those sites in the DNA prior to the attack. Components of this system also work to stitch together double helices that have been broken by genotoxic agents or by accident during replication. Altogether, mammalian cells depend on more than 160 distinct proteins to ensure that damage to DNA is unlikely to result in this damage being transmitted in the form of a mutation to daughter cells. Some of these DNA repair proteins figure large in the process of human carcinogenesis, because defects in these proteins result in increased rates of mutation, thereby accelerating the overall rate of tumor progression.

Cells deploy a wide variety of enzymes to accomplish the very challenging task of restoring normal DNA structure. Importantly, these functions differ from the mismatch repair (MMR) enzymes described above (see Section 12.3), because the MMR enzymes are largely focused on detecting nucleotides of normal structure that have recently been incorporated by DNA polymerases into the wrong positions, whereas the repair mechanisms discussed in this section detect nucleotides of abnormal chemical structure independent of their origin or location in the genome.

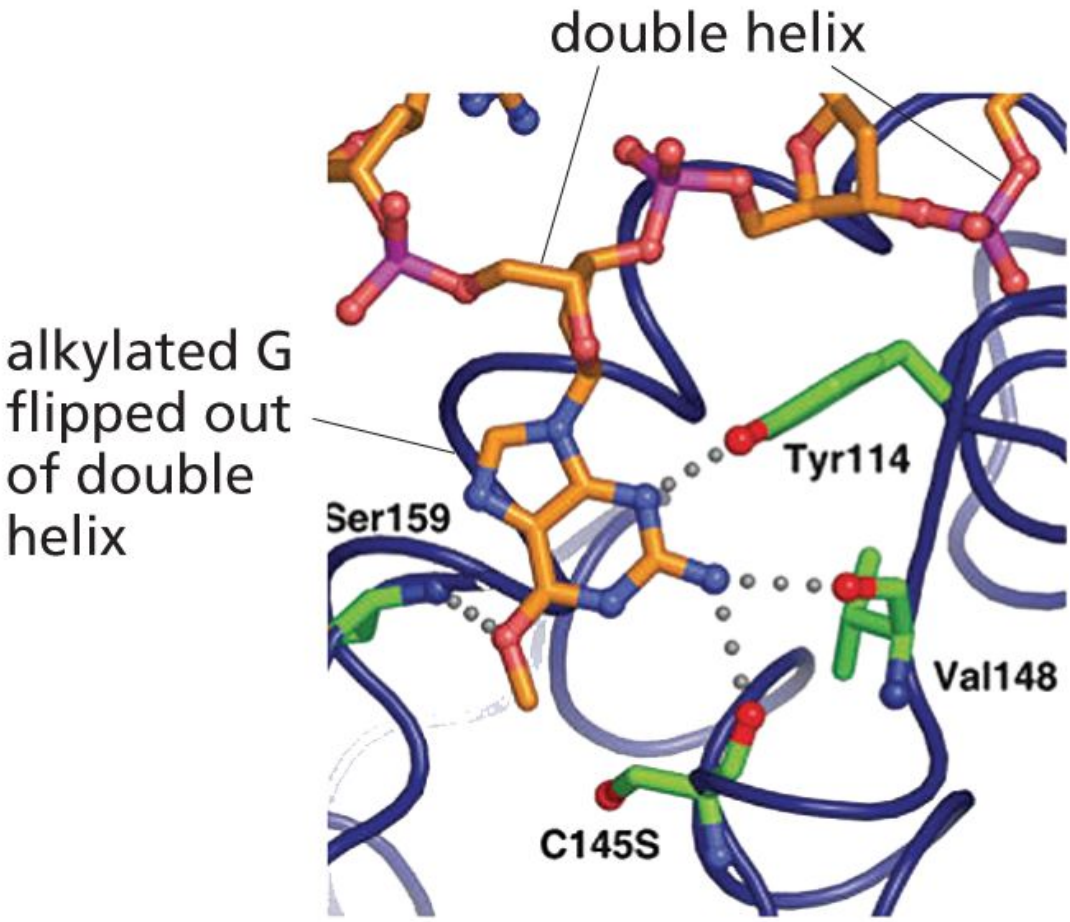
The simplest strategy for restoring the structure of chemically altered DNA involves an enzyme-catalyzed reversal of the chemical reaction that initially created the altered base. For example, one type of DNA alkyltransferase removes methyl and ethyl adducts from the O^6 position of guanine, thereby restoring the structure of the normal base (**Figure 12.19A and B**). The importance of this enzyme [O^6-methylguanine-DNA methyltransferase (MGMT), often referred to simply as DNA alkyltransferase] in the development of certain kinds of human tumors is suggested by observations that the *MGMT* gene is silenced by promoter methylation in as many as 40% of gliomas and colorectal tumors and in about 25% of non-small-cell carcinomas, lymphomas, and head-and-neck carcinomas. (In contrast, methylation of its promoter is not detected in a large cohort of other tumor types.) As was the case with detoxifying genes, such as the glutathione *S*-transferase-encoding *GST* alleles discussed earlier, we can imagine that the loss of MGMT's DNA repair function in certain tissues favors increased rates of mutation and hence accelerated tumor progression. (Conversely, when the *MGMT*

gene, in the form of a transgene, is experimentally overexpressed in the mouse mammary gland or thymus, such expression renders these tissues quite resistant to the otherwise potently carcinogenic effects of methylnitrosourea, a widely used alkylating mutagen; see, for example, Figure 12.19C).



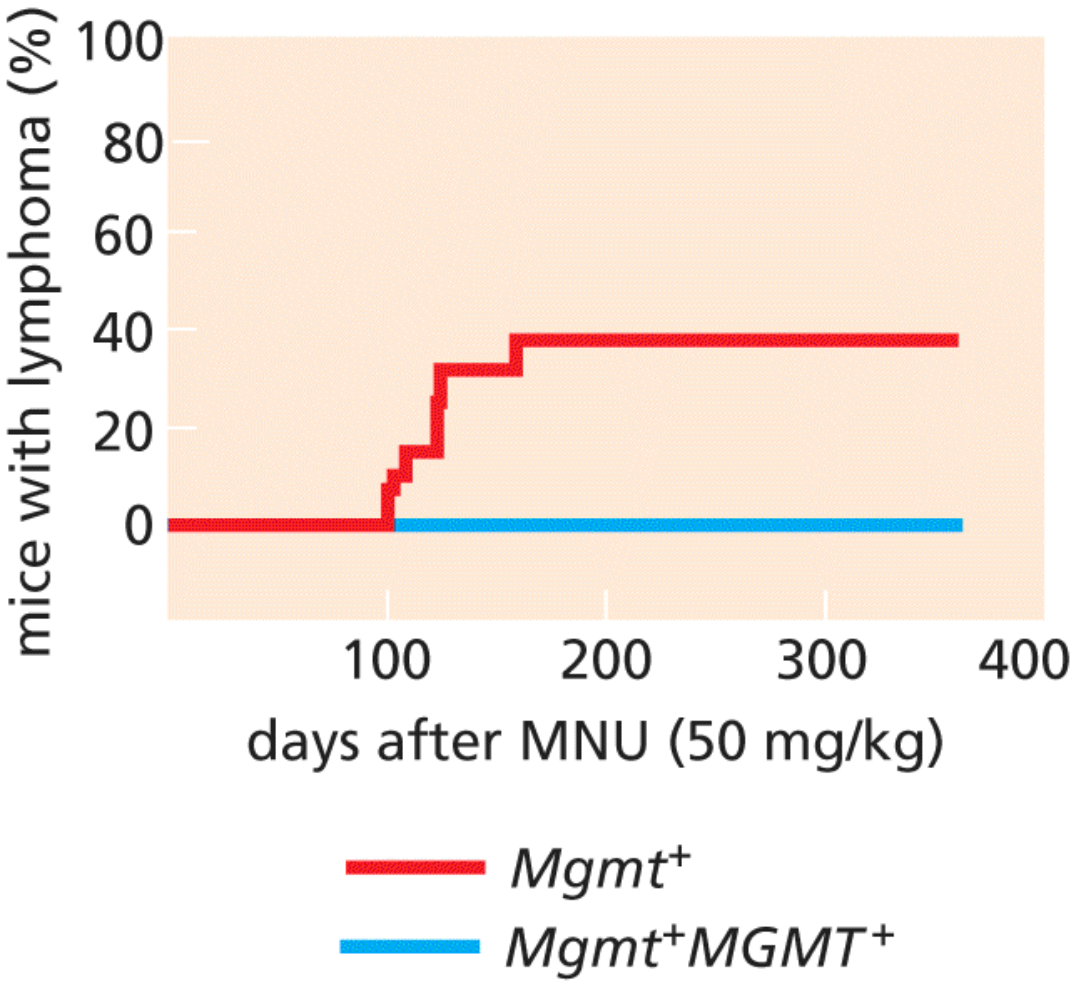
Deoxyguanosine is converted by E N U into O6-deoxyguanosine, which has an ethyl group attached to the exocyclic oxygen of deoxyguanosine. M G M T converts this back to deoxyguanosine.

(A)



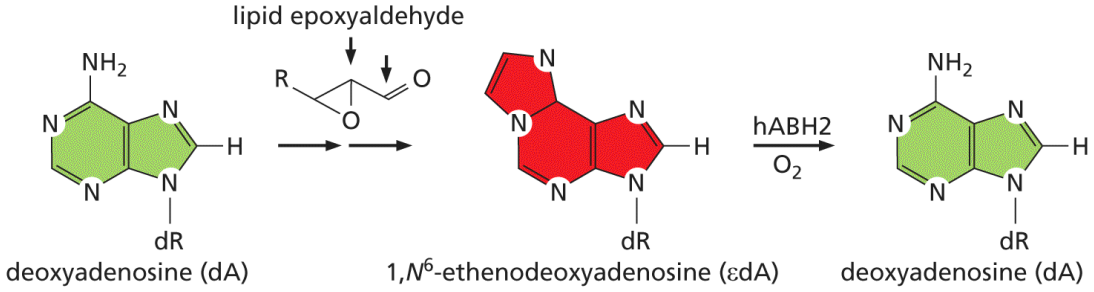
A molecular model showing M G M T at work removing the alkyl group from O6-deoxyguanosine. Four sites on M G M T play a role; they are labeled T y r 1 14, V “a” l 1 48, C 1 45 S, and S e r 1 59. The alkylated guanosine is flipped out of the double helix.

(B)



A line graph showing the percentage of mice with lymphoma as a function of time. Two types of mice were exposed to M N U, 50 milligrams per kilogram of body weight. Mice forced to overexpress the MGMT enzyme remained at 0 percent lymphoma for a full year, whereas wild-type mice began to develop lymphoma about 100 days after M N U exposure. The percentage eventually rose to 40 percent after just before 200 days and then leveled off.

(C)



A lipid epoxyaldehyde converts deoxyadenosine into 1,N6-ethenodeoxyadenosine. h A B H2 and oxygen convert this back to deoxyadenosine.

(D)

Figure 12.19 Restoration of normal base structure by dealkylating repair enzymes (A) The O^6 position of guanosine is especially vulnerable to alkylation by agents such as ethylnitrosourea (ENU). Unlike many DNA repair enzymes, which respond to altered bases by excising them or the entire nucleotide containing them from the DNA, the enzyme O^6-methylguanine-DNA methyltransferase (MGMT; also known as O^6-alkylguanine-DNA alkyltransferase, AGT) restores an altered deoxyguanosine to its normal structure. It does so by removing the alkyl group from the O^6 atom of guanine. In the absence of such repair, the alkylated deoxyguanosine often leads to a G>A transition mutation. (B) Structural analyses of DNA repair proteins have revealed much about how they function. In the case of the MGMT protein, this enzyme (*below, light and dark blue*) works by flipping the damaged base out of the double helix before removing the alkyl group. Moreover, the reaction between enzyme and substrate is stoichiometric, in that the cysteine 145 (C145S) residue (*below*, *red and green*) in the enzyme's active site becomes irreversibly alkylated following restoration of normal guanine structure; hence, each enzyme molecule is able to dealkylate only a single alkylated deoxyguanosine. (C) The effects of MGMT ectopic expression are shown for mice that were exposed to the alkylating carcinogen methylnitrosourea (MNU), which attaches methyl groups to guanosine. Wild-type mice ($Mgmt^+$) were highly susceptible to the induction of thymic lymphomas (*red curve*), whereas transgenic mice that were forced to overexpress the MGMT enzyme because of a transgene in their germ line ($Mgmt^+$ $MGMT^+$, *blue line*) were protected from developing these tumors. (D) Highly reactive lipid epoxyaldehydes (*shown here*) and peroxides (*not shown*), which are common in inflamed tissues, can attack and modify deoxyadenosine (*shown here*) as well as other DNA bases (*not shown*). The AlkB enzyme of bacteria can remove the resulting adducts as well as simpler methyl adducts, such as those shown in Figure 12.12C; a mammalian homolog of AlkB, hABH2 (*indicated here*), acts similarly in human cells. (A, adapted from S.L. Gerson, *Nat. Rev. Cancer* 4:296–307, 2004. B, from D.S. Daniels et al., *Nat. Struct. Mol. Biol*. 11:714–720, 2004. With permission from Nature. C, from L.L. Dumenco et al., *Science* 259:219–222, 1993. With permission from AAAS.)

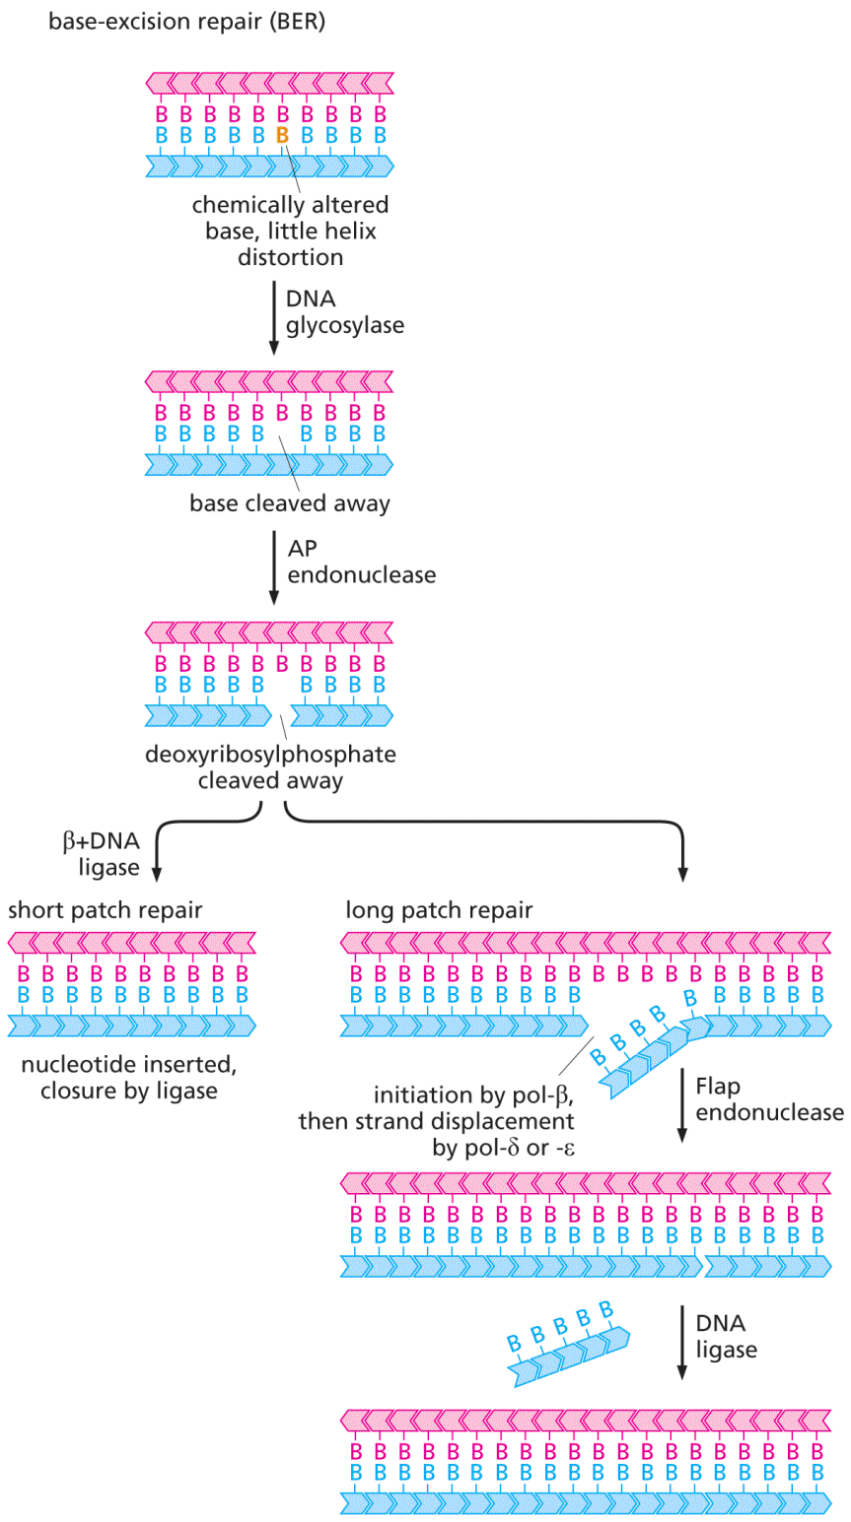
Expression of this and other repair enzymes can also influence the *types* of tumors caused by certain carcinogens in animal models of cancer, and quite possibly in

humans (**Sidebar 12.5**). Moreover, these DNA repair enzymes can influence responses to therapy. In one instance, after a group of glioblastoma patients whose tumors expressed normal levels of the MGMT enzyme were treated with temozolomide, an alkylating chemotherapeutic agent, they survived for another 12 months. Other patients in the same cohort, whose cancer cells expressed only very low levels of MGMT (from repression of the *MGMT* gene through promoter methylation), survived for 22 months after therapy—almost twice as long. This observation, subsequently extended in a number of other clinical studies, indicates that normally expressed levels of the MGMT enzyme are very effective in removing the methyl groups attached to DNA by the chemotherapeutic drug, thereby blunting its cytotoxic effects. Cells also use other mechanisms to deal with methylated bases (**Supplementary Sidebar 12.5**).

Sidebar 12.5 Expression patterns of repair enzymes explain certain tissue-specific susceptibilities to cancer

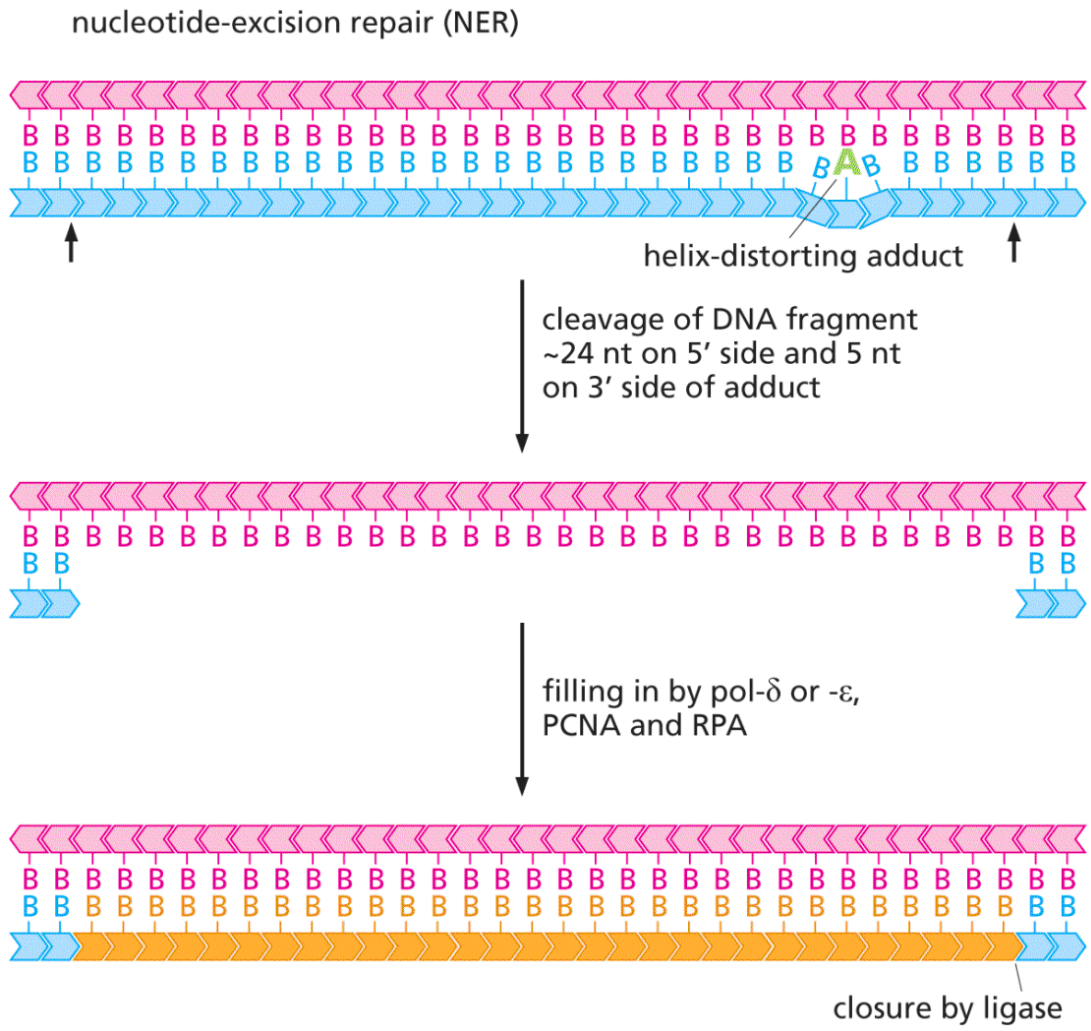
Mammalian cells seem to express only a single MGMT enzyme. The importance of this activity in influencing carcinogenesis is indicated by experiments in which pregnant rats are exposed to the carcinogen *N*-ethylnitrosourea (ENU) during the fifteenth day of gestation. Virtually all the rat pups that are born succumb to neuroectodermal tumors arising in the central nervous system several months after birth. The MGMT enzyme is expressed at significant levels throughout the bodies of developing embryos and newborns but is only minimally expressed in the central nervous system, which explains the peculiar ability of ENU to preferentially induce these tumors. Consequently, alkylated guanine residues that are formed in the cells of the nervous system persist rather than being quickly removed and are ultimately able to generate the point mutations that are responsible for the creation of the oncogenes in the resulting tumors. In one experiment conducted with newborn rats that had been exposed *in utero* to ENU or the related alkylating agent MNU (*N*-methylnitrosourea), the levels of O^6-alkylguanine adducts surviving in unrepaired form a week after exposure to these carcinogens were 20-fold (ENU) and 90-fold (MNU) higher in brain DNA than in liver DNA.

Far more important than these dealkylating enzymes, however, are the numerous cellular enzymes that recognize chemically altered bases in the DNA and respond in two other ways, depending on the specific modifications of the DNA. In some cases, specialized enzymes will cleave the bond linking a modified base to the deoxyribose sugar, the process of base-excision repair (BER; **Figure 12.20A**). In other cases, the entire nucleotide containing both the base and associated deoxyribose will be cut out, this being the process termed nucleotide-excision repair (NER; see Figure 12.20B).



Base-excision repair, or B E R. A chemically altered base produces little helix distortion. D N A glycosylase cleaves away the base. A P endonuclease then cleaves away the deoxyribosylphosphate to which the base was attached. From here, the repair may be either short-patch or long-patch. In short-patch

repair, polymerase beta and D N A ligase perform nucleotide insertion and close the gap. In long-patch repair, polymerase beta initiates the repair, and a D N A polymerase delta or epsilon displaces a longer strand at the repair site. Flap endonuclease removes the displaced strand, and a ligase seals the site. (A)



Nucleotide-excision repair, or N E R. This is necessary in the case of a helix-distorting adduct. Repair begins with cleavage of a D N A fragment that is about 24 nucleotides long on the 5 prime side of the adduct and 5 nucleotides long on the 3 prime side. The gap is filled by polymerase alpha or beta, as well as P C N A and R P A. The repair site is finally closed by a ligase.

(B)

Figure 12.20 Base- and nucleotide-excision repair (A) Base-excision repair (BER) is achieved by enzymes that recognize chemically altered bases having

minimal helix-distorting effect. These DNA N-glycosylase enzymes cleave the glycosyl bond linking the altered base (*yellow*) and the deoxyribose. The base-free deoxyribosylphosphate is then excised by an enzyme—apurinic/apyrimidinic endonuclease (APE)—specialized to remove base-free sugars. The resulting single nucleotide gap is filled by DNA polymerase β and sealed by a DNA ligase. In fact, there are two forms of BER. A single nucleotide may be excised and the gap may be filled in by a DNA polymerase (pol-β) and ligated (short patch repair). Alternatively, a strand-displacing DNA polymerase (δ or ε) may, following excision by APE and the addition, as before, of a single base by pol-β, extend the 3′ strand by several nucleotides beyond the original gap. The resulting displaced strand is removed by a Flap endonuclease and the remaining lesion is sealed by a ligase (long patch repair). (B) Nucleotide-excision repair (NER) is accomplished by enzymes that recognize bulky, helix-distorting lesions and cleave the flanking oligonucleotide sequences at sites approximately 24 nucleotides (nt) on the 5′ side and about 5 nucleotides on the 3′ side. The resulting approximately 29-nt single-strand gap in the DNA is then filled by DNA polymerase δ or ε, acting together with PCNA (proliferating-cell nuclear antigen) and RPA (which binds to single-strand DNA), and is finally sealed by a DNA ligase. The chevrons represent deoxyribose nucleotides, all pointing in a 5′-to-3′ direction.

Base-excision repair (BER) tends to repair lesions in the DNA that derive from endogenous sources, such as those attributed to the reactive oxygen species (ROS) and depurination events described earlier (Section 12.4). Nucleotide-excision repair (NER), in contrast, largely repairs lesions created by exogenous agents, such as UV photons and chemical carcinogens (for example, see Figures 12.12 and 12.14). BER seems to concentrate on fixing lesions that do not create structural distortions of the DNA double helix, whereas NER directs its attention to bulky, helix-distorting alterations.

BER is initiated by a group of DNA glycosylases, each specialized to recognize an abnormal base and cleave its covalent bond to deoxyribose. For example, a uracil base in the DNA is recognized readily by the proteins responsible for BER because U is not normally present in DNA. U is removed by the enzyme uracil-DNA glycosylase and soon replaced, usually with a C. (Figure 12.9 shows how uracil can arise in DNA through the spontaneous deamination of cytosine.) However, the presence of an inappropriately located thymine in DNA presents a quandary for these repair enzymes because T is a normal constituent of DNA. As we have read, 5-methyl-C occasionally undergoes spontaneous deamination, leading to a T, and thus to T:G base pairs (see Figure 12.9). In fact, evolution has responded to this problem by implanting a T:G glycosylase enzyme in our cells, which is designed specifically to excise T’s that happen to arise opposite G’s. Nonetheless, it is clear that the T:G base pairs formed by this deamination occasionally escape detection by this enzyme and persist to yield

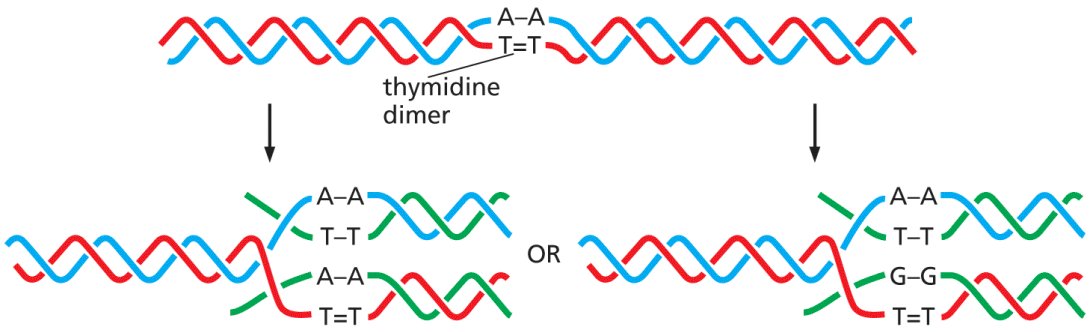
point mutations. In all of these examples, after an aberrant base is removed by a DNA glycosylase, a specialized repair system is used to restore the proper base pair (**Supplementary Sidebar 12.6**).

Nucleotide-excision repair (NER; see Figure 12.20B) is accomplished by a large multiprotein complex composed of almost two dozen subunits. This complex seems to require two distinct changes in DNA before it will initiate repair: significant distortion of the normal Watson–Crick structure of the double helix plus the presence of a chemically altered base. Once this large complex recognizes the problem, it proceeds to cleave the damaged strand upstream and downstream of the damaged base, yielding a single-strand fragment of 25 to 30 nucleotides in length, which is then removed. DNA polymerases that are specialized to fill in the resulting gap in the DNA (using the complementary, undamaged strand as a template) then take over, followed by a DNA ligase, which erases the final trace of the damage.

Included among the NER enzymes are those that can recognize and remove structures resulting from the formation of bulky base adducts (that is, those composed of complex molecular structures covalently bound to bases) created by certain exogenous mutagens, such as polycyclic hydrocarbons, heterocyclic amines, and aflatoxin B1, as well as the pyrimidine dimers formed by UV radiation (see Figure 12.12). For example, following exposure to UV radiation, cultured human cells can repair approximately 80% of their pyrimidine dimers within 24 hours. The NER apparatus active here will remove 5 nucleotides on the 3′ side of the photoproduct (the pyrimidine dimer) and 24 nucleotides on the 5′ side.

The various reactions that constitute NER can actually be divided into two subtypes. The first of these is focused specifically on the template strand of actively transcribed genes and is coupled to the actions of RNA polymerase molecules that are proceeding down the template strand during transcription; these actions are termed transcription-coupled repair (TCR). This form of specialized repair is ostensibly designed to reduce the likelihood that an RNA polymerase is stalled and thus trapped by a DNA adduct present on the strand that it is in the midst of transcribing. The second subtype of NER addresses the remainder of the genome, including the nontemplate strand of transcribed genes as well as the nontranscribed regions of the genome. This type of NER is sometimes termed global genomic repair (GGR). The p53 tumor suppressor protein activates expression of several genes encoding NER proteins involved in GGR, explaining the defectiveness of GGR in *p53*-mutant cells; in contrast, transcription-coupled repair is intact in these cells. This defect in GGR holds profound implications for the maintenance of cell genomes in the half of all human tumors in which the *p53* gene is mutant and in many of the remaining tumors in which it is compromised through various alternative mechanisms (see Figure 9.12).

As implied by much of the above discussion, the mechanisms designed to ensure genomic integrity strive to restore DNA molecules prior to their replication in S phase, lest persisting damage in template strands cause the copying of these still-mutant strands and the resulting introduction of mutations into the genomes of daughter cells and their descendants. Beyond these mechanisms, cells have yet another alternative strategy to cope with damaged DNA. This alternative—actually an act of desperation—involves DNA replication of a still-unrepaired stretch of template-strand DNA occurring in a cell that has already entered S phase. This process is termed *error-prone* DNA replication, because the replication apparatus involved must often "guess" which of the four nucleotides is appropriate for incorporation into the growing DNA strand when it encounters a still-damaged base or set of bases; these guesses are not always correct, leading quite frequently to misincorporated bases and mutant gene sequences (**Figure 12.21**).



An illustration of error during D N A repair. Initially, a double-stranded D N A has two successive adenines on one strand and, corresponding to them on the opposite strand, a defect in the form of a thymidine dimer. As the strands unwind during replication and a new strand forms on each template strand, the adenine-adenine sequence will produce a correct, error-free thymine-thymine sequence on the new strand. In most cases, the thymidine dimer will produce an adenine-adenine sequence on the new strand to match the original double-helix. However, it may instead produce an incorrect guanine-guanine sequence.

Figure 12.21 Error-prone repair Error-prone DNA synthesis occurs when an advancing DNA replication fork encounters a still-unrepaired DNA lesion, such as the thymidine dimer shown here. In most cases (left), the error-prone DNA polymerase (sometimes called a bypass polymerase) responds to this lesion in the damaged template strand (*red*) by inserting the appropriate bases (in this instance, an A–A dinucleotide) in the growing DNA strand (*green*). However, in several percent of these encounters (*right*), the error-prone polymerase will fail to properly "guess" the structure of the lesion in the template strand and will instead incorporate a G–G dinucleotide opposite the thymidine dimer.

To date, at least nine distinct mammalian error-prone human DNA polymerases have been discovered. Some of these can add a nucleotide to a growing strand even when a base in the complementary template strand is missing. Yet others can extend a nascent DNA strand, using as primer a nucleotide that has been misincorporated by another DNA polymerase. A third type can incorporate a base when the corresponding base in the complementary strand carries a bulky, covalently attached DNA adduct that has not yet been removed by nucleotide-excision repair. One of these enzymes, encoded by the *XPV* gene, is highly specialized, being able to recognize the TT thymine dimers created by UV radiation and insert two A's on the opposite strand (see Figure 12.21). Another "bypass polymerase," pol-κ, can also replicate past bulky adducts in the template strand and, in addition, advance through templates containing the much less bulky 8-oxo-deoxyguanosine (see Figure 12.11A); pol-κ incorporates an A more often than a C opposite the 8-oxo-dG, helping to explain the mutagenic effects of this common product of base oxidation. Whereas the DNA polymerases responsible for the bulk of DNA synthesis in a cell have error rates as low as 10^{-5}, these error-prone polymerases generally have error rates as high as 1 misincorporated base per 100 bases replicated.

The mistakes made by the error-prone polymerases would seem to generate unacceptably high rates of mutation in cell genomes. Still, the price paid for accumulating such mutations should be balanced against the alternative: the risk of imminent death confronted by a cell whose DNA replication forks are stalled indefinitely because of difficult-to-copy lesions in its DNA.

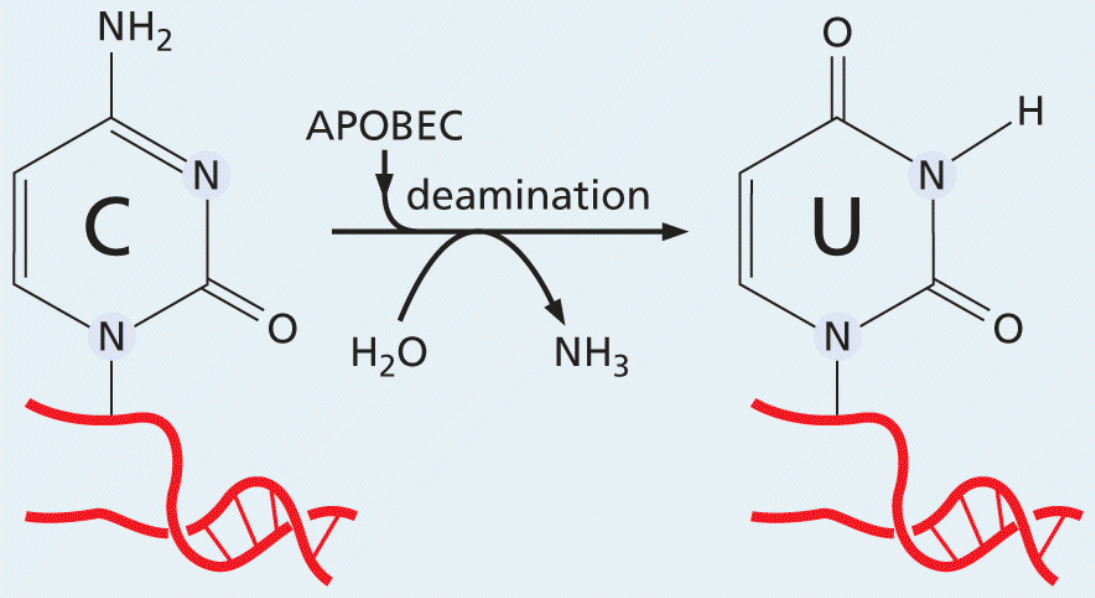
DNA polymerase β (pol-β) is error-prone for another reason: This relatively small polymerase molecule lacks the proofreading capabilities of the larger polymerase enzymes (see Section 12.3), which may explain much of its error-prone DNA replication activities. It is usually involved in replacing the nucleotides that have been removed because of BER. In a variety of ovarian carcinoma cell lines, this enzyme has been found to be overexpressed by as much as a factor of 10. The overexpression of the error-prone DNA polymerase β may represent an effective strategy that these cancer cells use to increase the mutability of their genes and hence accelerate the rate of tumor progression. In support of this idea, the forced overexpression of polymerase β in cultured human fibroblasts has been found to encourage microsatellite instability and to increase overall mutation rates as much as threefold.

Although not involved in DNA repair, the APOBEC family of cytosine deaminases is responsible for inserting mutations into the genome of normal and cancer cells. As described in **Sidebar 12.6**, these enzymes are involved in the cellular response to viral infection as well as the hypermutation of immunoglobulin genes during B-cell development. The documentation of APOBEC-mediated mutagenesis is currently increasing rapidly.

Sidebar 12.6 Normal and cancer cells may intentionally inflict damage on their own genomes

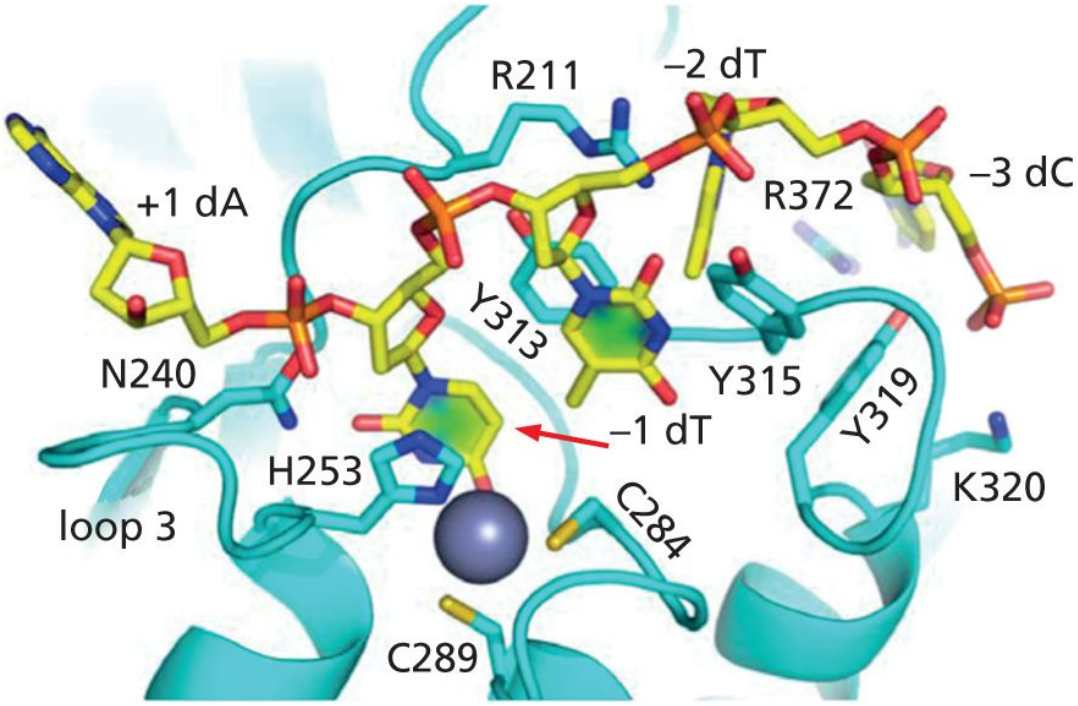
Much of the discussion in this chapter is centered around agents of exogenous origin that enter cells and inflict damage on cell genomes through a diversity of chemical and physical mechanisms. However, an unexpected source of mutagenesis is of endogenous origin and quite intentional. It derives from the APOBEC family of enzymes, which function to promote the promutagenic process of cytosine deamination. These enzymes seem to have originated in cellular defenses aimed at protecting cells against infecting RNA and DNA viruses, whose genomes could be inactivated by mutation via these enzymes; however, early in vertebrate evolution, at least one of these enzymes became specialized to diversify the genomic sequences that specify the antigen-combining sites of antibodies, a process discussed in detail in Chapter 15.

The best studied of the APOBECs is the **a**ctivation- **i**nduced cytidine **d**eaminase (AID) enzyme, which is normally responsible for deaminating cytidine bases in the 3-kb span downstream of the start site for transcription of the genes specifying antibodies and several other proteins. By stochastically converting cytidine to uridine residues in defined genomic regions (**Figure 12.22**), the APOBEC enzymes effectively insert C-to-T point mutations in the genome; in the case of immunoglobulin (antibody) genes, the resulting "somatic hypermutation" causes diversification of the antigen-binding sites of the encoded antibody molecules, enabling the immune system to develop antibodies of ever-increasing avidity for their antigen ligands. The AID enzyme seems to run amok in some human lymphomas, inserting point mutations in genes that are not its normally intended targets. And when the *AID* gene is ectopically expressed as a transgene in many tissues of the mouse, it causes high rates of T-cell lymphomas, many of which exhibit large numbers of genes, such as *myc*, with point mutations throughout their reading frames. APOBEC3B and other members of the APOBEC family have also been found to be overexpressed in solid cancers, including breast, head and neck, and lung carcinomas. As discussed below in Section 12.13, a number of cancer genome sequencing studies have implicated dysregulated APOBEC gene function in greatly increasing mutation rates in cancer.



A reaction begins with a cytosine base, part of a single strand of unwound double-stranded D N A. A P O B E C catalyzes a reaction in which H2O reacts with the cytosine to produce uracil and N H 3. This is called deamination, because the conversion of cytosine into uracil involves the amino group on the carbon-nitrogen 6 ring being replaced with a double-bonded oxygen.

(A)



A combination ribbon model and ball and stick model showing an enzyme in turquoise, a single-stranded D N A in yellow and orange, and a zinc atom as a blue sphere. A carbon-nitrogen 5 ring on the enzyme is labeled H 2 53. It lies up against the carbon-nitrogen 6 ring of cytosine in the D N A strand.

(B)

Figure 12.22 APOBEC enzymes induce mutations (A) The APOBEC family of cytosine deaminases catalyzes the deamination of cytosine residues in single-stranded DNA, producing uracil. Failure to repair these uracil residues results in C>T mutations. In addition, DNA repair intermediates such as abasic sites can also lead to C>G mutations and other outcomes. Certain APOBEC enzymes also deaminate cytosine residues in RNA. (B) Model of the active site of APOBEC3B bound to a ssDNA oligonucleotide. The target cytosine base (*red arrow*) can be seen in close proximity to the sidechain of the histidine residue at amino acid 253 (H253). H253 also coordinates a zinc atom (*blue sphere*), which is required for catalysis. (A, from C. Swanton et al., *Cancer Discov*. 5:704–712, 2015. Glossary

temozolomide
: A chemotherapeutic drug used primarily in the treatment of certain brain tumors. It is a type of alkylating agent that causes direct DNA damage.

base-excision repair
: A form of DNA repair that initially involves cleavage by a repair enzyme of the glycosidic bond between a base and a deoxyribose, leaving behind an abasic nucleotide. *Compare* **nucleotide-excision repair**.

nucleotide-excision repair
: Type of DNA repair in which the initial step involves the excision of nucleotides (rather than bases). *Compare* **base-excision repair**.

glycosylase
: An enzyme that cleaves a glycosidic bond, such as that linking a purine or pyrimidine base to a ribose or deoxyribose sugar.

transcription-coupled repair
: A form of nucleotide excision repair (NER) in which transcribed regions of the genome are preferentially repaired. RNA polymerase stalled at DNA lesions mediates the recruitment of NER enzymes to the damage site, initiating transcription-coupled repair.

global genomic repair
: Form of nucleotide excision repair that operates on all parts of the genome.

12.8 Inherited defects in nucleotide-excision repair, base-excision repair, and mismatch repair lead to specific cancer susceptibility syndromes

In 1874, two Austro–Hungarian physicians, Ferdinand Hebra and Moritz Kaposi, described an unusual syndrome that involved high rates of the development of squamous and basal cell carcinomas of the skin. (Kaposi subsequently described the unusual sarcoma that bears his name; *see* Section 4.6.) As became apparent later, affected individuals have extreme sensitivity to UV radiation, and infants will often suffer severe burning of the skin after only minimal exposure to sunlight (**Sidebar 12.7**). These individuals show dry, parchment-like skin (xeroderma) and many freckles ("pigmentosum"; **Figure 12.23**). In aggregate, individuals suffering from the xeroderma pigmentosum (XP) syndrome have a 2000-fold increased risk of skin cancer before the age of 20 compared with the general population and about a 100,000-fold increased risk of squamous cell carcinoma of the tip of the tongue. Skin cancers appear in XP children with a median age of ~10 years, compared with ~60 years in the general population (**Figure 12.24**).

Sidebar 12.7 Degenerate genomes lead to sunlight sensitivity and the need for sunscreen

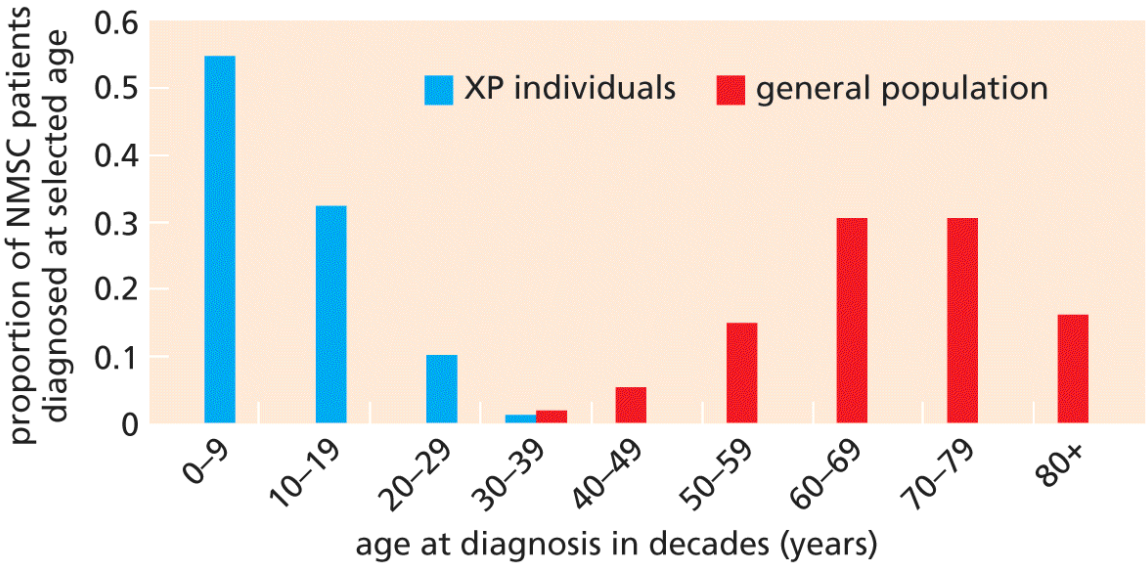
Humans as well as other placental mammals rely totally on the nucleotide-excision repair (NER) system to remove the highly mutagenic UV-induced pyrimidine dimers (see Figure 12.12). This situation contrasts with that seen in bacteria, lower eukaryotes, and plants, where redundant backup systems are in place to deal with these dimers if the first NER line of defense should fail. These simpler organisms, which may exhibit DNA repair capabilities mirroring those of our distant evolutionary ancestors, express (1) enzymes that can monomerize pyrimidine dimers (thereby directly reversing the UV-induced damage), (2)

glycosylases to cleave the dimerized bases from deoxyribose residues, and (3) nucleases to incise the DNA strand around the dimers.

It is possible that once our mammalian ancestors learned to grow coats of hair, the evolutionary pressures to retain these important backup DNA repair enzymes receded, and the encoding genes were lost through one or another genetic mechanism. Now, because of a quirk of recent primate evolution, we humans are left without protective coats of hair and, at the same time, without an ability to mobilize the backup repair systems to fix UV-damaged DNA in the event that our only remaining line of defense—the xeroderma pigmentosum genes and encoded proteins—fails to do this task. The lack of these extra layers of protection explains, in part, why the mutant XP phenotypes can be so devastating for those afflicted with this disease and why more light-complexioned people should make lavish use of sunscreen lotion when in the sun.

A close-up of the face of A xeroderma pigmentosum patient. The eyes are closed. The skin and lips are covered with scab-like crust that creates light and dark blotches. The nostrils appear partly eroded.

Figure 12.23 A xeroderma pigmentosum patient A patient suffering from xeroderma pigmentosum (XP) has severe and extensive lesions in all areas of sun-exposed skin. These lesions can develop into squamous and basal cell carcinomas as well as melanomas. The tumors develop at rates that are as much as 10,000-fold higher than in the general population. (Courtesy of K.H. Kraemer.)

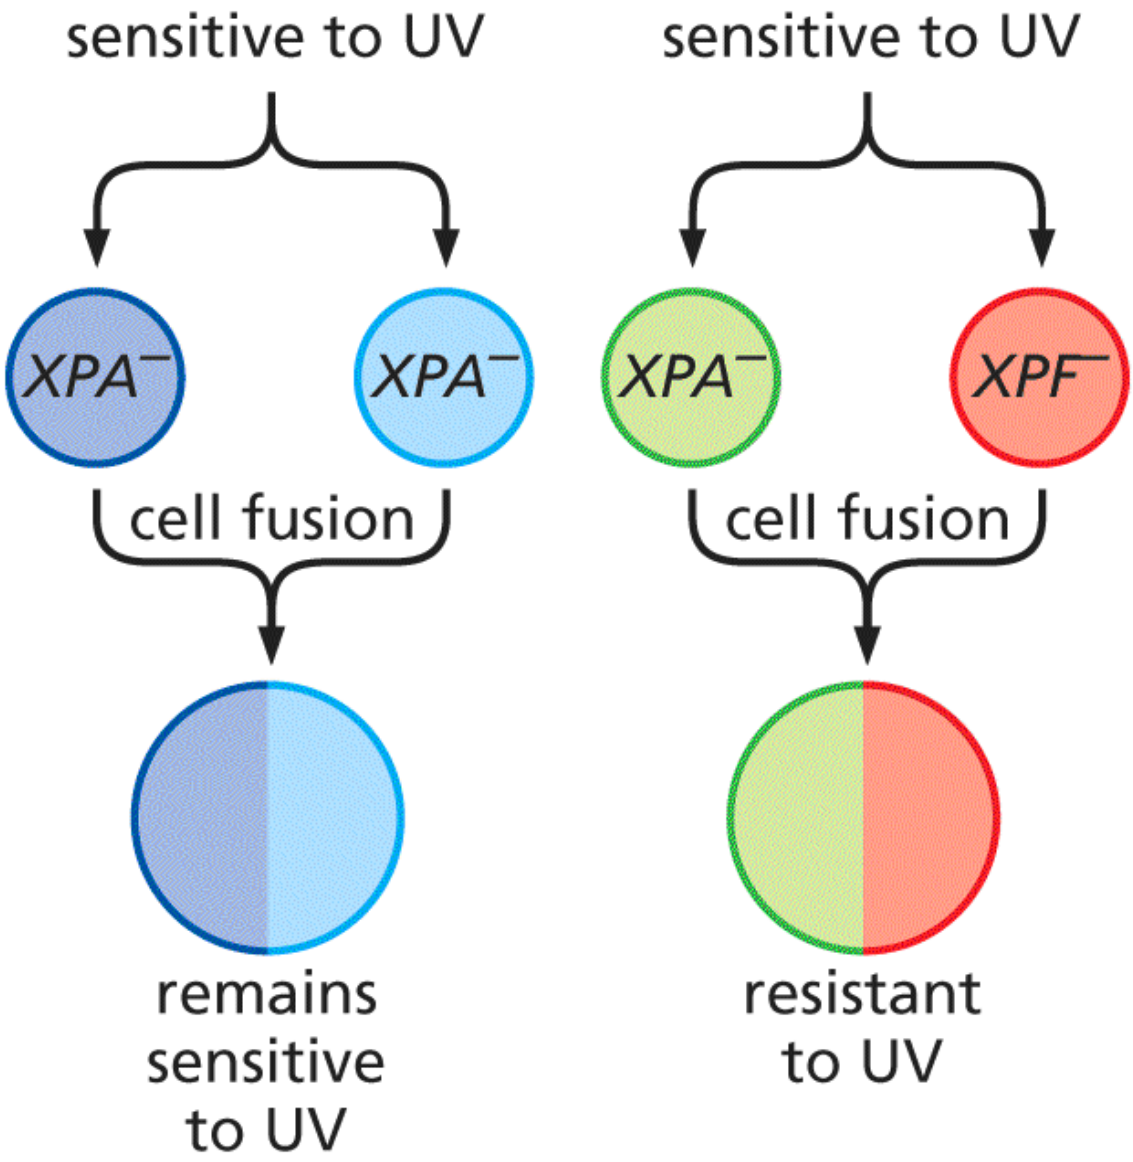


A histogram with age ranges across the bottom. Each vertical bar indicates the proportion of nonmelanoma skin cancer patients diagnosed while in a ten year age range. Over half of X P individuals were diagnosed with skin cancer between birth and age 9. All had been diagnosed with it by age 39. By contrast, in the general population, incredibly few people are diagnosed with skin cancer before age 30, and the most common ages at diagnosis are in the 60 to 79 range.

Figure 12.24 Significantly earlier onset skin cancers in individuals with xeroderma pigmentosum (XP) compared to the general population The graph shows the proportion of XP individuals (*blue bars*) and individuals in the general population (*red bars*) who were diagnosed with nonmelanoma skin cancer (NMSC) in different decades of life. The median age of diagnosis was 9 years for XP individuals and 67 years for individuals in the general

population. (From P.T. Bradford et al., *J. Med. Genet*. 48:168–176, 2011. With permission from BMJ.)

We now know that inherited defects in any one of eight genes can lead to xeroderma pigmentosum, but this number is arbitrary, as these genes overlap with other genes involved in NER and a variety of other syndromes resulting from defective DNA repair. The genetic complexity of the XP syndrome was first recognized through the use of somatic cell genetics. Thus, cells from two different XP patients were fused in culture in order to determine the repair phenotype of the resulting hybrid cells (**Figure 12.25**; see also Figure 7.1). On many occasions, the hybrids were found to repair DNA normally, indicating that the two parental cells carried defects in DNA repair that were associated with two distinct genes. For example, using nomenclature developed later, cells from an individual carrying a mutant *XPA* gene (and having a wild-type *XPC* gene) were able to repair DNA normally after being fused to cells from an individual carrying a mutant *XPC* gene (and having a wild-type *XPA* gene). Conversely, cells from two individuals, each carrying a mutant *XPA* allele, would continue to exhibit a DNA repair defect. Such collaboration, or "genetic complementation," (or lack thereof) led to the classification of XP-associated mutant alleles into eight complementation groups, each ostensibly defined by the identity of a responsible gene. Only years later were the responsible genes isolated by molecular cloning. Almost always, it has been possible to show that an affected individual has inherited two mutant, null alleles of a gene representing one or another XP complementation group. Thus, the pattern of inheritance of XP is autosomal recessive, in contrast to some of the other "caretaker" gene-associated familial cancer syndromes we have discussed in Chapter 7 and will return to below, which exhibit autosomal dominant patterns of inheritance at the organismic level.



A diagram describing two different outcomes of cell fusion experiments. The fusion of two U V sensitive X P A negative cells from different patients produces a cell that remains sensitive to U V. On the other hand, the fusion of a U V sensitive X P A negative cell from one patient with a U V sensitive X P F negative cell from another patient produces a cell that is U V resistant.

Figure 12.25 Discovery of XP complementation groups Cell fusion experiments using cultured cells from xeroderma pigmentosum (XP) patients have revealed that certain combinations of fibroblasts, each derived from a different patient (*dark blue, light blue, left*), when fused, yielded hybrid tetraploid cells that are as UV-sensitive as the two parental cell populations.

On other occasions, however (*right*), fusion of cells from two patients (*light green, light red*) yielded cell hybrids that are as resistant to UV-mediated killing as the cells from normal individuals. Such findings caused the pair of cells that did not complement one another's DNA repair defect (*dark blue, light blue*) to be assigned to the same complementation group, ostensibly because the two populations carried mutations in the same gene. Conversely, successful complementation by other pairs of cells (*light green, light red*) allowed the respective parental cell types to be assigned to two distinct complementation groups, indicating that mutant alleles of at least two distinct genes were involved in predisposing to XP. In this way, eight distinct XP complementation groups were eventually delineated; the responsible genes were isolated by gene cloning years later.

Seven of the eight XP-associated genes, termed *XPA* through *XPG*, encode components of the large, multiprotein nucleotide-excision repair (NER) complex. The eighth gene, *XPV*, specifies the error-prone DNA polymerase pol-ε that many cells use when their regular DNA polymerases (for example, pol-δ) are unable to copy over unrepaired DNA lesions in the template strand such as pyrimidine dimers. As mentioned in the last section, error-prone polymerases are able to copy a template strand of DNA containing the still-unrepaired TT dimers created by UV radiation, usually by incorporating two A's in the complementary strand. In general, pol-ε is thought to be so accurate that it incorporates AA nucleotides in the growing DNA strand opposite a TT dimer 95% of the time.

Individuals afflicted with XP also have some increased risk of other diseases, notably neurological problems, which are observed in about 18% of these patients. And mice that have been deprived of one of several XP genes suffer markedly increased susceptibility to tumors following exposure to chemical carcinogens. These two observations provide evidence that components of the nucleotide-excision repair system encoded by some of the XP genes are, not unexpectedly, responsible for repairing genetic damage created by other agents besides UV radiation. This finding raises the following question: Why does a human who lacks the function of one or another XP gene have relatively little increased risk of cancers in internal organs, even though an important component of the NER machinery is missing from all cells throughout this person's body? The simplest and possibly correct explanation is that UV rays are, by far, the most important environmental mutagen to which most humans are exposed, and thus the source of most of the lesions that require repair by the NER machinery. (By one estimate, strong sunlight can inflict as many as 100,000 DNA lesions per skin

cell per hour.) Accordingly, skin cancers represent the great majority of cancers in XP patients, with tumors of internal organs being greatly overshadowed and, quite possibly, never registered in these patients.

Several other inherited syndromes are also associated with defects in NER. For example, individuals suffering from Cockayne syndrome (CS) appear to be defective in one of two genes that are involved in transcription-coupled NER. Their cells have increased photosensitivity like those of XP patients. The median age of death of patients from this disease is 12 years of age. This disease is highly unusual, in that the significant defects in DNA repair are not associated with increased rates of cancer. Still unaddressed is the possibility that individuals who are *heterozygous* carriers for one of the XP- or Cockayne syndrome–associated mutant alleles have an elevated risk of developing certain types of cancer. (The fibroblasts of such carriers have been found to exhibit several-fold increased numbers of chromosomal breaks in response to X-irradiation.)

XP was only the first of many human cancer susceptibility syndromes that have been found to be caused by inherited defects in various types of DNA repair (**Table 12.1**). We will explore another one here—hereditary non-polyposis colon cancer (HNPCC; also referred to as Lynch syndrome). HNPCC is a familial cancer syndrome that represents a quite common cause of inherited predisposition to colon cancer, being responsible for 2 to 3% of all colon cancer cases. HNPCC is, as its name implies, distinct from the other type of hereditary colon cancer predisposition that we encountered previously—adenomatous polyposis coli (see Section 7.10). A subclass of HNPCC/Lynch syndrome patients, in addition to their 80% lifetime risk of developing colon carcinomas, have increased susceptibility to brain tumors as well as endometrial, stomach, ovarian, and urinary tract carcinomas.

Table 12.1 Human familial cancer syndromes arising from germ-line defects in DNA repair

Name of syndrome	Name of gene	Cancer phenotype	Enzyme or process affected
HNPCC/Lynch	(4–5 genes)[a]	colonic polyposis	mismatch repair enzymes

Name of syndrome	**Name of gene**	**Cancer phenotype**	**Enzyme or process affected**
XP[b]	(8 genes)[b]	UV-induced skin cancers	nucleotide-excision repair
ataxia telangiectasia (AT)[c]	ATM	leukemia, lymphoma	response to dsDNA breaks
AT-like disorder[c]	MRE11	lung, breast cancers	dsDNA repair by NHEJ
Familial breast, ovarian cancer	*BRCA1*, *BRCA2*,[d] *BACH1*, *RAD51C*	breast, ovarian, prostate carcinomas	homology-directed repair of dsDNA breaks
Werner	WRN	sarcomas, other cancers	exonuclease and DNA helicase,[e] replication
Bloom	BLM	leukemias, lymphomas, solid tumors	DNA helicase, replication
Fanconi anemia	(13 genes)[f]	AML, diverse carcinomas	repair of DNA cross-links and ds breaks

Name of syndrome	Name of gene	Cancer phenotype	Enzyme or process affected
Nijmegen breakage[g]	NBS	mostly lymphomas	processing of dsDNA breaks, NHEJ
Li–Fraumeni	TP53	multiple cancers	DNA damage alarm protein
Li–Fraumeni	CHK2	colon, breast carcinomas	kinase signaling DNA damage
Rothmund–Thomson	RECQL4	osteosarcoma	DNA helicase
Familial adenomatosis	MYH	colonic adenomas	base-excision repair
Familial breast cancer	PALB2	breast cancer	dsDNA repair by HR

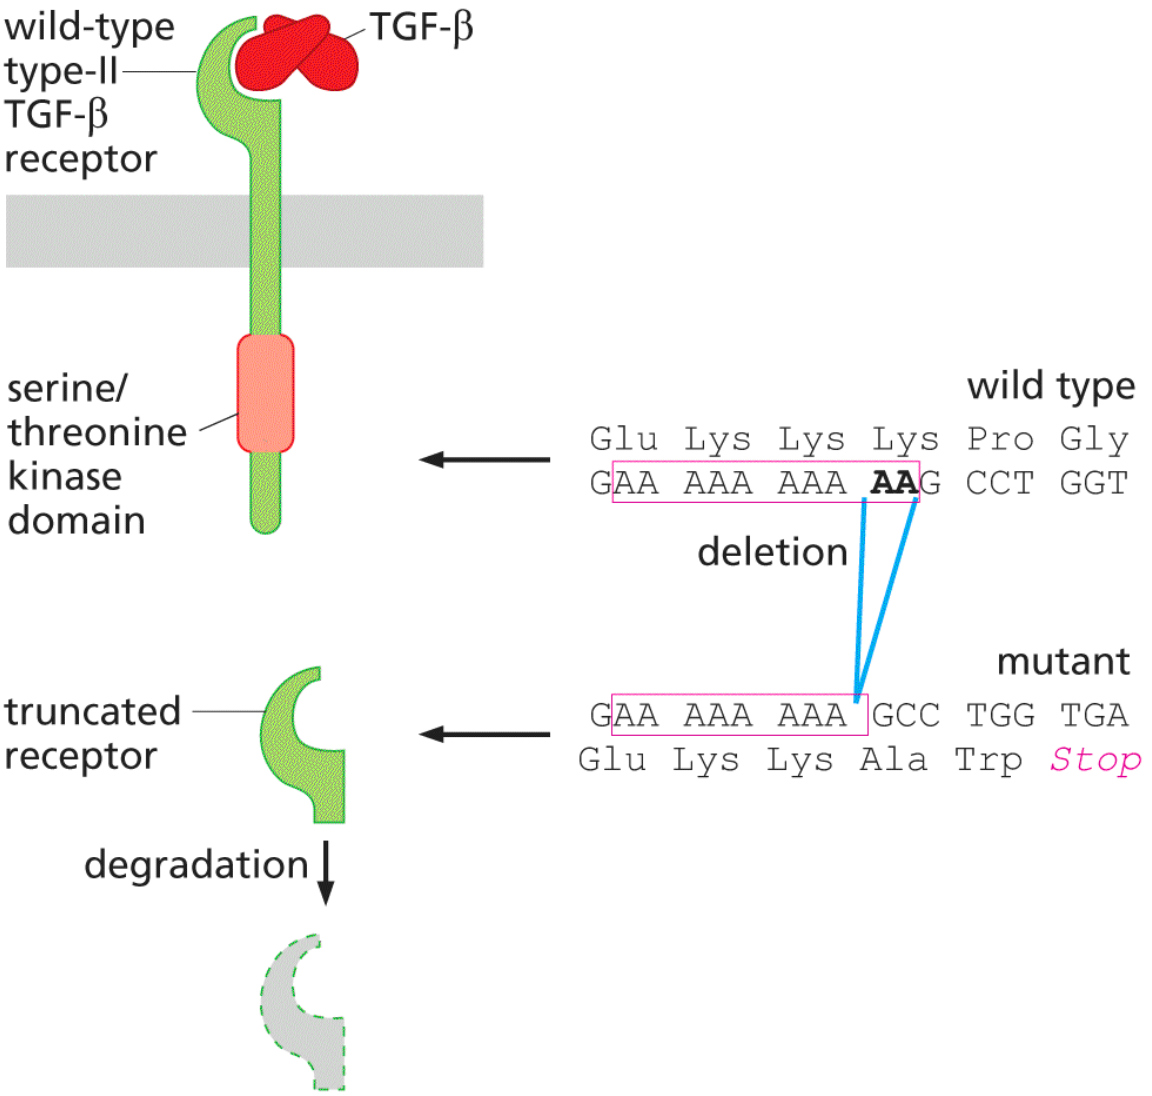
Adapted in part from B. Alberts et al., Molecular Biology of the Cell, 7th ed. New York: WW Norton & Company, 2022. Also from E.R. Fearon, *Science* 278:1043–1050, 1997.

The increased colon cancer susceptibility of the HNPCC patients can be traced back to the accelerated rate with which tumor progression proceeds in their colons: although the adenoma-to-carcinoma progression is estimated to require more than a decade in the general population (see Section 11.4), the genetic instability afflicting the cells of HNPCC patients allows this step to occur in only

2 to 3 years. Indeed, because their adenomas progress so quickly to carcinomas, these premalignant growths have a relatively short lifetime and are therefore not found in significant numbers in the colons of these patients. The responsible genes were discovered through clever genetic sleuthing (**Supplementary Sidebar 12.7**).

The majority (85–90%) of HNPCC cases result from germ-line mutations in the genes encoding two important mismatch repair proteins, MSH2 and MLH1. Mutant germ-line alleles of two other MMR genes, *MSH6* and *PMS2*, are involved in a small proportion (~15%) of these cases; however, two other MMR genes (*PMS1*, *MSH3*), which have been found to play equally important roles in DNA repair, are rarely if ever transmitted as mutant alleles in the human germ line. Similar to the genetics of most tumor suppressor genes, patients inherit one defective allele of an MMR gene and the genomes present in tumor cells that arise almost always undergo a loss of heterozygosity (LOH) that results in the discarding of the surviving wild-type gene copy.

The resulting inability to properly detect and repair sequence mismatches leads to, among other consequences, high rates of mutations in genes that have microsatellite repeats nested in their sequences (see Figure 12.7) as well as a very high mutation rate overall. A dramatic and early illustration of the consequences of this repair defect came from study of a group of 11 colorectal cancer cell lines that showed microsatellite instability. In 9 of these cell lines, the gene encoding the type II TGF-β receptor (TGF-βRII) was found to be mutant. More specifically, the wild-type reading frame of this gene carries a stretch of 10 A's in a row (**Figure 12.26**). However, in these 9 tumor cell lines, the TGF-βRII gene was found to have lost 1 or 2 A's of the normally present homopolymeric stretch of 10 A's. These sequence changes forced the coding sequence of the TGF-βRII gene out of its normal reading frame and resulted in nonfunctional TGF-βRII proteins. We can imagine that once tumor cell precursors no longer express functional TGF-βRII, they can escape the inhibiting effects of proliferation of this anti-mitogenic signaling protein (see Section 8.4)—a highly advantageous trait if it is acquired early in tumor progression by epithelial cells. In a subsequent study of a series of 111 colon carcinomas exhibiting microsatellite instability, 100 were found to carry mutant, defective alleles of the TGF-βRII gene, with almost all mutant alleles being present in homozygous configuration. Hence, once one of the receptor-encoding genes suffers an inactivating mutation, the surviving wild-type allele is discarded through loss of heterozygosity.



A diagram of a T G F beta receptor. The wild-type type 2 T G F beta receptor binds to T G F beta. The tail contains a serine/threonine kinase domain. In this domain, the base sequence G A A A A A A A A A A G C C T G G T encodes for the wild type amino acid sequence Glutamic acid, Lysine, Lysine, Lysine, Proline, Glycine. The deletion of the last two ayze produces the sequence G A A A A A A A A A G C C T G G T G A, which encodes for the mutant amino acid sequence Glutamic acid, Lysine, Lysine, Alanine, Tryptophan, stop. The result is a truncated receptor that soon undergoes degradation.

Figure 12.26 A TGF-β receptor gene affected by microsatellite instability
The type II TGF-β receptor (TGF-βRII) is frequently inactivated in human colon cancers exhibiting microsatellite instability and therefore carrying

defects in mismatch repair (MMR) genes. In the particular colon cancer whose DNA was analyzed here, the last 2 of 10 adenines (*boldface*) were deleted from the reading frame of the receptor-encoding gene, ostensibly because of an MMR defect. This particular deletion ($A_{10} \rightarrow A_8$) resulted in a nonsense mutation that caused premature termination of translation of the nascent TGF-βRII protein and hence loss of functionally critical signaling domains in the C-terminus of the receptor. This loss, in turn, allowed the progenitors of the colon carcinoma cells to become resistant to the growth-inhibitory effects of TGF-β. Alterations of this tract of A's in the TGF-βRII gene were subsequently found in 100 of 111 colorectal carcinomas showing defective MMR, in which they caused translation of the TGF-βRII mRNA to yield polypeptides of either 129 or 161 amino acid residues (depending on how many A's were deleted) rather than the 565 amino acid residues in the wild-type receptor. (From C. Lengauer, K.W. Kinzler and B. Vogelstein, *Nature* 396:643–649, 1998. With permission from Nature.)

Later, yet other genes were found to have suffered similar mutations in mismatch repair–defective cancer cells (**Table 12.2**). In most cases, the MMR defect and resulting mutant alleles were discovered in sporadic (rather than familial) cancers. These observations suggested that in nonfamilial tumors, MMR genes, like tumor suppressor genes, can be rendered defective either by somatic mutation or, alternatively, by promoter methylation and resulting transcriptional silencing (see Section 7.7). In fact, the second mechanism is responsible for the lion's share of defective MMR in these tumors: about 15% of sporadic gastric, colorectal, and endometrial tumors show defective MMR, and in almost all of these, the observed microsatellite instability can be traced to the methylation and resulting silencing of the *MLH1* gene. Interestingly, in the histologically normal endometrial tissue directly adjacent to tumors with defective MMR, the *MLH1* gene is often found to be methylated, suggesting that this methylation is one of the earliest events of tumor progression in this tissue (**Figure 12.27**); this alteration would appear to be another manifestation of the field cancerization described in Section 11.5. As we discuss in Section 12.13, genomic analysis of a large number of colon cancers and other cancers carrying MMR gene mutations has revealed an extremely high mutation frequency, involving length changes of microsatellite sequences as well as base-pair substitutions outside of repetitive sequences. Thus, the genes shown in Table 12.2 represent only a small proportion of genes mutated in MMR-deficient tumors.

Table 12.2 Genes and proteins that have been inactivated in human cancer cell genomes because of mismatch repair defects

Gene	Function of encoded protein	Wild-type coding sequence	Colon	Stomach	Endometrium
ACTRII	GF receptor	A_8	X

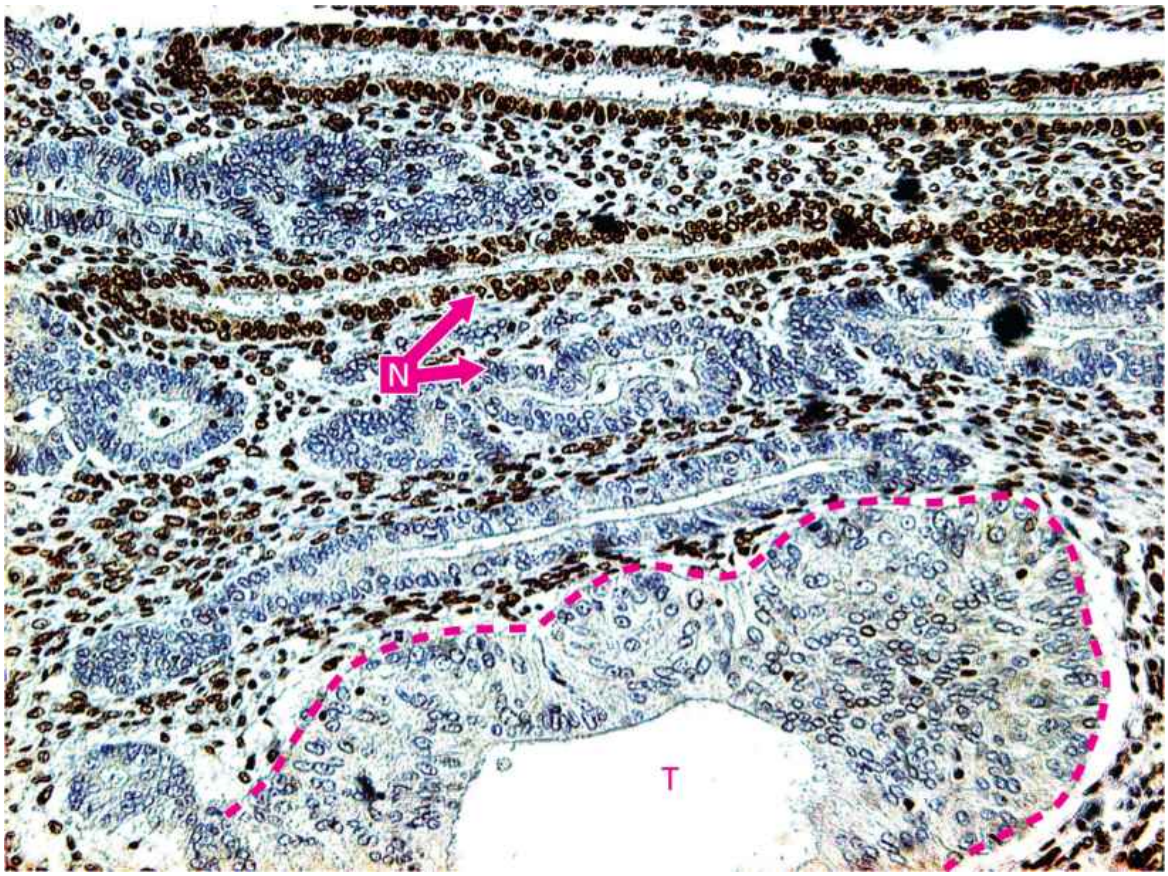
Abbreviations: GF, growth factor; MMR, mismatch repair; TF, transcription factor.



A histology image. The upper part of the image contains band-like regions where the nuclei are stained dark brown and other regions where the nuclei are stained a pale blue. The cells are generally well organized and uniformly stained, but a region at the bottom of the image contains disorganized cells with minimally stained nuclei.

Figure 12.27 Suppression of MLH1 activity in endometrial tissue Anti-hMLH1 antibody coupled to a peroxidase enzyme generates a dark brown spot wherever it binds MLH1 protein. Here, the normal endometrial tissue of an endometrial cancer patient shows areas of intense, dark brown staining, indicating high hMLH1 expression (N, *upper pink arrow*), and areas of weak staining (N, *lower pink arrow*) where cell nuclei have been stained light blue with DAPI (a DNA-specific stain) but little MLH1 staining is seen. The endometrial carcinoma tissue (*below, dashed pink line*, T) is virtually devoid of hMLH1 staining and exhibits only light staining of cell nuclei by DAPI. Molecular analysis (*not shown*) indicated that the promoter of the *hMLH1* gene in the carcinoma cells was strongly methylated. Expression of hMLH1 was reduced or absent in some of the histologically normal tissue adjacent to the tumor, indicating that loss of hMLH1 expression occurred relatively early

in tumor progression and preceded the histopathological alterations that led to the formation of this carcinoma. (From T. Kanaya et al., *Oncogene* 22:2352–2360, 2003. With permission from Nature.)

Although MMR gene mutations are associated with high mutational burden in cancers, an even higher mutation rate is observed in cancers with mutations in the proofreading domains of the replicative DNA polymerases pol-δ and pol-ε. As discussed in Section 12.3, the proofreading mechanism recognizes and removes misincorporated bases during DNA replication. Germ-line mutations in the human *PolD1* and *PolE* genes, which encode the catalytic domains of pol-δ and pol-ε, respectively, lead to predisposition to colon cancer and other malignancies (see Figure 12.5B). In functional studies in yeast, several of these mutations have been shown to affect proofreading function and raise the mutation rate. Moreover, somatic mutations in the proofreading-encoding domains of the *PolD1* and *PolE* genes have been observed in endometrial cancer, colon cancer and other tumor types (see Figure 12.5B). Tumors carrying these mutations exhibit what has been characterized as an "ultra-mutated" phenotype, which leads to as many as one million base substitutions in the genomes of certain tumors (see Section 12.13). In contrast to MMR-deficient tumors, these tumors do not exhibit microsatellite instability.

OceanofPDF.com

Glossary

xeroderma pigmentosum
: Syndrome resulting from an inherited inability to repair UV-induced DNA lesions in the skin, resulting in severe burning of the skin following exposure to sunlight and the development of skin cancers at a high rate.

complementation
: Ability of two mutant genotypes, when coexisting in the same cell or organism, to compensate for each other's defects and thereby create a wild-type phenotype, indicating that the two genotypes carry changes in distinct genes and therefore can be classified as belonging to distinct complementation groups. *See also* **complementation groups**.

Lynch syndrome
: A form of familial colorectal cancer caused by inherited mutations in one of several mismatch repair genes; also known as hereditary non-polyposis colorectal cancer (HNPCC). Beyond colorectal cancer, individuals with Lynch syndrome are also at increased risk of developing brain, stomach, and endometrial cancer as well as other cancer types. *See also* **hereditary non-polyposis colorectal cancer**.

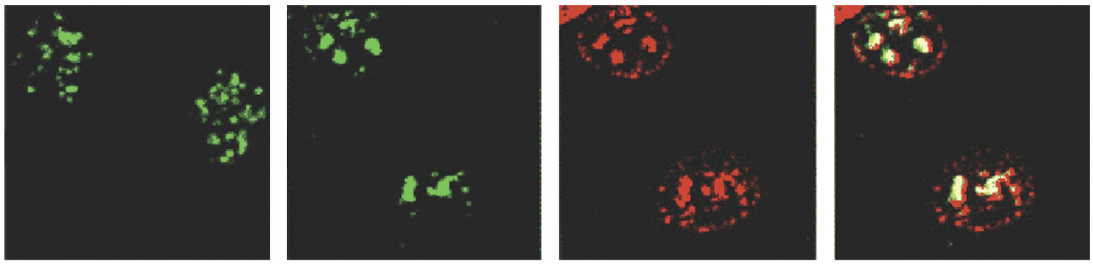
12.9 A variety of other DNA repair defects confer increased cancer susceptibility

By far the most notorious genes associated with cancer, at least in the mind of the public, are *BRCA1* and *BRCA2*. Mutant germ-line alleles of either of these genes confer an inborn susceptibility to breast and ovarian carcinomas. More specifically, almost half of all identified familial breast cancers involve germ-line transmission of a mutant *BRCA1* or *BRCA2* allele; by some estimates, 70 to 80% of all familial ovarian cancers result from mutant germ-line alleles of *BRCA1* or *BRCA2*. Stated differently, carriers of mutant germ-line *BRCA1* or *BRCA2* alleles have a 50–70% risk of developing breast cancer before the age of 70. Ovarian carcinoma risk is also high: 40–50% of *BRCA1* mutation carriers and 10–20% of *BRCA2* carriers develop disease before the age of 70. In addition, mutant *BRCA2* germ-line alleles have been associated in males with a >7-fold elevated risk of developing prostate cancer before the age of 65. Germ-line mutations in *BRCA1* and *BRCA2* increase the risk of pancreas cancer as well. Somatic loss of *BRCA1* function also appears to be important: 20–30% of sporadic (non-familial) ovarian carcinomas (that is, arising in women carrying wild-type *BRCA1* and *BRCA2* germ-line alleles) and almost as many sporadic breast cancers exhibit loss of function of one of these genes as a result of promoter methylation (see Section 7.7).

When these two genes were first discovered, it seemed that they should be included among the tumor suppressor genes, which are known to be involved in regulating the dynamics of cell proliferation, survival, and differentiation (see Chapter 7). But diverse lines of evidence built an increasingly persuasive case that these two genes are actually involved in the maintenance of genomic integrity and that their products therefore should be considered “caretakers” (DNA repair proteins) rather than “gatekeepers” (tumor suppressor proteins) (see Section 7.12).

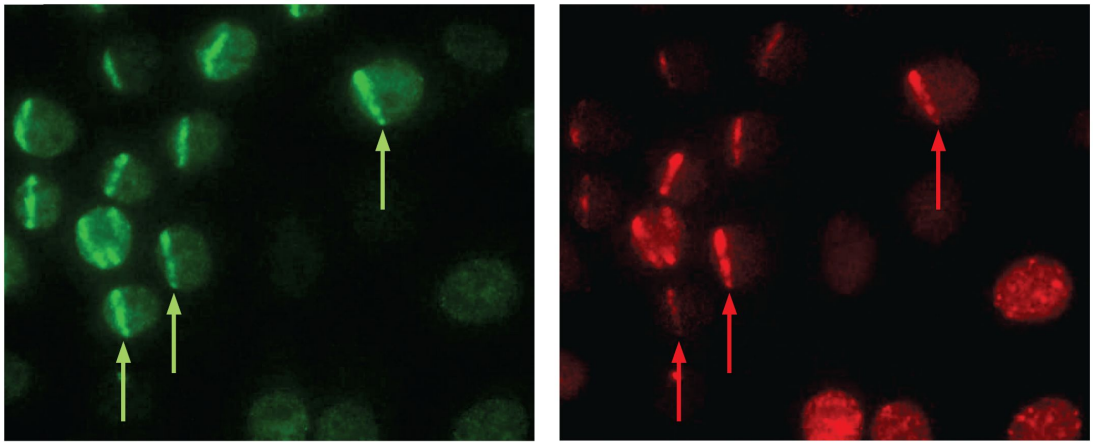
The case for the participation of BRCA1 and BRCA2 in genomic maintenance can be argued using guilt-by-association evidence. The BRCA1 and BRCA2 proteins are found in large multi-subunit complexes with one another and with a large number of other proteins in the cell nucleus. These massive complexes carry, among other components, both the RAD50/Mre11 and the RAD51 proteins—homologs of two proteins in yeast that were initially discovered because of the important roles they play in repairing DNA breaks caused by ionizing radiation (that is, X-rays). Mismatch repair proteins have been found in these complexes as well.

Quite dramatically, treatment of cells with hydroxyurea, which results in a stalling of replication forks during S phase, causes BRCA1 molecules to cluster at discrete sites in the nucleus. Many of these stalled forks are thought to be sites of dsDNA breakage caused by accidental breaks in the still-unreplicated single-stranded DNA at the forks (see Figure 12.8); the breaks are usually fixed by a mechanism that is variously termed homologous recombination–mediated repair or homology-directed repair (abbreviated HR or HDR). As visualized by immunofluorescent microscopy, BRCA1 molecules are normally distributed in a large number of tiny dots throughout the nucleus; hydroxyurea causes the BRCA1 molecules to leave these dots and flock together in a far smaller number of large, discrete spots, in which the proliferating-cell nuclear antigen (PCNA)—known to be localized to replication forks—is also found (**Figure 12.28A**). These spots have also been found to contain a number of other known DNA repair proteins, including RAD50 and RAD51. The BRCA2 protein is also found in these spots, providing additional presumptive evidence of its collaboration in DNA repair processes. Moreover, when dsDNA breaks are intentionally created in discrete areas within cell nuclei using a focused laser beam, the BRCA1 protein co-localizes in these areas together with γ-H2AX, a phosphorylated histone that is present in the chromatin flanking sites of dsDNA damage (Figure 12.28B). Altogether, 20 distinct cellular proteins, most known to be involved in DNA repair, have been found to be recruited to these areas of damage, and the list is growing.



Four fluorescence microscopy images. The first one is labeled B R C A 1 without hydroxyurea. Two nuclei each have many small green dots throughout. The second image is labeled B R C A 1 with hydroxyurea. Two nuclei have a few large green splotches in them. The third image is labeled P C N A with hydroxyurea. It shows the same two nuclei as the second image, with large and small red splotches. The fourth image is labeled B R C A 1 and P C N A overlap with hydroxyurea. It is a composite of the second and third images, with overlapping areas shown as yellow.

(A)



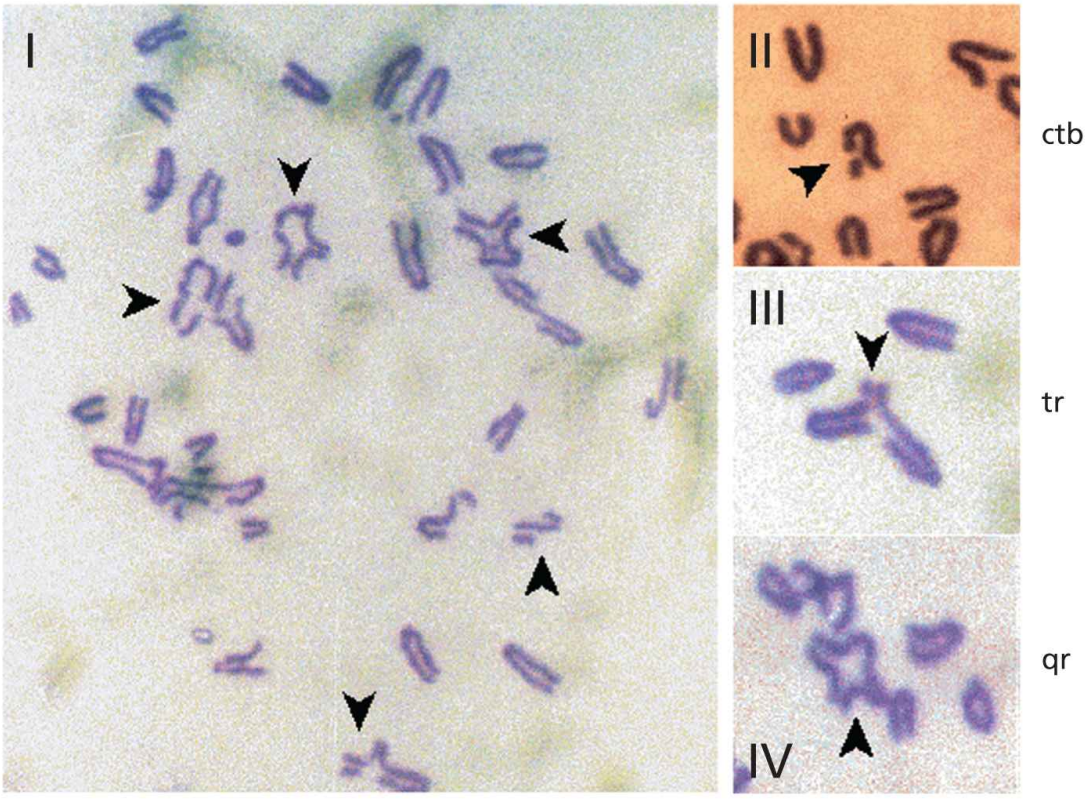
Two fluorescence microscopy images. The first one is labeled gamma H 2 A X. It shows ten nuclei in green, each with a bright stripe across it. The second image is labeled B R C A 1. It shows the same ten nuclei, with similarly positioned stripes, only the image is red instead of green.

(B)

Figure 12.28 BRCA1 and the response to DNA damage (A) The BRCA1 protein, which can be detected by fluorescence-labeled antibodies, is normally found during S phase in numerous discrete, small dots throughout the nucleus (*green, first panel*). However, when cells in S phase are treated with hydroxyurea, which stalls forward progress of the replication forks, the BRCA1 protein molecules leave these dots and congregate in a small number of quite large spots (*green, second panel*). A similar BRCA1 relocalization pattern can be observed with the proliferating-cell nuclear antigen (PCNA), which is known to be associated with replication forks (*red, third panel*). Substantial co-localization of the BRCA1 and PCNA proteins is indicated by the yellow spots (*fourth panel*); i.e., *red + green → yellow*. These stalled replication forks often are sites of double-strand (ds) DNA breaks caused by the accidental breakage of the still-unreplicated (and thus fragile) single-strand DNA (see Figure 12.8); these observations suggest that BRCA1 is recruited to sites of dsDNA breaks. (B) A 355-nm UV laser was used to paint narrow stripes across individual nuclei, which were then analyzed by immunostaining with antibodies reactive with either γ-H2AX (a phosphorylated histone that is known to localize to chromatin flanking dsDNA breaks; *green*) or BRCA1 (*red*). This co-localization indicates that BRCA1 is attracted to areas of dsDNA breaks. (A, from R. Scully et al., *Cell* 90:425–435, 1997. With permission from Elsevier. B, from R.A. Greenberg et al., *Genes Dev*. 20:34–46, 2006. With permission from Cold Spring Harbor Laboratory Press.)

Mouse embryos carrying homozygous *BRCA1* mutations die at various stages of development, depending on the mutant allele. More revealing, however, are genetic strategies that limit the loss of BRCA1 function to specific, already-formed tissues after birth. Thus, conditional deletion (see Section 7.9) of segments of *BRCA1*, specifically in the developing mammary gland, leads to mammary tumors that appear after long latency. Interestingly, concomitant deletion of *p53* in these models shortens the latency considerably.

When taken together, these observations are consistent with a role for p53 in responding to the DNA damage caused by failed HDR in BRCA1-deficient cells. This response is likely to explain the long latency of *BRCA1*-mutant mice bearing wild-type *p53* alleles, in which ongoing p53 function appears to lead to significant attrition of incipient breast carcinoma cells. When p53 is also eliminated in such cells (yielding the $BRCA1^{-/-}p53^{-/-}$ genotype), they exhibit high levels of genomic instability, this being indicative of ongoing defects in DNA damage repair. In addition, mutant germ-line alleles of *BRCA2* that cause only partial loss of function result in susceptibility to lymphoid malignancies and unusual chromosomal aberrations. These aberrations have structures that suggest high rates of illegitimate recombination, that is, recombination events (or fusions) between two nonhomologous chromosomal arms (**Figure 12.29**). Such chromosomal structures result characteristically from improper repair of dsDNA breaks (DSBs), many of which may arise accidentally at replication forks during a typical S phase of the cell cycle.



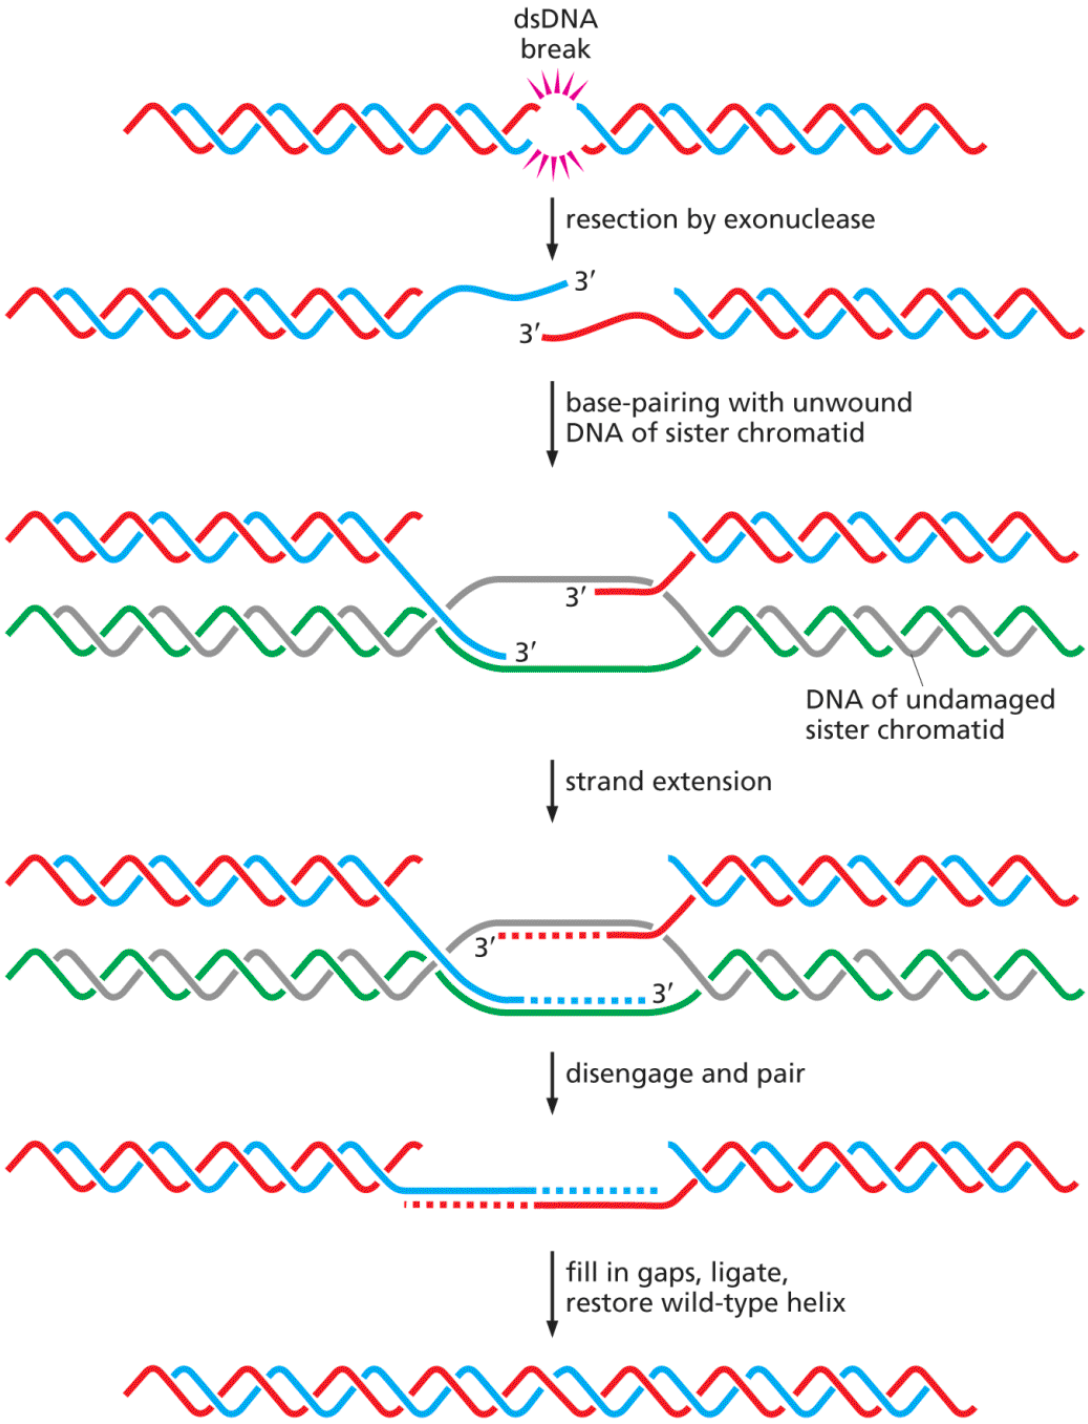
Four images of mouse chromosomes during mitosis metaphase. In image 1, which is larger than the others, many chromosomes are U shaped or Y shaped, but five, indicated by arrows, have more unusual shapes. In image 2, labeled c t b, an arrow indicates a U shaped chromosome in which one leg of the U is broken. In image 3, labeled t r, two U shaped chromosomes are attached on one side with their open ends facing each other. The two attached arms meet at a wide angle away from the two ewes. In image 4, labeled q r, four U shaped chromosomes join with their open ends facing the center, to form an X shape.

Figure 12.29 Karyotypic alterations from partial loss of BRCA2 function
Various karyotypic abnormalities (*arrowheads*) have been observed in cultured fibroblasts prepared from a mouse embryo that was homozygous for an allele encoding a truncated BRCA2 protein. These include fusions between chromosomal arms, resulting in chromosomal translocations that often manifest aberrant chromatid pairings at the metaphase of mitosis. The fusions are often caused by unrepaired or improperly repaired dsDNA breaks. When the hybrid chromatids resulting from such fusions pair with unaffected sister chromatids, structures such as those seen here are observed (*panel I*). Among the aberrations resulting from dsDNA breaks are chromatid breaks (ctb, *panel II*), triradial chromosomes (tr, *panel III*), and quadriradial chromosomes (qr, *panel IV*).

Chromatid pairings like these are rarely observed in wild-type cells. (From K.J. Patel et al., *Mol. Cell* 1:347–357, 1998. With permission from Elsevier.)

BRCA2 deficiency results additionally in deregulation of centrosome number, indicating defective functioning of the mitotic spindle, a condition that generates, in turn, aneuploidy. Cells that have reduced levels of BRCA2 also exhibit prolonged cytokinesis at the end of M phase (see Figure 8.3). Yet other indications of defective DSB repair in *BRCA1* and *BRCA2* mutant cells come from experiments that test the ability of cells to recover from DSBs introduced into their chromosomal DNA by X-rays. Cultured cells lacking the bulk of BRCA1 function show greatly increased sensitivity to killing by both X-rays and by chemotherapeutic drugs, such as cisplatin, that generate DSBs and inter-strand cross-links, respectively, in the DNA. As cited again in Section 17.3, the increased sensitivity of cells with defective homology-directed repair (such as *BRCA1* and *BRCA2*-mutant cells) to such DNA damaging agents has led to novel treatments for cancers carrying these mutations that take advantage of their reduced DNA repair capacity.

The repair of a DSB formed in one chromatid often depends on the ability of the repair apparatus to consult the undamaged, homologous DNA sequences in a sister chromatid and to use those sequences to instruct the repair apparatus on precisely how to reconstruct the broken double helix (**Figure 12.30**; see **Supplementary Sidebar 12.8** for a more detailed molecular description). Thus, such homology-directed repair (HDR) occurs largely during the late S and the G_2 phases of the cell cycle, when the double helix in a sister chromatid can provide the sequence information for repairing the damaged chromatid. Recall that during S phase, DNA replication results in the production of two identical chromatids that remain associated as part of a common chromosome until they are separated during the next mitosis (see Figure 8.3). HDR is also used if inter-strand covalent cross-links within a double helix should arise.

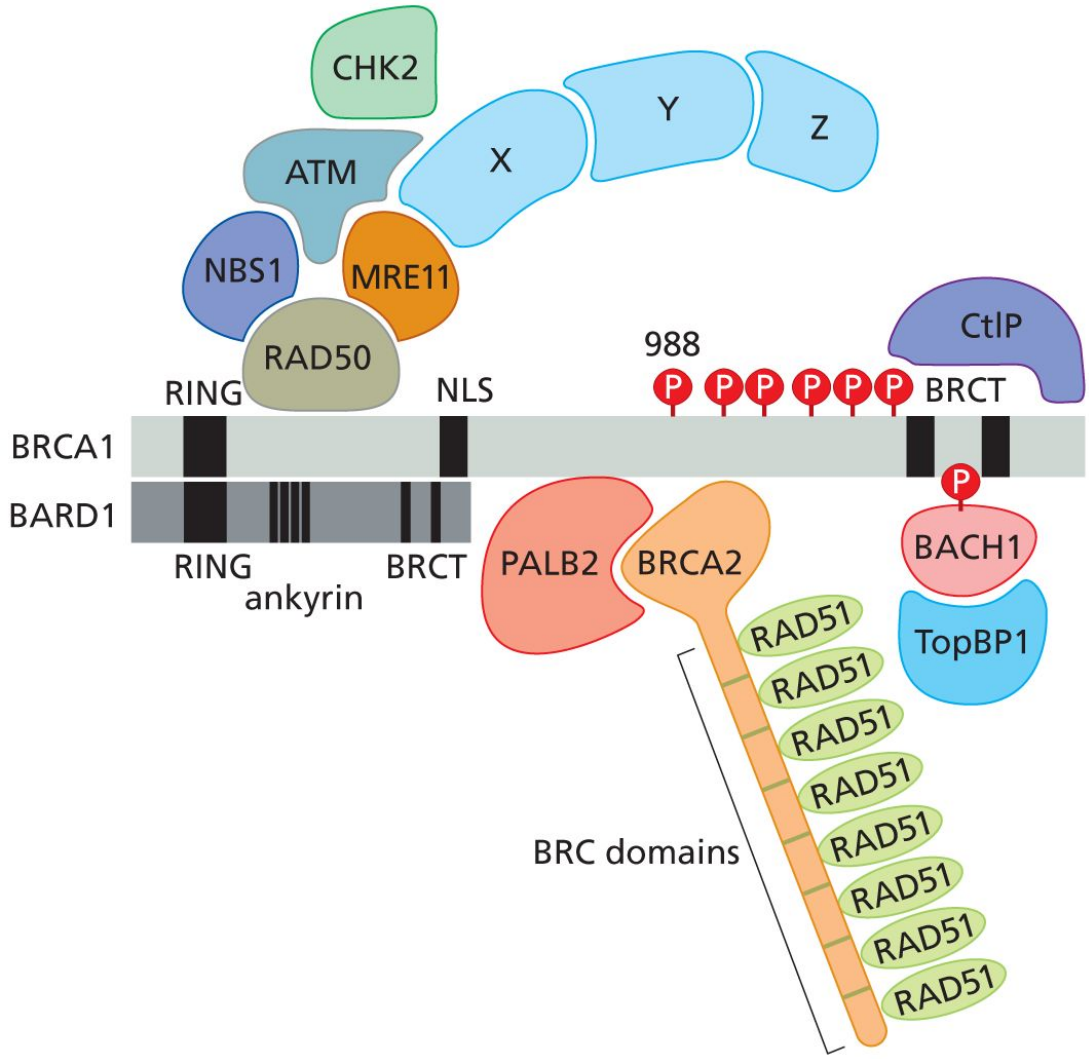


Homology-directed repair. It begins with a break in a double-stranded D N A. After resection of single strands by exonuclease, each side of the break has a longer 3 prime end than a 5 prime end. Base-pairing with the unwound D N A of a sister chromatid allows the strands of the undamaged sister chromatic to serve as templates for the repair of the damaged strands. The newly repaired D N A

disengages from the other chromatid, the two repaired strands pair up, gaps are filled in, ligation occurs, and the wild-type helix is restored.

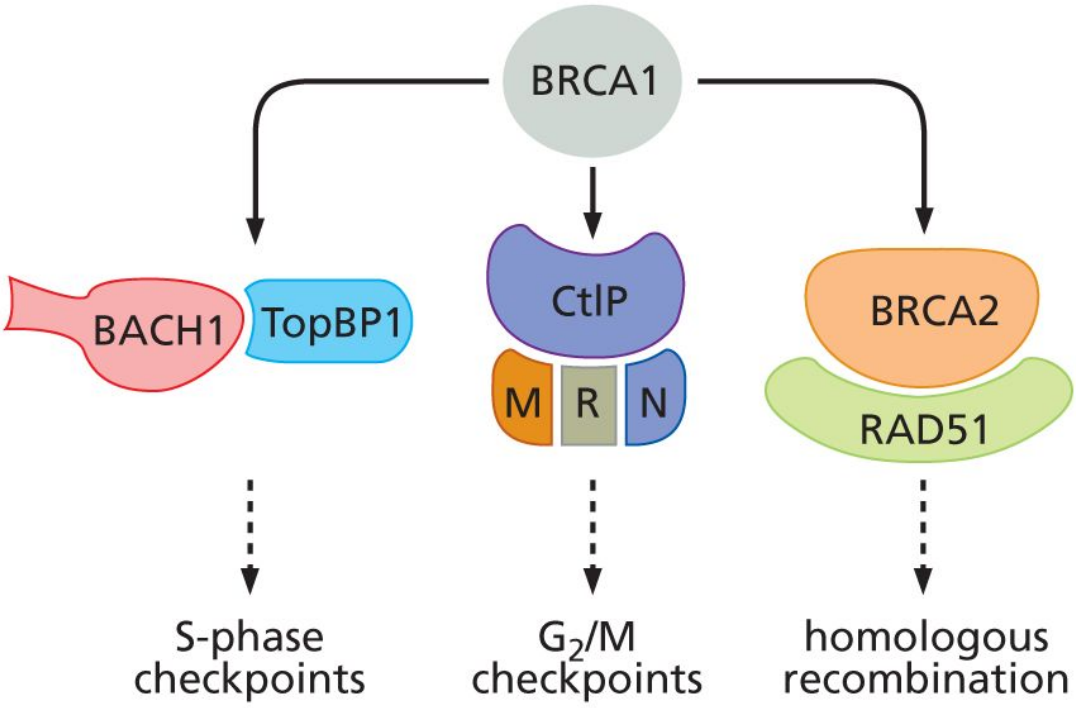
Figure 12.30 Homology-directed repair The repair of dsDNA breaks during the late S phase and G_2 phase of the cell cycle often depends on the ability of the repair apparatus to consult the sequences in the undamaged sister chromatid that was formed, together with the damaged chromatid, during the most recent S phase. Such homology-directed repair (HDR) begins (*top*) with the resection (removal) by an exonuclease of one of the two DNA strands at each of the ends formed by a dsDNA break. Each of the resulting ssDNA strands (*blue, red*) then invades the undamaged sister chromatid, whose double helix (*green, gray*) has been unwound by the repair apparatus in order to accommodate the pairing of the invading ssDNA strands with complementary sequences in the undamaged sister chromatid. The ssDNA strands from the damaged chromatid are then elongated in a 5′-to-3′ direction by a DNA polymerase, using the strands of the sister chromatid's DNA as templates. Thereafter, the extended ssDNA strands are released from the sister chromatid and caused to pair with one another, allowing further elongation by a DNA polymerase and a ligase, which together reconstruct a double helix possessing wild-type DNA sequences. Included among the DNA repair proteins known or thought to facilitate these complex steps of HR are RAD51, BRCA1, and BRCA2.

All types of HR are compromised in cells lacking either BRCA1 or BRCA2 function. This compromised function may be explained, in part, by the behavior of the RAD51 protein, with which BRCA1's partner, BRCA2, associates directly (**Figure 12.31A**). RAD51 is known to bind single-stranded DNA molecules, enabling them to invade (and thereby unwind) homologous double-strand helices, a process essential to initiating HDR (see Figure 12.30). [BRCA2 carries eight "BRC domains," each of which can, in principle, bind a RAD51 molecule, suggesting that BRCA2 assembles strings of RAD51 molecules that bind coordinately to an ssDNA strand.] In the absence of BRCA1 or BRCA2, RAD51 may not be properly recruited to sites of dsDNA breaks, and the subsequent steps of HR are unlikely to occur correctly. The triradial and quadriradial chromosomes that are encountered in the metaphase of *BRCA2*-mutant cells (see Figure 12.29) are manifestations of the inability of the repair apparatus in these cells to exploit HDR to fix dsDNA breaks.



A structural schematic of a protein complex. B R C A 1 forms the horizontal spine of the structure, with a RING domain, an N L S domain, and two B R C T domains. Alongside the B R C A 1, running from the RING domain to the N L S domain, is a B A R D 1, with its own RING domain, an ankyrin domain, and a B R C T domain. Attached to the B R C A 1 between the RING and N L S domains is a complex of ten proteins, namely RAD 50, N B S 1, M R E 11, A T M, C H K 2, X, Y, and Z. Attached to the B R C A 1 between the N L S domain and the first B R C T domain are a P A L B 2 and a B R C A 2. The latter has a long tail of B R C domains, each with a RAD 51 attached. Also attached to the B R C A 1 between the N L S domain and the first B R C T domain are a series of six phosphate groups, beginning at position 988. A seventh phosphate group is attached to the B R C A 1 between its two B R C T domains. Attached to this phosphate, in turn, is a B A C H 1 that has a Top B P 1 attached to it. Also attached directly to the B R C A 1 between its two B R C T domains is a C t l P protein.

(A)



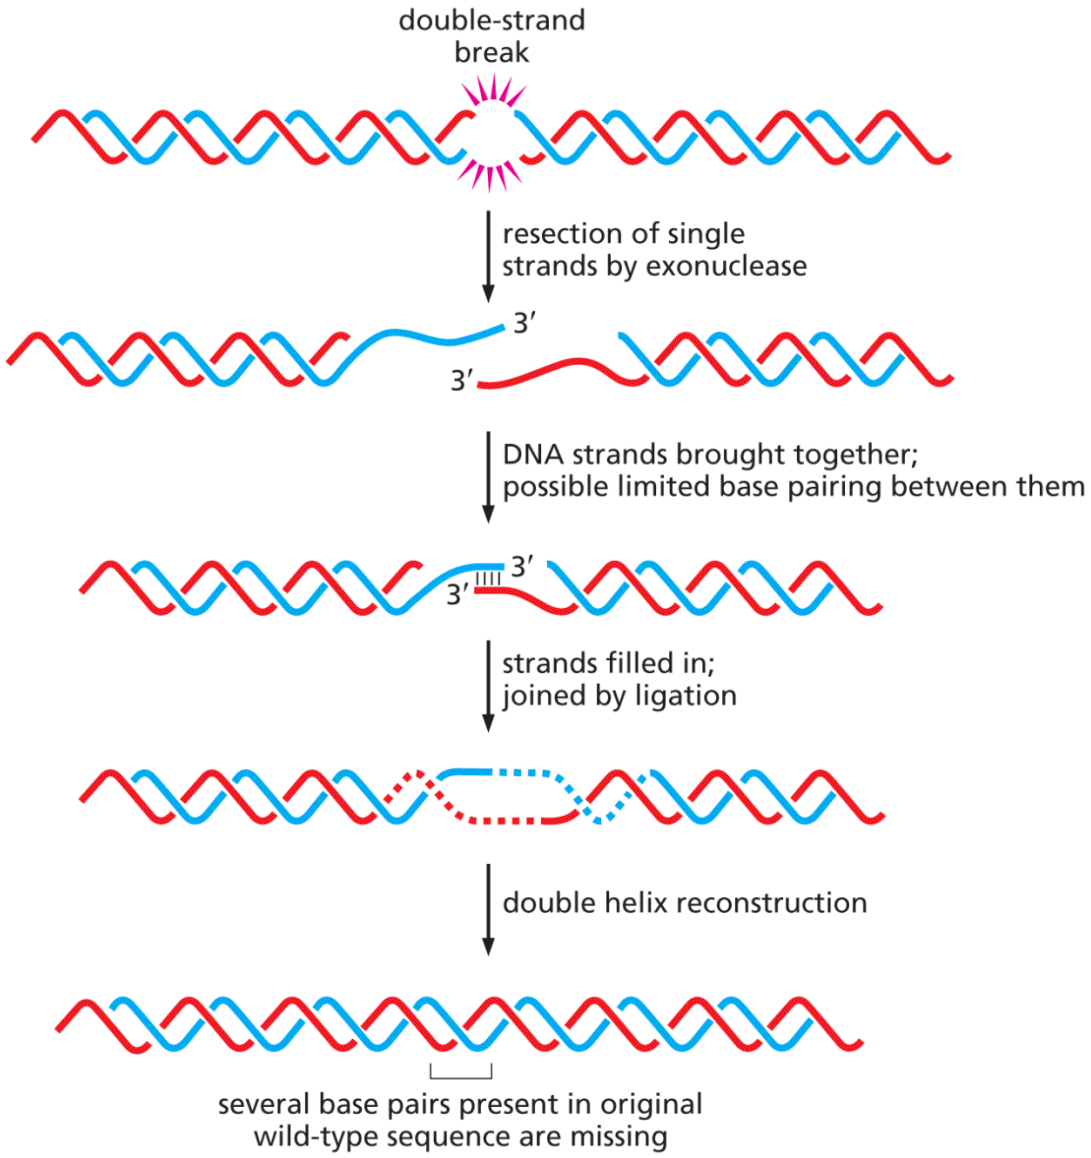
A diagram illustrating the central role of B R C A1. It interacts with the B A C H 1 Top B P 1 complex to regulate S-phase checkpoints; it interacts with a C t l P, RAD 50, N B S 1, and M R E 1 complex to regulate G2 slash M checkpoints; and it interacts with the B R C A 2 RAD 51 complex to regulate homologous recombination.

(B)

Figure 12.31 BRCA1, BRCA2, and their partners (A) The BRCA1 and BRCA2 proteins act, at least in part, as scaffolds to assemble a cohort of other DNA repair proteins into large physical complexes. Once assembled, these multiprotein complexes aid in the repair of dsDNA breaks, usually via homology-directed repair (HR). For example, one exon of the *BRCA2* gene encodes eight copies of a "BRC domain"; these aid in the recruitment of multiple RAD51 molecules, which form filaments and coat ssDNA strands as part of the HR process illustrated in Figure 12.30. The MRN complex, composed of MRE11, RAD50, and NBS1, appears to recognize the end created by a dsDNA break and to activate ATM kinase function in response. BRCA1 acts in different situations and locales (see panel B) as a scaffold for a variety of alternative partners, not all of which are concomitantly bound to BRCA1; for this reason, this image depicts a single complex that never exists in a living cell. Moreover, this image does not capture the full complexity of BRCA1-associated proteins. For example, in the

hydroxyurea-induced nuclear spots containing stalled replication forks (see Figure 12.28A), additional proteins have been discovered beyond those depicted, including MDC1, RPA32, γ-H2AX, RNF8, RNF168, 53BP1, FANCD2, and FANC1. (B) The loss of different partners of BRCA1 specifically affects different checkpoint controls in the cell cycle, in addition to compromising the processes of homologous recombination and homology-directed repair (HR). These interactions illustrate the central role that BRCA1 plays as a scaffolding for a diverse array of proteins mediating a variety of processes involving DNA function. The checkpoint controls ensure that a cell halts before either S or M phase of the cell cycle if its genome carries significant unrepaired lesions, such as DSBs (see Figure 8.4). (A and B, courtesy of R.A. Greenberg and D.M. Livingston.)

Homology-directed repair is also defective in patients suffering from Nijmegen breakage syndrome (see Table 12.1). Their cells, which lack the NBS1 protein (nibrin; see Figure 12.31A), fail to execute the initial steps of HDR and resort instead to fusing two dsDNA ends via the process termed nonhomologous end joining (NHEJ; **Figure 12.32**). NHEJ is inevitably an error-prone process, simply because the alignment between the two DNA segments being fused is not informed by the corresponding wild-type DNA sequences present in a sister chromatid. Consequently, the resulting end-to-end fusions generate mutant sequences at the site of joining, which appear to be responsible for the high rates of hematopoietic malignancies in patients suffering from Nijmegen breakage syndrome. Mice that are defective for one or another component of the NHEJ machinery and that also lack p53 function develop lymphomas at extremely high rates.



The process of Nonhomologous end joining. Initially there is a break in a double-stranded D N A. After resection of single strands by exonuclease, each side of the break has a longer 3 prime end than 5 prime end. The two 3 prime ends are brought together, possibly with limited base pairing between them. The gaps remaining in both strands are filled in and joined by ligation. Finally, the double helix is reconstructed. However, several base pairs present in the original wild-type sequence are now missing.

Figure 12.32 Nonhomologous end joining NHEJ is used to restore a DNA double helix following a double-strand break when the nucleotide sequences from a sister chromatid are not available to instruct the repair apparatus how these ends should be properly joined (see Figure 12.30). In NHEJ, the resection of single strands from both broken ends results in ssDNA overhangs that can then be joined

to one another, possibly by a limited degree of base pairing between them; three base pairs are shown here. The subsequent filling in of single-strand gaps and the ligation of any remaining ssDNA breaks results in the reconstruction of a double helix that lacks some of the base pairs that were present in the original undamaged DNA helix. (Adapted from M.R. Lieber et al., *DNA Repair (Amst.)* 3:817–826, 2004.)

Interestingly, NHEJ occurs largely in the G_1 phase of the cell cycle, when sister chromatids (formed during S phase and segregated to different daughter cells during mitosis) are not available to support HDR. NHEJ is virtually unique among the DNA repair processes because it plays a role in a normal, physiological function unrelated to repairing DNA damage, namely, the normal process of gene rearrangement that leads to the formation of functional antibodies and T-cell receptors. For example, the formation of the DNA sequences encoding antigen-binding domains depends on the rearrangement and fusion of chromosomal V, D, and J DNA segments (see Section 15.5). In the absence of the full complement of repair proteins needed for NHEJ, such DNA segment fusions cannot occur. This results in the inability to make proper immunoglobulin (antibody) molecules and T-cell receptors, compromising both the humoral and cellular arms of the adaptive immune system described in Chapter 15 and creating the syndrome of severe combined immunodeficiency (SCID).

To return to BRCA1/2, it is still unclear precisely how these two proteins contribute to the maintenance of normal chromosomal structure and thereby ward off cancer. Because BRCA1 and BRCA2 can bind to so many distinct nuclear proteins, many involved in DNA repair (see Figure 12.31A), it appears that these two act, at least in part, as a molecular scaffolding that helps to assemble large complexes of these other proteins and coordinate their actions. Once assembled, these various repair proteins presumably collaborate in fixing lesions, largely double-strand breaks, in the DNA. Altogether, as many as 215 distinct proteins have been found to associate with BRCA1 in multiple combinations and permutations, some of which are implicated in various aspects of DNA repair beyond its much-studied role in HR. For example, as Figure 12.31B illustrates, loss of BRCA1 can cripple certain cell cycle checkpoint controls that normally respond to damaged DNA and halt progress through this cycle until the damage is repaired.

We also do not know why inheritance of mutant alleles of the *BRCA1* and *BRCA2* genes leads preferentially to cancers of the breast and ovary, or why somatic mutation of *BRCA2* is occasionally associated with prostate and colon carcinomas. In addition, the penetrance of *BRCA1*- and *BRCA2*-mutant germ-line alleles (that is, the degree to which each allele exerts an observable effect on phenotype) has also been difficult to quantify (**Sidebar 12.8**). Beyond their well-defined roles in DNA damage repair,

BRCA1 and BRCA2 have additional biochemical functions, the disruption of which contribute to tumor formation as well (**Supplementary Sidebar 12.9**).

Sidebar 12.8 Ethnic groups with unusual histories are valuable for studying the penetrance of mutant *BRCA1* and *BRCA2* germ-line alleles

The precise effects of mutant *BRCA1* and *BRCA2* germ-line alleles on cancer risk have been difficult to gauge because both of these genes are very large and the detection of germ-line mutations in their reading frames is made correspondingly difficult. Moreover, many hundreds of mutant germ-line alleles of these genes have been cataloged in the human population, each having its own penetrance, that is, its relative ability to induce clinical disease in a person carrying it in the germ line. Each of these variant alleles operates in the complex genetic background of an individual, and this background also influences disease development; together these two dimensions of variability (the particular *BRCA1/2* mutation and the genetic background) make it almost impossible to gauge with any precision the disease penetrance of most of these alleles.

Many of these mutant alleles are of ancient vintage, having entered into the human gene pool hundreds, even thousands of years ago. Once present, many have been retained in the gene pool because they usually induce disease long after reproduction has occurred and are therefore not rapidly eliminated by Darwinian selection.

The peculiar histories of certain ethnic groups often simplify these analyses. For example, Ashkenazic Jews, who derive from Central and Eastern Europe, descend from a Jewish population of several million that lived in the late Roman Empire. Genetic analyses suggest, however, that the modern population derives from a founding population of only several hundred or so individuals who lived during the last days of this period. This genetic history seems to explain why this population harbors essentially only three mutant *BRCA1* and *BRCA2* germ-line alleles, all of ancient origin, which in aggregate are carried by some 2.5% of contemporary Ashkenazim. These three "founder mutations" contrast with the situation in the general population, in which more than 1500 distinct inherited alleles of *BRCA1* have been reported (a small portion of which may be functionally neutral polymorphisms). Each of these other alleles has been detected by arduous sequence analysis.

These facts explain why the detection of mutant germ-line alleles of the *BRCA1* and *BRCA2* genes in the Ashkenazic population is relatively simple: polymerase chain reaction (PCR)–based DNA primers can be designed that are focused specifically on the detection of only these three alleles, rather than on the countless others that have been reported to date. The most common Ashkenazic *BRCA1* allele, for example, is the *BRCA1 185delAG* allele, which, as its name indicates, involves the deletion of two

nucleotides; this mutant allele was found to be carried by 4.2% of women from this population who presented with invasive breast cancer in a New York City cancer clinic. Further studies revealed that the three mutant alleles conferred comparable risks of invasive breast cancer, which exceeded 80% by the time carriers of one or another of these alleles reached the age of 80.

Provocatively, the risk of developing breast cancer by the age of 50 among carriers of the *185delAG* mutation who were born before 1940 was 24%, whereas this risk was 67% among those carriers born after 1940. This indicates that nongenetic factors play a major role in cancer development, even in those born with a heritable DNA repair defect. (In the case of mutant alleles of *BRCA1*, changes over the past half century in nutrition and reproductive practices may have played major roles.) In addition, this type of epidemiology reveals the power of studying the biological effects of a single mutant allele operating in the context of variable genetic background and lifestyle changes.

OceanofPDF.com

Glossary

illegitimate recombination
: Process of recombination between two DNA molecules in which the two participating molecules do not share significant sequence identity. *Also called* **illegitimate recombination**.

nonhomologous end joining
: Type of DNA repair consisting of fusion of two dsDNA ends, in which the precise joining of the two ends is not informed or directed by sequences present in a normal sister chromatid or homologous chromosome.

penetrance
: Extent to which an allele of a gene can or cannot influence phenotype, e.g., the likelihood that a germ-line allele will or will not induce a clinical phenotype in a carrier of this allele. *See also* **expressivity, incomplete penetrance**.

conditional
: Referring to a phenotypic state or genetic change that only occurs under certain conditions, often in response to physiological signals or those induced experimentally. *See also* **constitutive**.

founder effect
: Phenomenon in which multiple individuals within a species, often not known to share any genealogical relationship with one another, are found to carry a common germ-line allele that testifies to their actual descent from a common ancestor that bore the allele.

12.10 The karyotype of cancer cells is often changed through alterations in chromosome structure

More than a century intervened between the discovery of aberrant karyotypes in cancer cells and the period when subtleties of DNA damage and repair, such as those described above, came to light. The triradial and quadriradial metaphase chromosomes seen in cells lacking BRCA1 or BRCA2 function are examples of these aberrations (see Figure 12.29). Stepping back for a moment from these particular aberrations, we can recognize that two distinct classes of karyotypic abnormalities can be seen in cancer cells: changes in the *structures* of individual chromosomes and changes in chromosome *number* that have no effect on chromosome structure.

One frequent deviation from the normal diploid karyotype involves an increase or decrease in the number of specific chromosomes. On occasion, through various accidents occurring during mitosis, cancer cells may acquire polyploid genomes, where an additional haploid complement of chromosomes is acquired (leading to a triploid state) or even an extra diploid complement of chromosomes is acquired (leading to a tetraploid state). Alternatively, extra copies of individual chromosomes may be present, or, less commonly, a chromosome copy may be missing.

The term aneuploidy is usually reserved for a deviation from a normal (or euploid) karyotype that involves changes in chromosome *number*. In recent years, however, use of the term aneuploid has occasionally been broadened to include changes in the *structures* of individual chromosomes, which are prevalent in cells of the great majority (>85%) of solid tumors; a more specific term is “chromosomal aberration,” which we will use here. These two major types of karyotypic alteration arise through fundamentally different mechanisms.

Changes in chromosome number are discussed in the next section. Here, we review the mechanisms responsible for changes in chromosome structure, some of which we have already encountered at various points in this text. For example, as we saw in the previous section, unrepaired dsDNA breaks, many of which occur accidentally at DNA replication forks, are thought to be a major source of chromosomal translocations.

In addition, far earlier (see Chapter 4) we learned of a class of cancer-associated chromosomal alterations as part of a discussion of the mechanisms leading to the creation of the *MYC* and *BCR-ABL* oncogenes. Recall the well-studied case of the

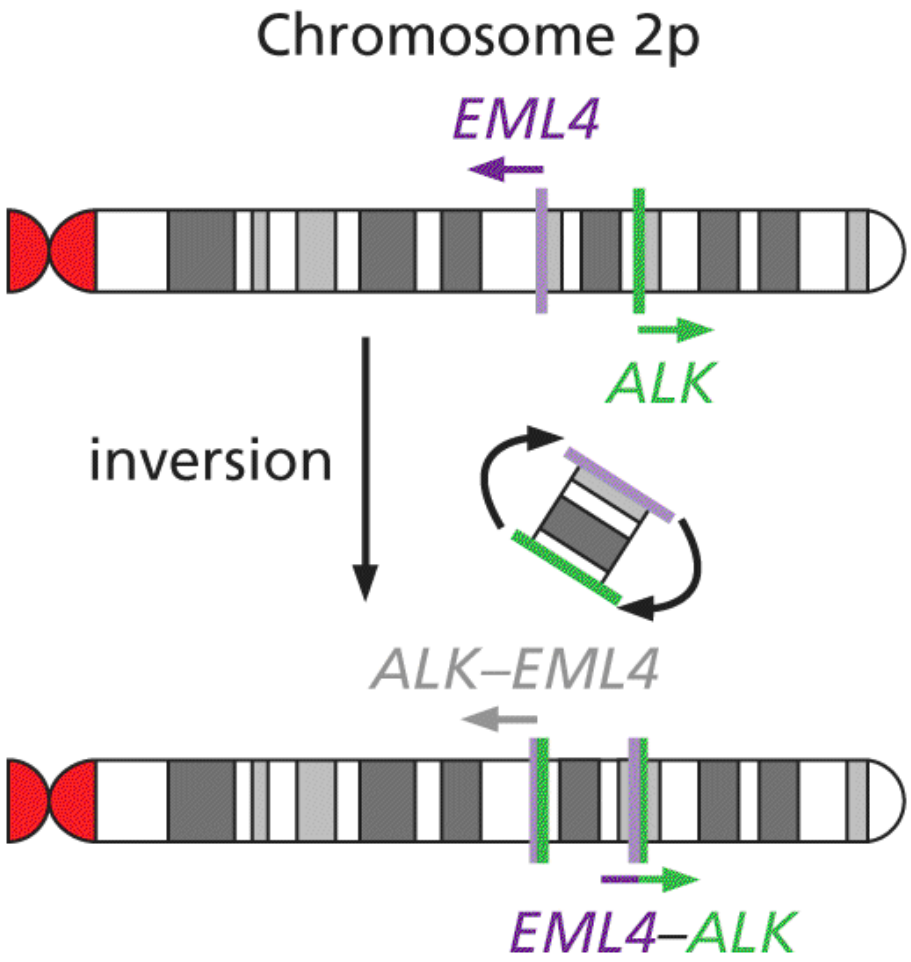
translocations that fuse the *myc* proto-oncogene to promoter/enhancer sequences deriving from one of three alternative immunoglobulin genes (see Section 4.4). In these and other lymphomas, it is likely that the complex machinery dedicated to rearranging the immunoglobulin and T-cell receptor (TCR) genes misfires. Instead of rearranging the immunoglobulin or TCR gene sequences (see Section 15.5), this machinery inadvertently catalyzes inappropriate interchromosomal recombination events that join the immunoglobulin genes promiscuously with sequences scattered throughout the genome, the *myc* gene being only one of them. Those rare translocations that happen to involve the *myc* proto-oncogene and deregulate its transcription seem to confer special proliferative advantage on cells, resulting in the appearance of cell clones and ultimately lymphomas that carry these very characteristic karyotypic alterations.

The first characterized translocations were documented in a variety of hematopoietic malignancies (see, for example, Tables 4.4 and 4.5), largely a result of the ease of carrying out karyotype analyses of cells derived from these tumors. Although many mechanisms likely contribute to the formation of structurally aberrant chromosomes, one well-studied mechanism was presented in Chapter 10, where we read about telomere collapse resulting in breakage–fusion–bridge (BFB) cycles (see Figure 10.9). These cycles create large-scale aberrations in the structures of individual chromosomes, apparently striking all chromosomes with comparable frequency. On occasion, translocations may generate fusion genes and other rearrangements that provide proliferative advantage to the cells carrying them, which one imagines results in the clonal outgrowth of these cells. Below we consider another disruptive process—chromothripsis (or chromosome shattering)—in which a limited stretch of a chromosome undergoes massive fragmentation with subsequent rejoining of the resulting fragments.

With the advent of high-throughput DNA sequencing technologies (see Section 12.12), genome-scale analyses of human cancers have increased dramatically. In addition to the discovery of more subtle mutations (base alterations or small insertions and deletions), many larger-scaled alterations have also been detected across virtually all cancer types. Many of these are termed recurrent because they have been seen on multiple occasions in a series of independently arising human tumors; as described in Section 11.6, these alterations are considered to be “driver mutations” and the affected genes “drivers.” By now, hundreds of these recurrent translocations have been cataloged in hematopoietic and solid tumors. Because recurrent translocations map to highly specific chromosomal sites, it would seem that the molecular mechanisms creating them are distinct from the breakage–fusion–bridge cycles cited above, which appear to act totally randomly via BFB cycles in generating fused chromosomal segments.

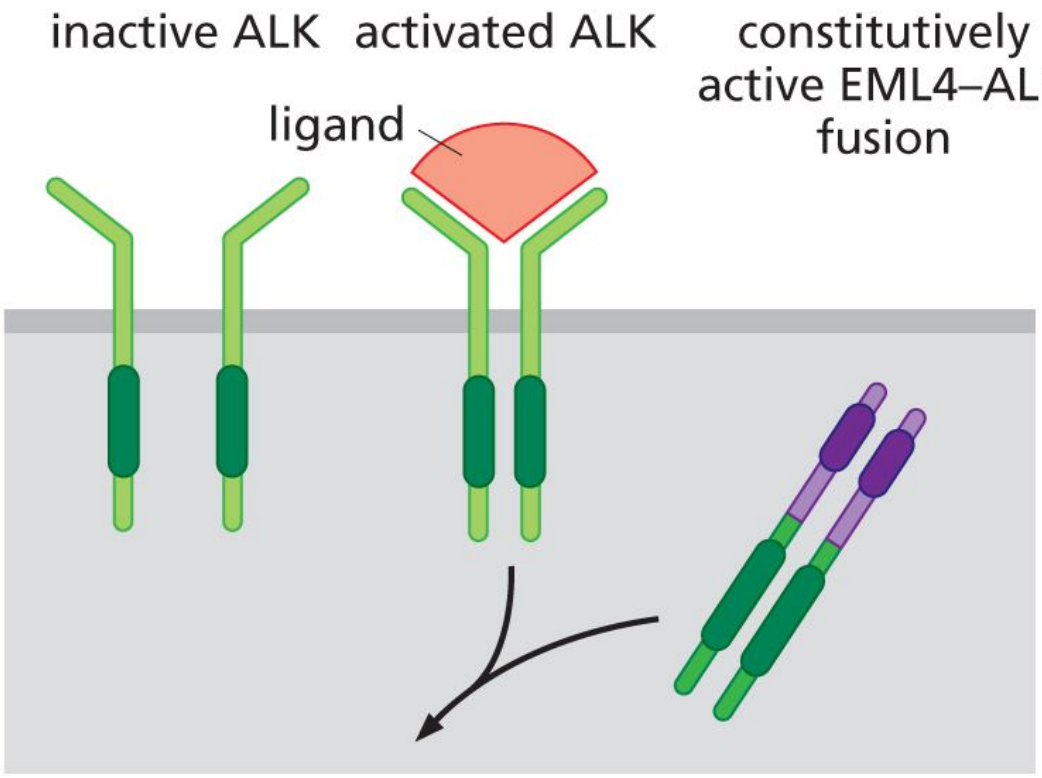
Chromosomal translocations were thought for many decades to be present uniquely in hematopoietic tumors, as discussed above. However, beginning in 2000, the availability of new DNA sequencing strategies, the resulting sequencing of the human genome, and new bioinformatics tools began to reveal chromosomal translocations and other chromosomal aberrations, some quite common, in solid tumors. For example, in 2005, a specific recurrent translocation, involving a gene encoding an androgen-regulated serine protease and an ETS transcription factor, was discovered. This particular translocation (*TMPR32/ERG*) is now known to be present in the tumors of ∼50% of the patients bearing localized prostate carcinomas, and translocations involving *TMPR32* and other *ERG*-related transcription factors bring the total to ∼70%. These discoveries in a commonly occurring human carcinoma triggered surveys of a variety of solid tumor genomes and a spate of additional discoveries, many of them driven by the powerful new genome sequencing technologies.

In another example, approximately 5% of non-small-cell lung adenocarcinomas express a fusion oncoprotein termed EML4-ALK, which is the product of an intrachromosomal inversion and fusion event. In particular, this inversion event fuses the EML4 protein's N-terminal domain to the tyrosine kinase domain of the ALK RTK, leading to constitutive activation of its kinase function and uncontrolled proliferative signaling (**Figure 12.33**). Like the fusion proteins described in Figure 5.12, this particular one causes constitutive receptor activation, in that the trimerization domain of EML4 drives formation of oligomerized ALK kinase domains. This chromosomal event also places the fusion gene under the control of the *EML4* promoter. In these lung carcinomas, this EML4-ALK fusion is seen to be mutually exclusive with activating mutations of the EGF receptor, indicating that it is likely to function similarly in the transformation process. Interestingly, the kinase function of ALK is also activated in several hematopoietic malignancies via chromosomal translocation events. More generally, comprehensive genomic analyses of many tumor types have revealed that chromosomal translocations and other aberrations occur at greatly differing frequencies among various solid tumors (**Figure 12.34**). The functional rationales that would explain these tissue-specific associations remain elusive.



A chromosome 2p with a long E M L 4 segment on the centromere side, a long A L K segment on the free end, and a short segment between the two. During chromosomal inversion, this short segment flips end over end and is reinserted in the same location. Now the segment on the centromere side is labeled A L K–E M L 4, and the segment on the free end is labeled E M L 4–A L K.

(A)

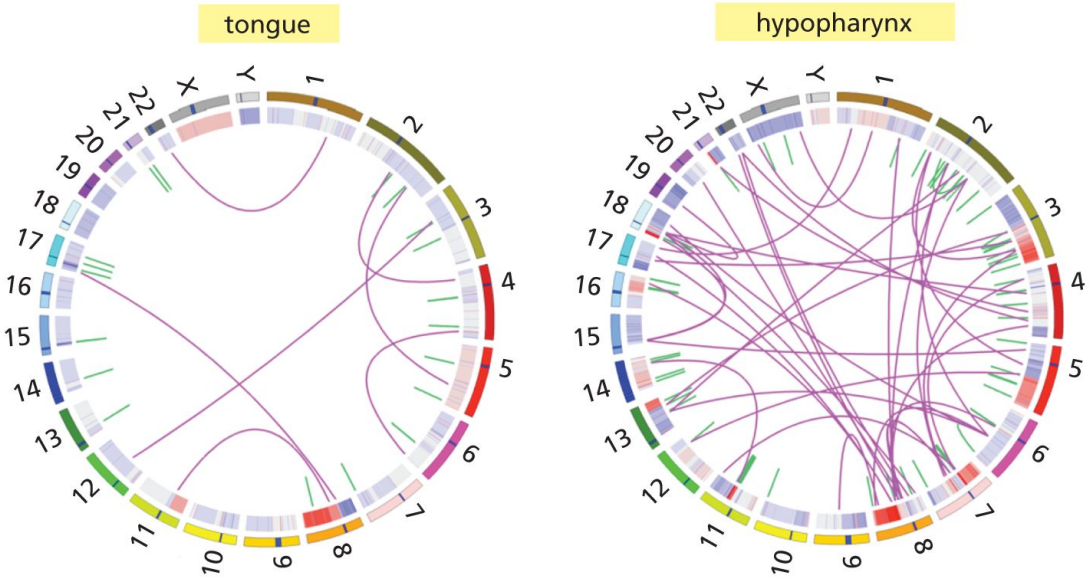


An initially inactive A L K receptor dimerizes when bound by a ligand and is now active. Also shown is a dimerized protein with two parallel green ends, similar to the A L K receptor's ends, and two parallel purple ends. This proteir is labeled constitutively active E M L 4–A L K fusion. This protein and the active A L K receptor both contribute to signal transduction, as shown by two black arrows that merge into one.

(B)

Figure 12.33 Chromosomal inversion produces a fusion oncogene A subset of lung adenocarcinomas carry the EML4–ALK fusion oncogene, which is formed by a chromosomal inversion event. (A) The *EML4* (*purple arrow*) and *ALK* (*green arrow*) genes are oriented in opposite directions on the p arm of Chromosome 2. Following the chromosomal inversion event, the promoter and 5′ exons of EML4 are fused to the 3′ exons of ALK, including exons encoding the kinase domain, forming the EML4-ALK fusion. (B) The wild-type ALK protein is a receptor tyrosine kinase that is normally expressed in cells of the nervous system and not in the adult lung. Binding to its ligand leads to homodimerization and activation of the kinase domain (*indicated by the dark green bars*), leading to signal transduction (*forked black arrow*). Under control of the *EML4* promoter, which is transcribed in the lung, the EML4-ALK fusion protein is expressed in lung cancer cells. The dimerization domain of the EML4 protein (*dark purple bars*) permits

unregulated dimerization of the tyrosine kinase domain of the fusion protein, constitutively activating downstream signaling pathways and contributing to oncogenesis. (From J.N. Rosenbaum et al., *Mod. Pathol.* 31: 791–808, 2018. With permission from Nature.)

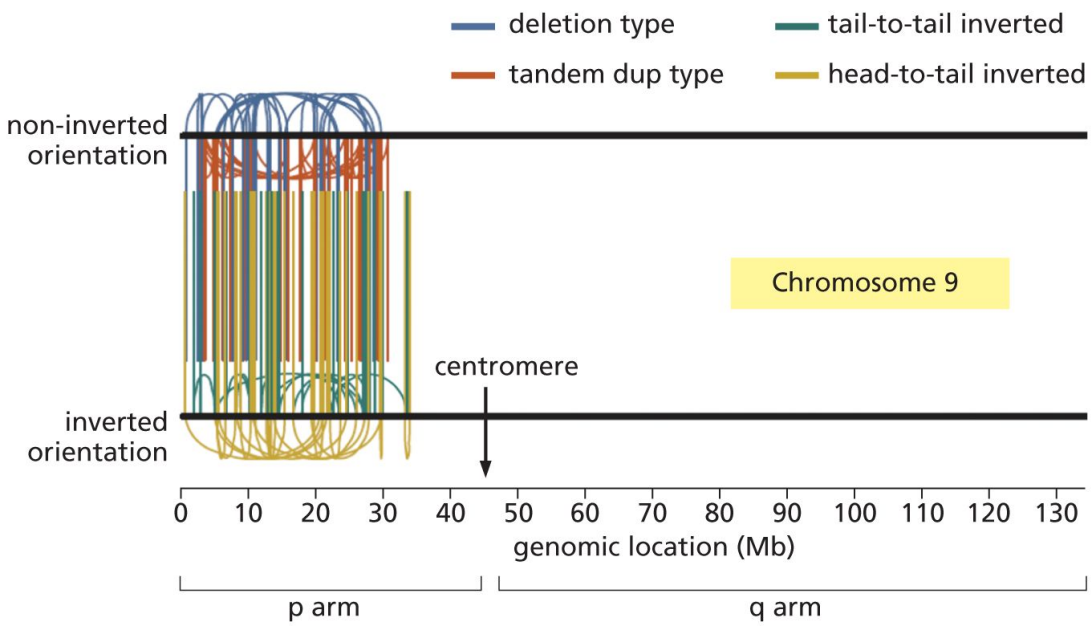


Two Circos plots, one for the tongue and one for the hypopharynx. Each plot is a circle with the human chromosomes listed clockwise around the outside, starting with 1 and ending with X and Y. The one for the tongue records seven translocations, including two each involving chromosomes 2, 4 and 8. This plot also records 19 local rearrangements, including 3 on chromosome 17. The plot for the hypopharynx records at least 30 translocations between chromosomes and roughly 50 local rearrangements. Chromosome 8 is especially susceptible to translocations.

Figure 12.34 Chromosomal translocations in head-and-neck carcinomas of smokers This graphic convention of depicting chromosomal translocations places the chromosomes around a circle according to their number or letter (sometimes termed a Circos plot) with fusions between previously unlinked chromosomal segments depicted by purple lines. Short green ticks pointing toward the center of the circle indicate regions of local intrachromosomal rearrangements, including translocations, small amplifications, deletions, and inversions. The genomes of two head-and-neck squamous cell carcinomas (HNSCCs) of smokers—a tongue and a hypopharyngeal carcinoma—are depicted here. None of these translocations were associated with a recurrent translocation documented in other similar tumors. (With permission from N. Stransky et al., *Science 333*:1157-1160, 2011. With permission from AAAS.)

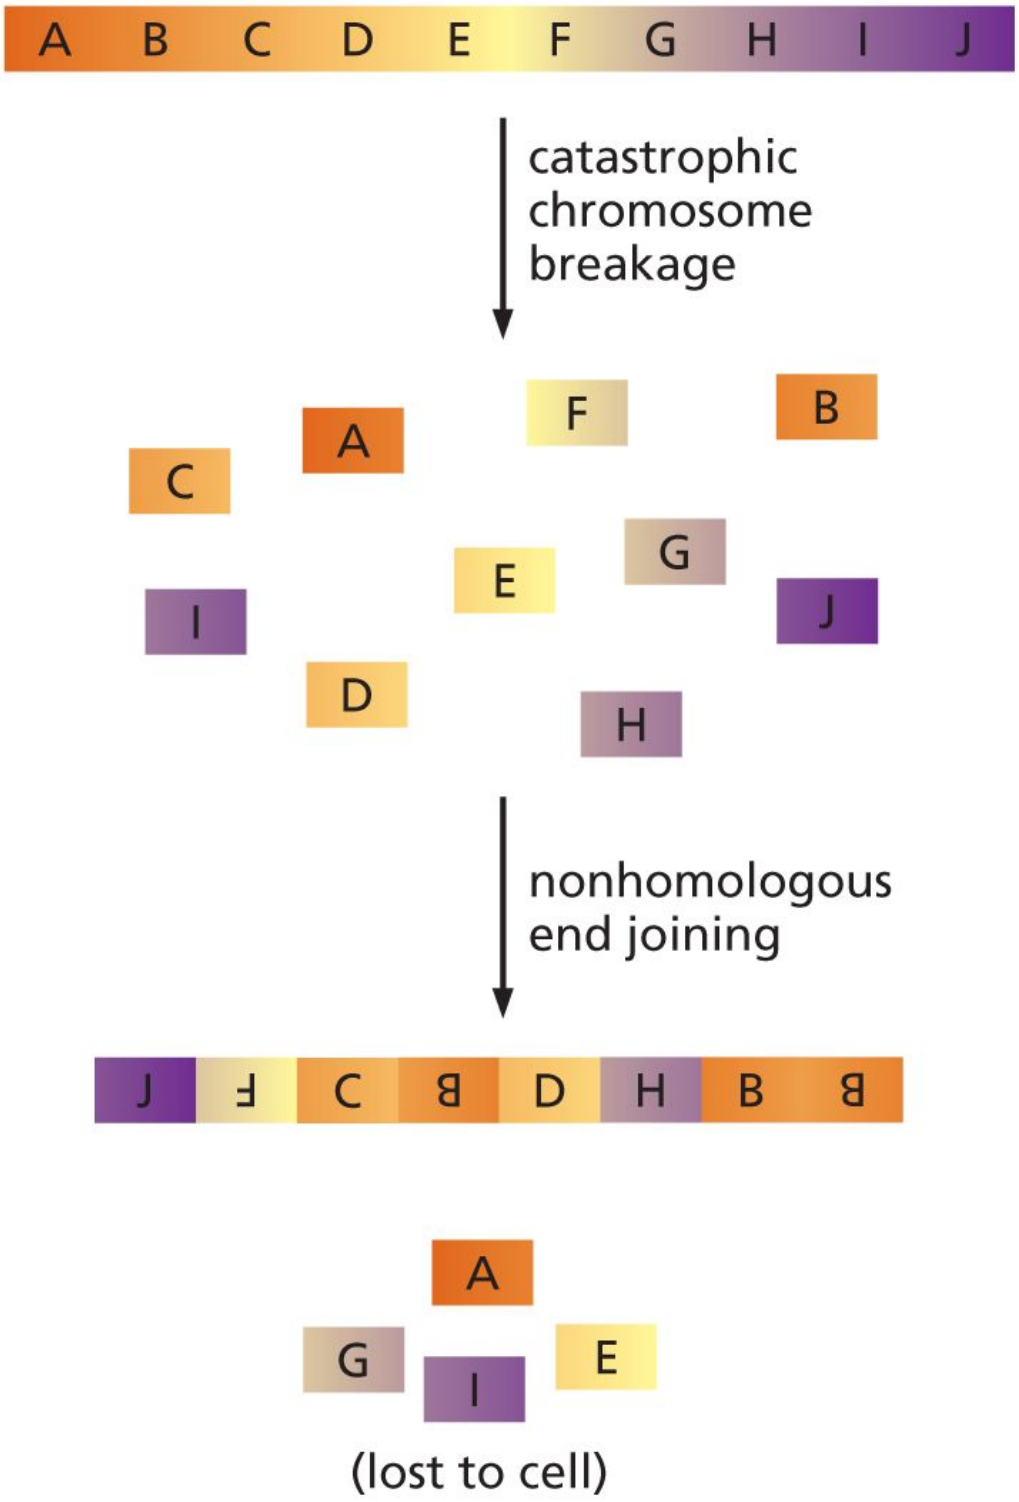
The enzymes involved in the rearrangement of immunoglobulin genes and T-cell receptor genes (see Section 15.5) are unlikely to be responsible for most of the commonly encountered translocations found in hematopoietic and non-hematopoietic tumors, simply because these enzymes are not expressed in the normal cells of origin of these diverse tumors. Hence, the molecular mechanisms responsible for these translocations are yet to be discovered. Sequence analyses of the DNA flanking translocation breakpoints have revealed duplications, deletions, and inversions of sequence blocs, findings that suggest but hardly prove the involvement of some type of "error-prone" DNA repair mechanism, such as the nonhomologous end joining (NHEJ) discussed earlier (see Figure 12.32).

Implementation of new DNA sequencing technologies led in 2011 to discovery of a totally novel type of aberration in the genomes of ~25% of bone cancers and a significant fraction of cancers overall—the localized firestorms of chromosomal rearrangements representing the chromothripsis cited earlier. In the example shown in **Figure 12.35**, a single catastrophic event seems to have shattered a limited stretch of the genome, followed by multiple rejoining events between the resulting fragments in an apparently random set of configurations. The mutational mechanism underlying such chromothripsis is still under active investigation. In some instances, at least, it appears to be the product of improper chromosome segregation during mitosis, leading to the formation of micronuclei surrounding mis-segregated chromosomes that are initially stranded in the cytoplasm after mitosis. The defective nuclear envelope structure of these micronuclei may be insufficient to guard the chromosome housed within from endonucleases that initiate the damage that results in chromothripsis. Telomere dysfunction and resulting breakage–fusion–bridge events (see Figure 10.9) have also been associated with the development of chromothripsis.



Many local errors on the p arm of human chromosome 9, nearly all between genomic locations 0 and 30 megabases. The errors are of four types: deletion type, tandem dup type, tail-to-tail inverted, and head-to-tail inverted.

(A)



An orderly sequence of letters, A through J, undergoes catastrophic chromosome breakage into 10 individual parts. After the B is duplicated twice, all three bees and 5 of the other letters combine in random order, some

upside down and some right side up. Four letters, A E, I and J, are lost to the cell.
(B)

Figure 12.35 Localized firestorms of chromosomal rearrangement The development of high throughput DNA sequencing technologies has made it possible to discover certain types of chromosomal damage that previously eluded detection. (A) In the genome of a thyroid carcinoma, a cluster of 77 distinct chromosomal rearrangements affecting the short arm of Chromosome 9 (i.e., 9p) have been documented. Each of the lines indicates the direct fusion of two DNA segments that are normally located at some distance from one another in this chromosomal arm; these rearrangements involve four distinct types of changes in DNA configuration listed *above right.* (B) The scheme illustrated here provides one explanation of how such a focally localized set of chromosomal rearrangements, which has been termed chromothripsis, may have arisen. According to one attractive model, the formation of single-chromosome-containing micronuclei results in individual chromosomes undergoing extensive intrachromosomal rearrangement prior to becoming reassociated with the larger complement of chromosomes during a subsequent mitosis. (From P.J. Stephens et al., *Cell* 144:27–40, 2011. With permission from Elsevier.)

To conclude, chromosomal aberrations and chromothripsis leave us with two major puzzles: (1) Which components of the DNA repair machinery are normally on guard to prevent the formation of these aberrations? (2) How do most of these chromosomal abnormalities, once formed, contribute functionally to cancer formation?

OceanofPDF.com

Glossary

polyploid
: Referring to a genome in which the entire haploid array of chromosomes is represented in copy numbers larger than two. *See also* **haploid**, **diploid**.

triploid
: Describing a karyotype or a genetic state having precisely three haploid complements of a chromosome, chromosomal array, or copies of a gene.

tetraploid
: Describing a karyotype having precisely four haploid complements (or two diploid complements) of chromosomes.

euploid
: (1) Referring to a collection of chromosomes that corresponds precisely in number and structure to the array present in normal, wild-type cells. (2) Describing a karyotype having such a complement of chromosomes. *See also* **karyotype.**

chromothripsis
: The presence of multiple chromosomal rearrangements usually limited to a single chromosomal region and suggesting the involvement of an initial catastrophic shattering of a chromosomal domain followed by rejoining of the fragmented segments in random order and orientation. *See also* **kataegis**.

aneuploid
: (1) Describing a karyotype that deviates from diploid because of increases or decreases in the numbers of certain chromosomes. (2) Less commonly, describing a karyotype that carries structurally abnormal chromosomes.

micronucleus
: (1) A small fragment of a nucleus that has its own nuclear membrane and results from certain aberrations in cell division or from damage inflicted on a cell; micronuclei often carry only a single chromosome and arise when this chromosome fails to be incorporated into the previously formed mitotic spindle, thereby escaping inclusion in the normal karyotypic array of a daughter cell. (2) Smaller of the two

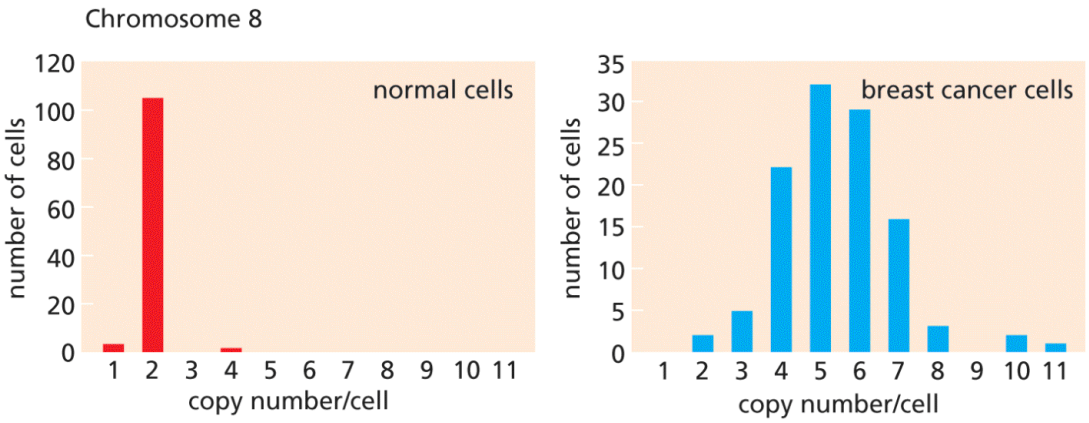
nuclei in many ciliate cells, which is used to carry and transmit the ciliate genome to progeny cells.

OceanofPDF.com

12.11 The karyotype of cancer cells is often changed through alterations in chromosome number

As stated earlier, some types of genetic instability affect karyotype by altering the *number* of individual chromosomes without affecting their structure. These changes create aneuploidy (in the usual sense of this term). Although the term “mutation” is often reserved for changes in DNA sequence (and thus includes changes in chromosome structure), we should recognize that alterations in chromosome number also represent significant changes in a genome that can have equally profound effects on cell behavior and are, strictly speaking, also a type of mutation. As discussed in Section 12.13 below, comprehensive cancer genome sequencing analysis has demonstrated that whole chromosome gains or losses are an almost-universal feature of solid tumors.

Changes in chromosome number are a feature of the carcinoma cells that are afflicted by the condition termed *chromosomal instability* (CIN). When CIN-positive cancer cells are removed from patients and propagated *in vitro*, the consequences of CIN become evident, for these cells continue to reshuffle their complement of chromosomes during subsequent propagation in the Petri dish. Such cancer cells were already quite aneuploid when they were removed from the patient, and their karyotypic instability seen *in vitro* is presumably only a continuation of the instability that existed *in vivo* during tumorigenesis (**Figure 12.36**).



Two histograms compare the number of copies of chromosome 8 in normal cells with the number in breast cancer cells. In the normal histogram, over 100 cells

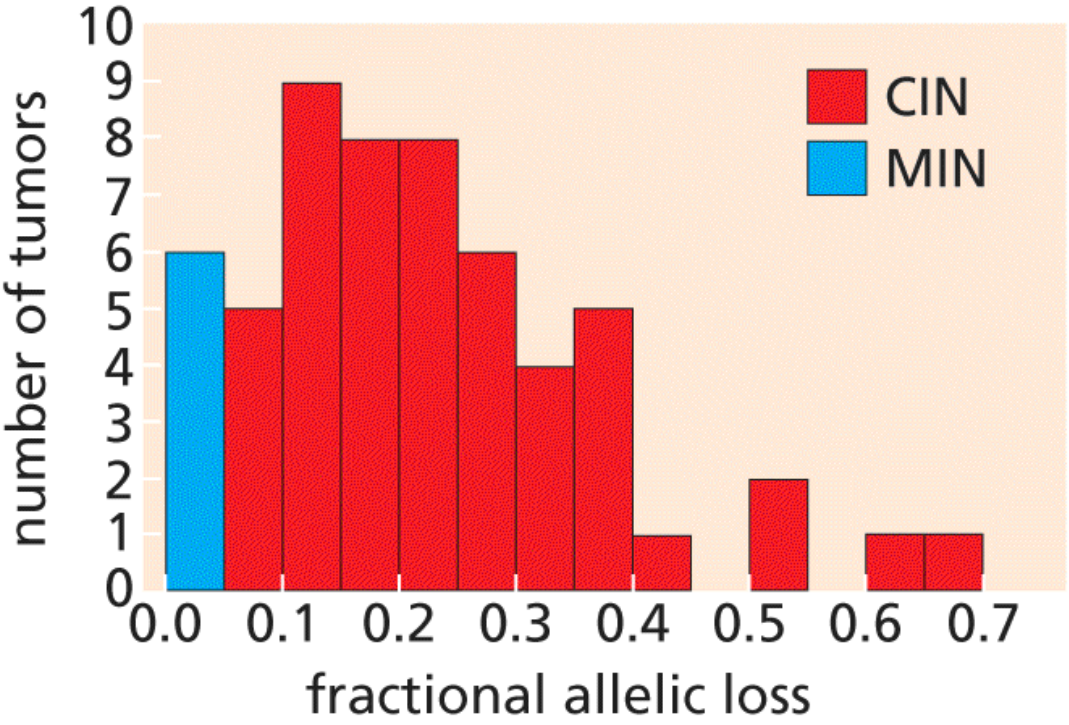
have 2 copies of chromosome 8, a few have just 1 copy, and even fewer have 4 copies. In the breast cancer histogram, the most common number of copies of chromosome 8 was 5, the number in over 30 cells. Just under 30 cells have 6 copies. The rest of the distribution tails downward like a bell curve. No cells have 9 copies, but there are a few that have 10 copies, outnumbering the cells with the normal 2 copies.

Figure 12.36 Chromosome instability in cultured cancer cells The copy number of Chromosome 8 was measured here using fluorescence *in situ* hybridization (FISH) in normal cells (*left*) and also in cultured breast cancer cells (*right*) that exhibited chromosomal instability (CIN). As indicated, almost all the normal cells had two copies of Chromosome 8, whereas the copy number of Chromosome 8 varied extensively in the cells with CIN. (An essentially identical distribution of chromosome copy number was observed upon study of a second, arbitrarily chosen chromosome.) This great cell-to-cell variability of chromosome number indicates that fluctuations of this number continue to occur frequently as these cancer cells are propagated in culture. (From G.A. Pihan et al., *Cancer Res*. 58:3974–3985, 1998. With permission from American Association for Cancer Research.)

The aneuploid karyotypes of cancer cells can be interpreted in two ways. One point of view portrays aneuploidy as a *consequence* of the general chaos that progressively envelops cancer cells as they advance toward highly malignant states. The other point of view ascribes a *causal* importance to aneuploidy, arguing that it is an essential component of tumorigenesis. Thus, some contend that most cancer cells require chromosomal instability during their development in order to scramble their genomes and arrive at chromosomal configurations that are more favorable for neoplastic growth. According to this second line of thinking, in the absence of the increased mutability associated with aneuploidy, most clones of incipient cancer cells could never succeed in acquiring all the genetic alterations needed to complete multi-step tumorigenesis.

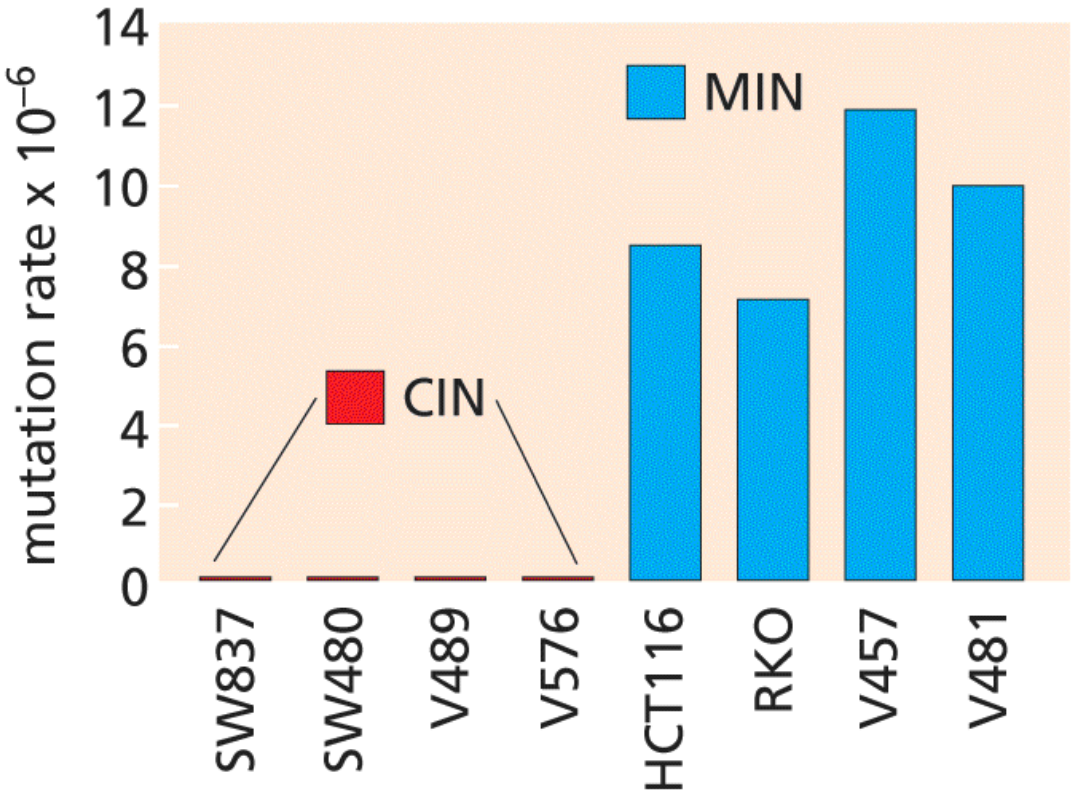
An important observation that will help settle this debate has come from the study of a series of human colon and rectal carcinomas. The few tumors that exhibit microsatellite instability (MIN) show relatively little aneuploidy and virtually no chromosomal instability (CIN). Conversely, the far more numerous tumors that have CIN are not prone to show nucleotide sequence alterations that are characteristic of MIN (**Figure 12.37**). Together, these observations suggest that, at least in the case of colorectal carcinomas, tumor cells must acquire increased mutability of their genomes and that either one or the other of these two mechanisms suffices to provide such mutability. This conclusion begins to persuade one that CIN, like MIN, is an effective mechanism for remodeling the cellular genome in a way that favors evolution toward neoplasia. (Of note, contrary to the depiction in Figure 12.37, CIN and MIN are not

always mutually exclusive states, and some tumors exhibit both types of instability concomitantly.)



A histogram that specifies the number of tumors exhibiting a fractional allelic loss, ranging from 0 to 0.7 in increments of 0.1. For all six M I N tumors, the fractional allelic loss is zero. All 50 C I N tumors exhibit some loss, ranging from 0.05 to 0.65. The most common allelic loss rate is 0.1, with 9 tumors.

(A)



A bar graph that specifies the mutation rate for 4 C I N cell lines and 4 M I N cell lines. The mutation rate is almost zero for the C I N cell lines, these being S W837, S W480, V489, and V576. The mutation rate is higher for the M I N cell lines, these being H C T116, R K O, V457 and V481. It ranges from 7 times 10 to the negative 6 to 12 times 10 to the negative 6.

(B)

Figure 12.37 Chromosomal instability vs. gene mutation The presence of chromosome instability (CIN) can be gauged by measuring the loss of alleles from chromosomal arms. (A) In the colorectal carcinomas studied here, analyses of a large number of tumors revealed that many lost heterozygosity (LOH; see Section 7.4) at a substantial number of chromosomal loci. On the *abscissa*, 0.3 allelic loss, for example, refers to tumors in which 30% of the loci that were previously heterozygous, as revealed by analyses of chromosomal markers, no longer exhibit heterozygosity (*red bars*). Most of this LOH is attributable to the loss of whole chromosomes. In contrast, among the tumors afflicted with microsatellite instability (MIN; *blue bar*), the loss of alleles and hence the loss of entire chromosomes is negligible. (B) In colorectal tumor cell lines that exhibit CIN, as gauged by the loss of chromosomal markers, the rate of inactivation of the HPRT (hypoxanthine phosphoribosyltransferase) gene is virtually zero (*first four bars*,

red). In contrast, in those that exhibit MIN, the rate of mutation of this gene is significant and is occasionally 100-fold higher than in CIN tumor cell lines (*last four bars*, *blue*). (A, from C. Lengauer, K.W. Kinzler and B. Vogelstein, *Nature* 396:643–649, 1998; and B. Vogelstein et al., *Science* 244:207–211, 1989. With permission from AAAS. B, from C. Lengauer, K.W. Kinzler and B. Vogelstein, *Nature* 396:643–649, 1998; and J.R. Eshleman et al., *Oncogene* 10:33–37, 1995. With permission from Nature.)

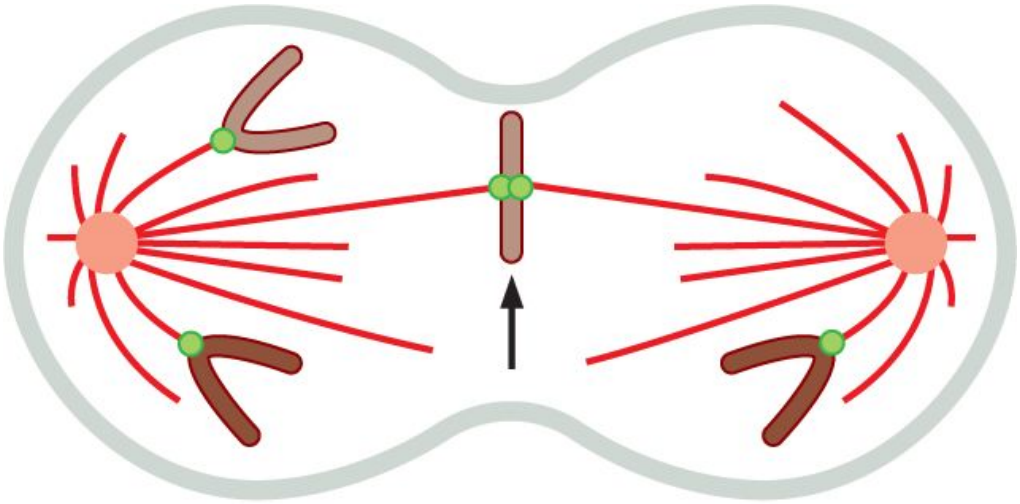
Whether this logic pertains as well to the genetic mechanisms creating hematopoietic malignancies remains unclear. Unlike carcinoma cells, which almost invariably exhibit widespread karyotypic chaos, hematopoietic tumor cells often exhibit karyotypes that are diploid, with the exception of one or two reciprocal translocations that seem to be responsible for initiating the cancer or triggering a specific step of tumor progression (for example, the one creating the *BCR-ABL* oncogene; see Section 4.5). Still, it is highly unlikely that the small number of observable karyotypic alterations found in most hematopoietic cancer cells suffice on their own to enable full neoplastic proliferation. (In one case—that of chronic myelogenous leukemia—the acquisition of the *BCR-ABL* oncogene is often followed during blast crisis relapse by the loss of p53 function; point mutations cause this loss, and they are, of course, karyotypically invisible.) Moreover, hematopoietic tumor cells have not been reported to suffer from microsatellite instability. It therefore remains unclear which genetic or epigenetic mechanisms enable hematopoietic cells to acquire the entire ensemble of neoplastic functions needed in order for them to proliferate as fully neoplastic cells. Indeed, we do not even know whether the formation of hematopoietic tumors requires as many genetic changes as those required for the formation of solid tumors (see Section 11.9).

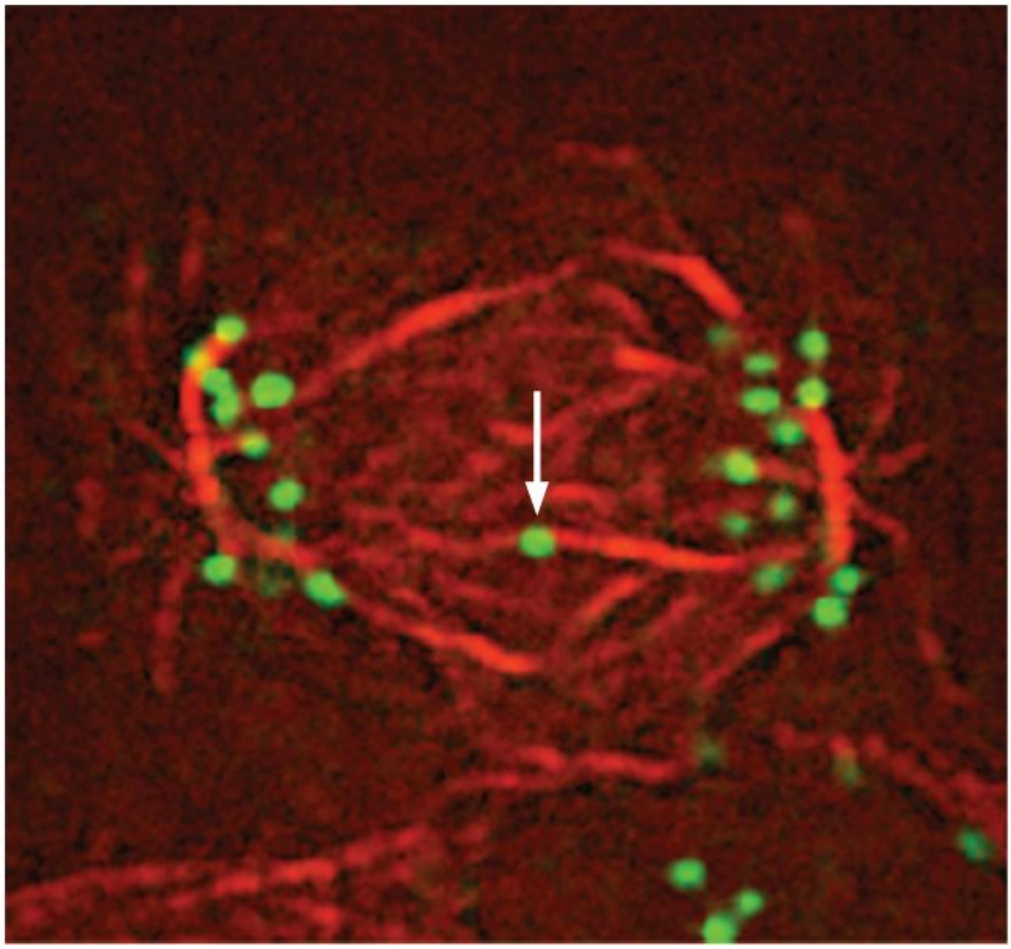
The changes in chromosome number that characterize chromosomal instability are usually (and perhaps always) the consequences of mis-segregation of chromosomes during mitosis. During the normal M phase of the cell cycle, the chromosomes line up in a plane, the metaphase plate, and associate with spindle fibers (see Figure 8.3A). The fibers together form a metaphase spindle, a bipolar structure in which each half spindle is constituted of microtubule fibers, many of which extend from the kinetochores on the chromosomes (the complex nucleoprotein bodies associated with the centromeric DNA segments of the chromosomes) back to the centrosomes; the latter are responsible for organizing the entire metaphase spindle structure. When this apparatus is working properly, the spindle fibers pull sister chromatid pairs apart, so that each chromatid moves toward one of the two centrosomes. This ensures that the two daughter cells that will eventually arise after cell division receive precisely equal allotments of chromosomes.

This complex process of chromosome segregation is monitored by a series of checkpoint controls, which ensure initially that precisely two centrosomes and two

half-spindles form; that each chromatid in a pair associates via its kinetochore with its own, distinct half-spindle; and that chromatid separation is not allowed to proceed unless and until all pairs of chromatids are properly aligned on the metaphase plate. When these checkpoint mechanisms fail to impose quality control on chromosomal segregation, both sister chromatids in a pair may be pulled to one or the other centrosome (the process of nondisjunction). As a consequence, one of the subsequently arising daughter cells may become haploid for this chromosome and the other triploid. Alternatively, a chromatid may fail to attach to a spindle fiber, may land in the cytoplasm of a daughter cell after the completion of M phase, and may nucleate the formation of a micronucleus as cited earlier; the single chromosome borne in the latter may rejoin the bulk of the chromosomes during the course of the next mitosis or, more frequently, disintegrate and thus fail to contribute to the chromosomal array of descendant cells.

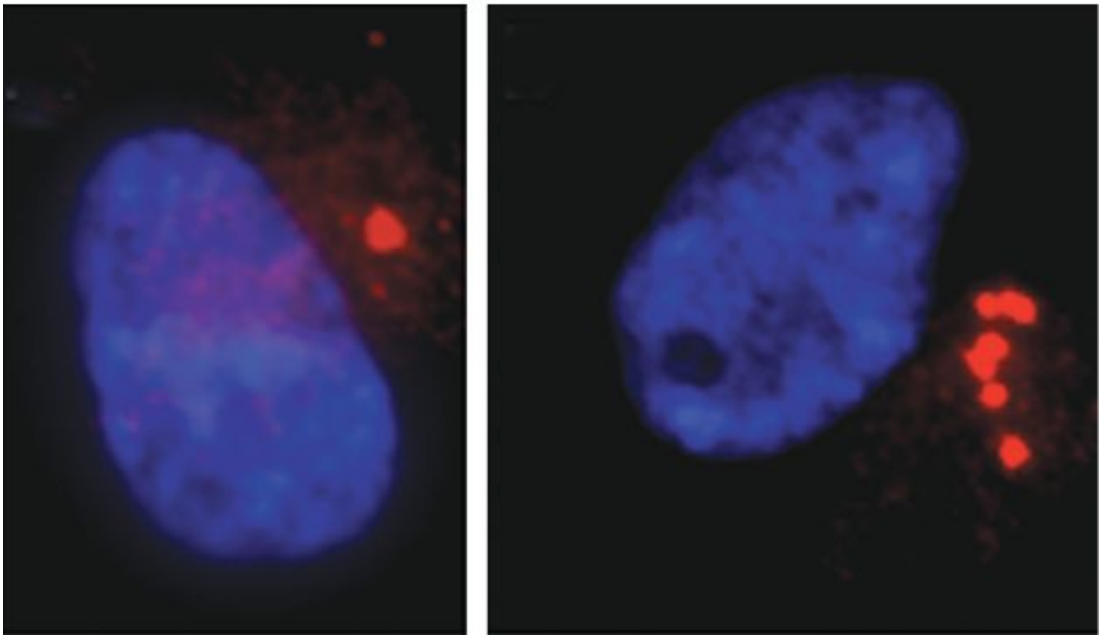
A possibly more important source of aneuploidy derives from malfunction of the complex machinery that normally ensures that each kinetochore is bound appropriately to its own set of 20–25 microtubules that form a spindle fiber; these attachments allow each pair of sister chromatids, initially linked by their paired kinetochores, to be pulled in opposite directions at anaphase. However, in many cancer cells, this control mechanism does not operate properly, and individual kinetochores become associated instead with *too many* spindle fibers. For example, merotely occurs when a kinetochore (belonging to a single chromatid) becomes attached simultaneously to two oppositely oriented sets of spindle fibers, which then proceed to engage in a microscopic tug-of-war; this competition is often unresolved by the end of mitosis, leaving the chromatid carrying this kinetochore stranded between the two groups of properly segregating chromatids (now called chromosomes; **Figure 12.38A**). The fate of this orphaned chromosome is unclear; it may be lost entirely or eventually associate with one or another daughter nucleus. A number of studies indicate that merotely represents the major source of CIN in cancer cells. As discussed above, the formation of micronuclei surrounding improperly segregated chromosomes can lead to chromothripsis.





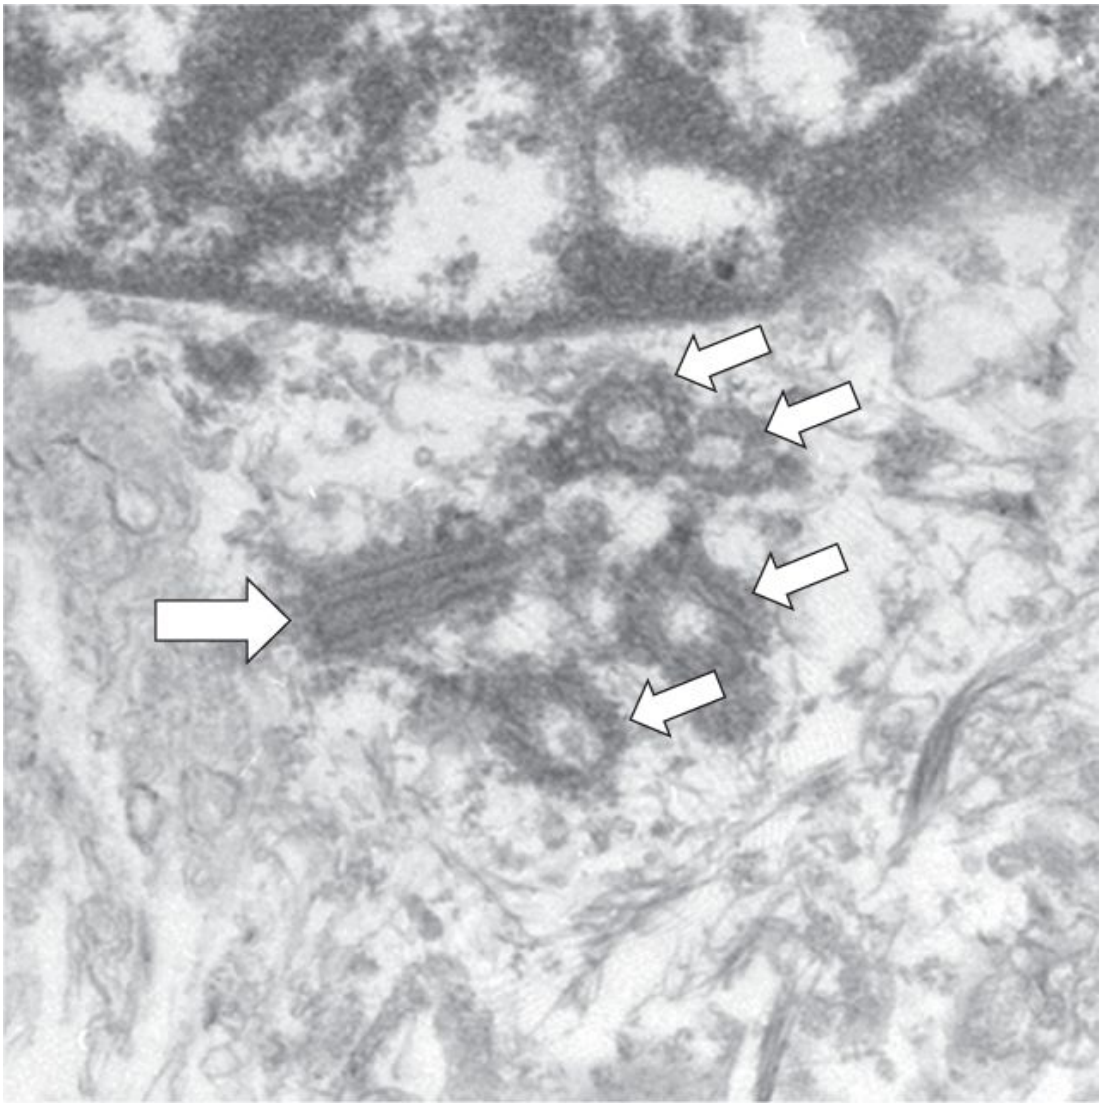
A diagram and a fluorescence microscopy image illustrate the phenomenon called merotely, in which a chromatid is caught in the middle of the two separating portions of a dividing cell and is pulled in two directions by opposing spindle fibers.

(A)



Two fluorescence microscopy images. The one on the left shows a blue nucleus and a single red dot beside it. The one on the right shows a blue nucleus with a cluster of seven red dots beside it.

(B)



A transmission electron microscopy image with four centrioles, shown in cross section, appearing as circles, and a fifth viewed from the side, appearing as a bar.

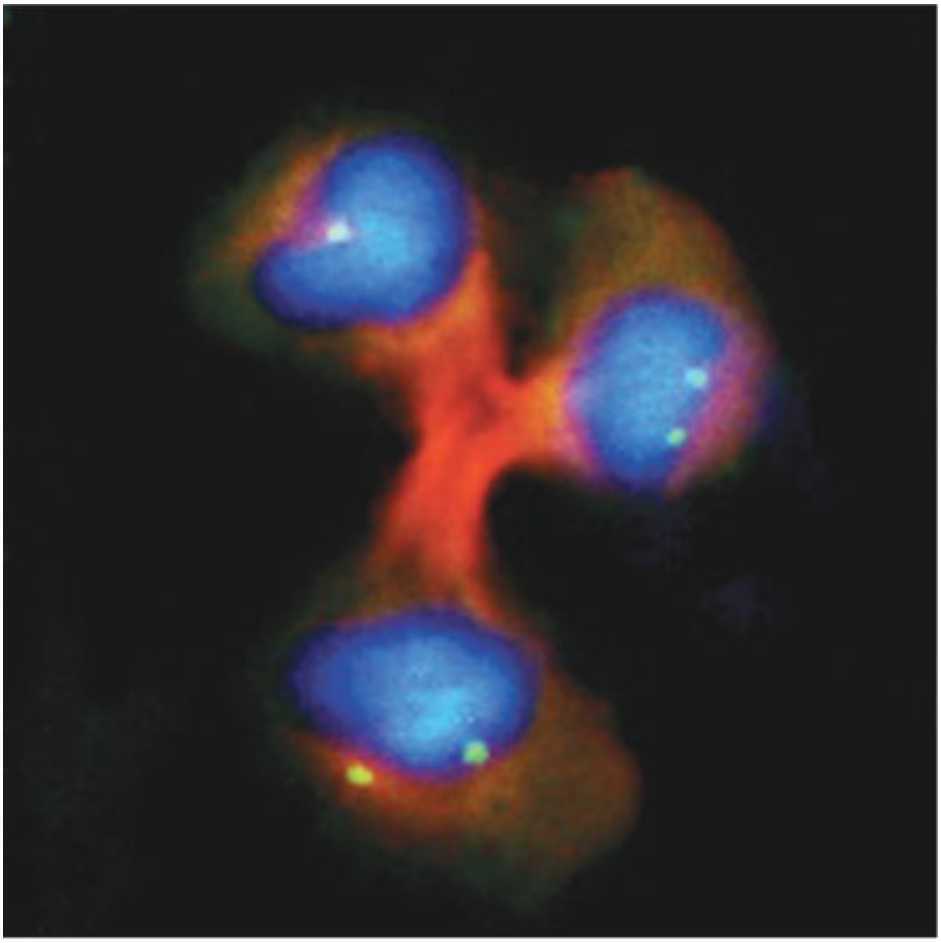
(C)

Figure 12.38 Centrosomes and the organization of the mitotic spindle
Centrosomes are responsible for organizing the microtubule spindle fibers at mitosis. (A) Above, the kinetochore (*green*) of an individual chromatid (*arrow*) may be connected inappropriately to two opposite spindle fibers (*red*) at the same time—the condition termed merotely—causing the spindle fibers to pull in opposite directions and, quite frequently, leave the chromatid stranded between the two properly segregated populations of chromatids (*left*, *right*), now called chromosomes. Below, in the micrograph, only the spindle fibers (*red*) and

kinetochores (*green*) are visualized by immunofluorescence. The isolated chromosome (*green dot, arrow*) in the middle, revealed only by its kinetochore, may not be incorporated into either of the soon-to-be-formed daughter nuclei (assembled around the kinetochore clusters, *left, right*) and may therefore be lost from descendant cells. More likely, however, it may become associated with one of the daughter nuclei. Association with the inappropriate daughter nucleus will result in aneuploidy. (B) In these immortalized but nonmalignant interphase cells (*left*), the presence of a single centrosome is discernible in the cytoplasm through use of an antibody that detects pericentrin, a centrosome-associated protein (*red*). In normal cells, a centrosome is duplicated at the G_1/S transition to generate the two centrosomes found at the poles of the mitotic spindle. In contrast, during interphase of human breast cancer cells (*right*), multiple centrosomes are often observed. These will frequently create multipolar spindles (see Figure 12.39) when such cells enter mitosis. (C) The pair of centrioles that forms the core of each centrosome can be best seen using transmission electron microscopy (TEM), in this case of a human colon carcinoma cell. Four centrioles are seen here in cross section (*small arrows*), while a side view of a fifth (*large arrow*) is apparent, together indicating a deregulation of centriole number. The nucleus is seen above. (A, above, adapted from D. Cimini, *Biochim. Biophys. Acta* 1786:32–40, 2008; with permission from Elsevier; below, courtesy of D. Cimini and from W.T. Silkworth et al., *PloS ONE* 4:e6564, 2009. © 2009 Silkworth et al. This is an open-access article distributed under the terms of the Creative Commons Attribution License. B, from G.A. Pihan et al., *Cancer Res*. 58:3974–3985, 1998. With permission from American Association for Cancer Research. C, courtesy of M.J. Difilippantonio and T. Ried.)

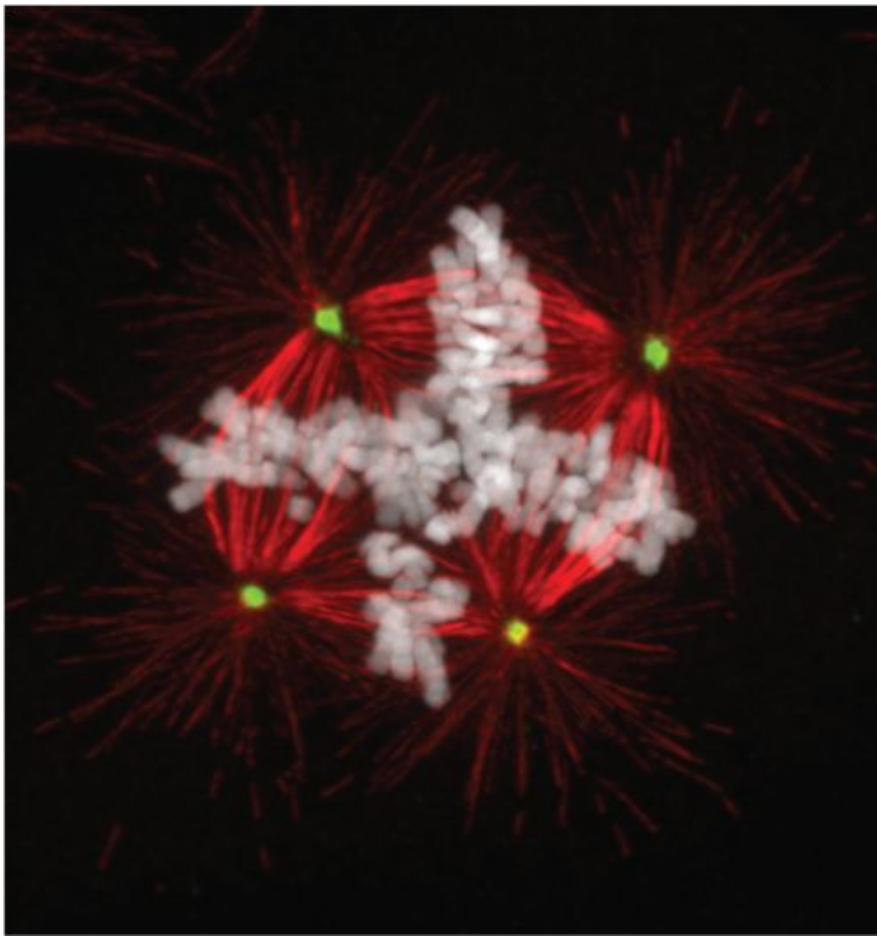
In normal cells, merotely is usually cured by the time cells advance through metaphase into anaphase (see Figure 8.3A). Such curing is critical to normal cells because merotelic chromosomes fail to trigger the spindle assembly checkpoint (SAC), which is designed to halt progress into anaphase in the event that spindle fibers are not properly attached to the kinetochores of all chromatids. (In normal cells, despite these elaborate corrective mechanisms, by some estimates about 1% of mitoses result in some type of mis-segregation; in cancer cells, in stark contrast, as many as one-half of mitoses may result in some form of mis-segregation.) Cancer cells seem to be more tolerant of merotely, which therefore can contribute to their aneuploid karyotypes. Indeed, cancer cells often exhibit defects in one or more of the fourteen distinct proteins that have been implicated in orchestrating the SAC. Of note here, mice that have been genetically engineered to express subnormal levels of certain SAC proteins exhibit elevated levels of spontaneous tumor formation.

More widespread karyotypic chaos may occur if the spindles themselves are not properly assembled. Aberrant mitoses, which result from inappropriate spindle organization, were noticed as early as 1890 and, in retrospect, represented the first clue that cancer cells are genetically abnormal. In normal interphase cells, a single centrosome can be visualized in the cytoplasm (Figure 12.38B); during mitosis, two centrosomes are arrayed at opposite poles within the cell. Cancer cells, however, often show marked defects in this organization, including multiple centrosomes at interphase (see Figure 12.38B and C). The result may be mitotic spindles that have multiple poles rather than the two seen in normal cells (**Figure 12.39A and B**). Often, supernumerary (extra) centrosomes coalesce into the normal set of two as cells proceed through mitosis; however, the spindle fibers that they initially generated may end up forming dysfunctional spindle–kinetochore attachments, such as that seen in Figure 12.38A. Alternatively, the extra centrosomes may persist, causing the chromosomal array to be divided among three or more daughter cells (see Figure 12.39C). The resulting mis-segregation of chromosomes into daughter cells may lead to wild fluctuations in chromosome number and overall karyotype. Strong evidence supporting a causal role for supernumerary centrosomes comes from studies in mice genetically engineered to overexpress the Plk4 serine/threonine kinase, which stimulates centrosome duplication. These mice develop aneuploidy and tumor formation in many tissues, and the tumors in these animals exhibit complex, abnormal karyotypes.



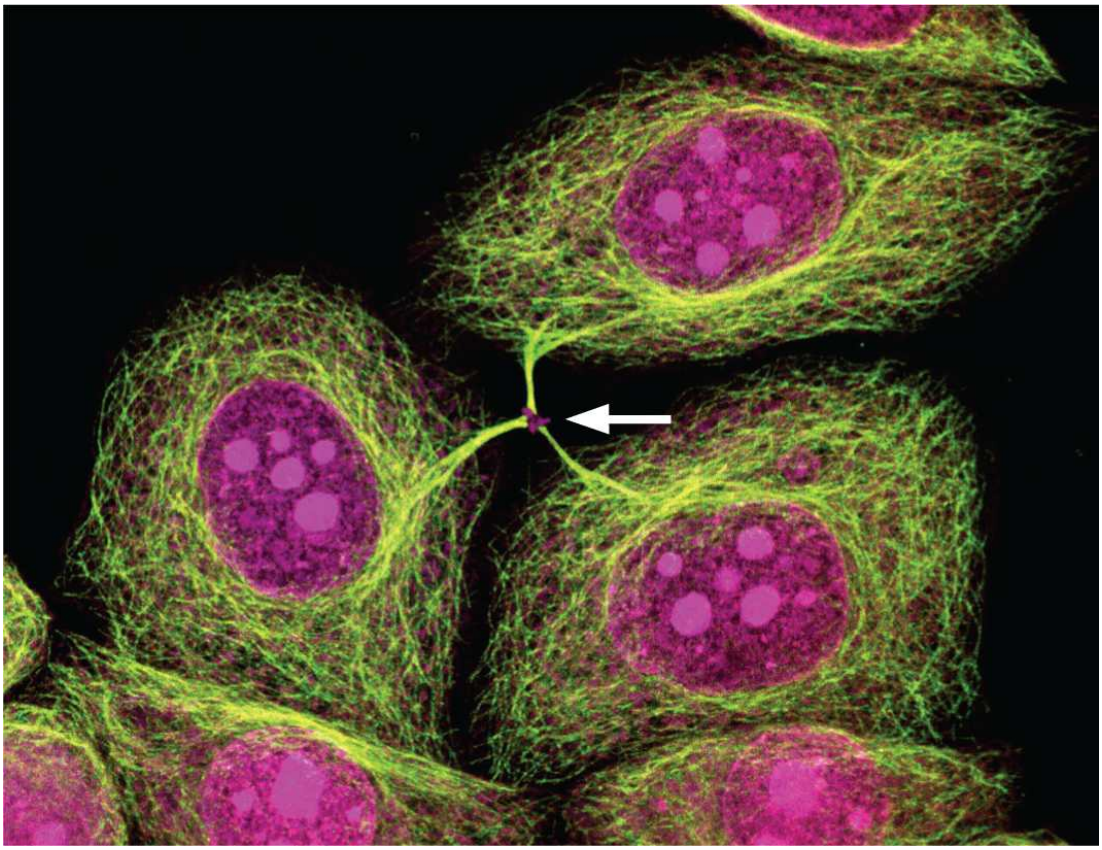
Three blue blobs, each with one or two green dots near the edge. The blobs are joined by thick arms of red fibers, forming a sort of Y shape.

(A)



White chromosomes during mitosis metaphase are arranged in an X instead of the usual line. There are four centrosomes, one within each angle of the X. Spindle fibers run from each centrosome to the nearest chromosomes.

(B)



Three cells look like bright green bird nests with large pink eggs at their centers. The three cells are joined by fibers that converge to a single point in the middle of the cell group. At the point where the fibers converge, there is a triangular purple structure.

(C)

Figure 12.39 Multipolar mitotic apparatuses In a normal mitotic metaphase of cultured cells, the spindle fibers, which are composed of microtubules, reach from the two centrosomes at the mitotic poles to the kinetochores—the multiprotein complexes that are associated with the centromeric DNA of each chromosome. (A) In this micrograph of *p53*$^{-/-}$ mouse embryo fibroblasts, the formation of multiple centrosomes has resulted in a triradial mitotic spindle array. The spindle fibers have been immunostained *red* with an antibody reactive with α- and β-tubulin, and the chromosomal clusters have been stained *blue* with DAPI, a DNA dye. The five centrosomes (immunostained with an antibody reactive with γ-tubulin) are seen as small light yellow or light green spots. Observations like these implicate p53 in the regulation of centrosome number (also see **Supplementary Sidebar 12.10**). (B) The four centrosomes in this quadriradial mitotic spindle array in a prometaphase human fibroblast have been stained *yellow-green*; the microtubules forming the spindle fibers, *red*; and the chromosomes, *white*. (C)

Here, just after cytokinesis, which follows directly after telophase (see Figure 8.3) three daughter cells of a human HeLa cervical carcinoma cell line have formed from a mother cell that ostensibly assembled a triradial spindle during mitosis; these daughters are trying to divide the maternal dowry of chromosomes in three ways rather than the usual two. Microtubules are stained *yellow*; DNA is stained *purple*. The abscission of these cells at the end of cytokinesis clearly did not proceed properly, leaving the cells connected to one another via a chromosomal fragment (*purple dot, arrow*). (A, from P. Tarapore and K. Fukasawa, *Oncogene* 21:6234–6240, 2002. B, from N.J. Ganem, S.A. Godinho and D. Pellman, *Nature* 460:278–282, 2009. Both with permission from Nature. C, from K.G. Murti, *Biotechniques*, Oct. 2004, cover. Courtesy of K.G. Murti.)

It seems that once the complex apparatus designed to ensure proper chromosomal segregation has been damaged, such damage is irreversible. For example, as was seen in Figure 12.36, the enormous cell-to-cell variability in the number of Chromosome 8 copies in certain breast cancer cells indicates that chromosome instability (CIN) persisted in these cells long after tumor progression had reached completion. In this respect, CIN differs from the breakage–fusion–bridge (BFB) cycles (see Section 10.4), which seem to plague the genomes of cancer cells for a limited window of time during tumor progression and then cease once these cells succeed in acquiring telomerase and thus the ability to stabilize their aberrant karyotypes.

In recent years, additional molecular defects that contribute to various types of chromosomal instability have come to light. Not surprisingly, the duplication of centrosomes is closely coordinated with cell cycle advance; it seems to occur at or near the G_1/S transition. Thus, an increasing body of evidence indicates that centrosome duplication is coordinated in some way by the cyclin E– and A–containing cyclin-dependent kinase (CDK) complexes, which are master regulators of entrance into and progression through S phase (see Section 8.3). Defects in the regulation of these processes, including those triggered by cancer-associated viruses such as HBV and EBV, can lead to deregulation of centrosome number (**Supplementary Sidebar 12.10**).

The great complexity of mitosis causes us to consider how prone this process is to error and how many regulatory proteins, including checkpoint control proteins, are in place to monitor the progression of the various steps of M phase. Yeast genetic analyses have revealed as many as 100 distinct genes and proteins that are involved in the various steps of spindle assembly and dynamics, spindle attachment, and the separation of chromosomes during mitosis; mutation of many of these genes results in chromosome instability in yeast. Many of these proteins are highly conserved evolutionarily, and their homologs are likely to be components of the mammalian

mitotic machinery. As described in **Supplementary Sidebar 12.11**, to date only a small proportion of these genes have been found to be mutated at high frequency in human cancer.

OceanofPDF.com

Glossary

mis-segregation
: The failure to properly segregate chromosomes during mitosis or meiosis.

metaphase plate
: A plane or region that is approximately equidistant from the two poles of a dividing cell at which chromosomes align prior to the anaphase portion of the cell cycle.

kinetochore
: Nucleoprotein complex that is associated with the centromeric DNA of a chromosome and is responsible during mitosis or meiosis for forming physical connections between the chromosome and the microtubules of the spindle fibers.

nondisjunction
: (1) Failure of two chromatids to separate from one another during mitosis or two homologous chromosomes to separate from one another during meiosis. (2) State created by this failure of separation.

merotely
: Condition established during the prophase of mitosis when a single kinetochore becomes linked simultaneously to two opposing spindle fibers.

spindle assembly checkpoint
: The complex mechanism that monitors proper attachment of spindle fibers to kinetochores and blocks entrance into the anaphase of mitosis and meiosis if these attachments are not properly formed.

supernumerary
: Referring to a greater-than-normal number of some object.

12.12 Advances in genome sequencing technologies have fueled a revolution in cancer genomics

In 1990, the Human Genome Project was launched as an international research effort to determine the complete sequence of the human genome. Over the course of more than a decade, this effort resulted in the publication in 2003 of a near-complete sequence of a “reference” human genome, that is, one that was purportedly typical of humans, although actually being a composite of genome segments from several volunteers. The full extent of the genetic polymorphisms (see Section 7.6) that exist between individual members of our species is not reflected in this reference genome. This reference sequence appears to contain the coding and regulatory information required to construct a human being. (Even now, however, the genetic information harbored in certain difficult-to-sequence segments of the genome remains elusive.)

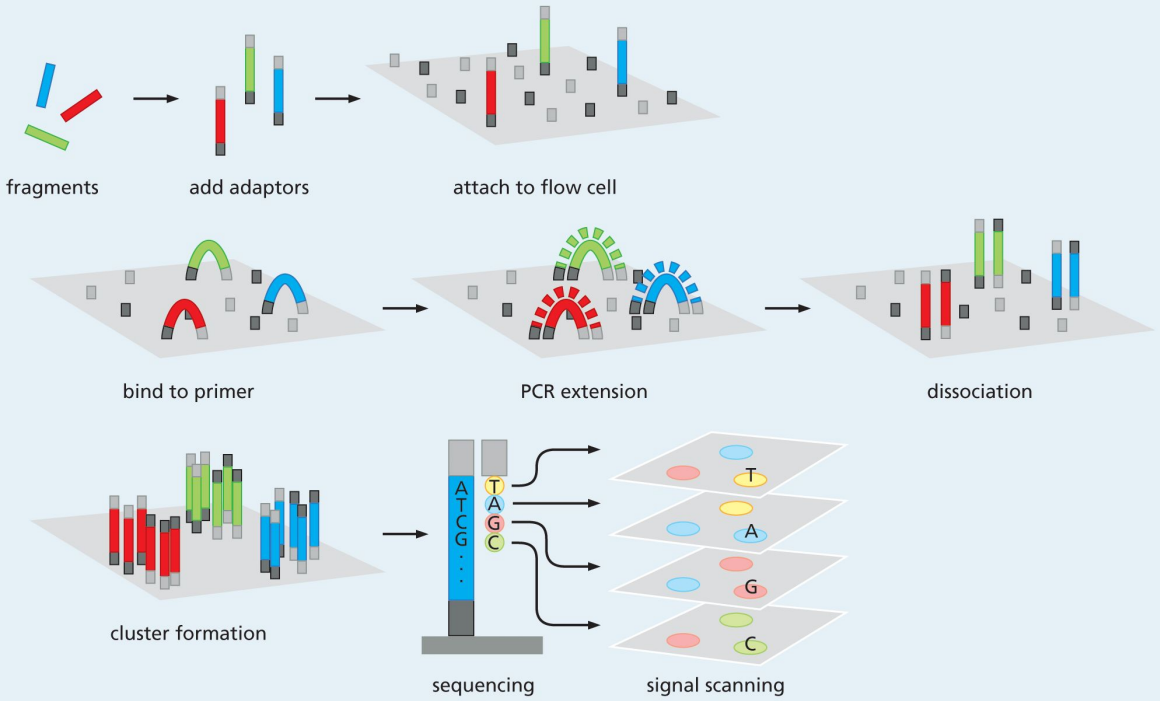
The importance of this milestone in human cancer biology cannot be exaggerated. Thus, the availability of the human genome sequence together with the genome sequences of a great many other species has greatly accelerated the pace of biological and biomedical research by providing ready access to the sequences of genes, regulatory regions, and other chromosomal elements. Today, it is straightforward to perform comparative genomic analyses between species and highlight differences computationally, to design oligonucleotide primers used to amplify a segment of genomic DNA of interest, and to undertake a diversity of other applications that depend in one way or another on genomic sequence information. Until recently, these procedures were laborious and highly time-consuming.

The opportunities enabled by the availability of the human genome sequence inspired the development of new DNA sequencing technologies that improved the speed and reduced the cost of genome sequence analysis. Within a decade of the publication of the first human genome sequence, a number of alternative technologies to traditional Sanger sequencing—referred to collectively as next-

generation sequencing (NGS) technologies—were developed, leading to progressively lower sequencing costs (**Sidebar 12.9**). Whereas the first human genome sequence was estimated to cost nearly $3 billion, the most advanced sequencing technologies available today have allowed the cost of the sequencing of an entire genome to fall well below $1000 (**Figure 12.40**).

Sidebar 12.9 "Next-generation," massively parallel DNA sequencing has enabled large-scale genomic studies

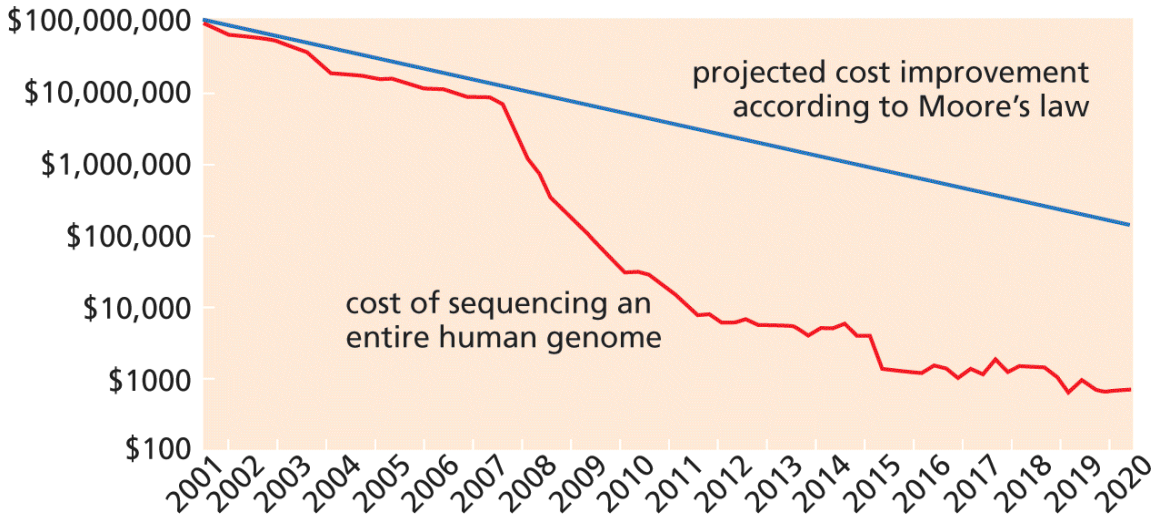
The genomics revolution has been fueled by advances in DNA sequencing technologies, which collectively allow for very high-throughput sequencing at a fraction of the cost of what was possible only a decade ago (see Figure 12.40). Today, the most widely adopted next-generation sequencing (NGS) technology has been a method termed "sequencing by synthesis," in which thousands of DNA templates are sequenced simultaneously on a glass slide through the repeated addition of fluorescently labeled chain-terminating nucleotides. With each round of nucleotide addition, the identity of the added bases in each reaction is determined by fluorescence imaging. Following removal of the chain-terminating moiety on the inserted nucleotides, the next round of sequencing can be undertaken in the same fashion. With sophisticated automation, hundreds of bases of sequence can be determined per template in only several hours (**Figure 12.41**). Although initially developed for whole-genome sequencing, this method (as well as other NGS methods), has been adapted to allow for sequencing only the exonic portions of the genome (called whole-exome sequencing), which has been used extensively in cancer genomics as described in Section 12.12. In addition, these methods can be used to rapidly sequence cDNA libraries for assessment of the mRNA content of cells or tissues; they can also be used to determine the DNA methylation pattern in genomic DNA as well as other applications.



The process for Massively parallel DNA sequencing. It begins with short D N A fragments. A very short adaptor sequence is added to each end of each fragment. The fragments are then attached to a flow cell–initially just at one end, but then the other end is bent down and attached as well. Polymerase chain reaction is then used to duplicate the strands along their lengths. After one end of each strand is dissociated from the flow cell surface, there are now twice as many strands as there were before, each attached at one end. This process is repeated to form clusters of strands. Sequencing and signal scanning can now proceed.

Figure 12.41 Massively parallel DNA sequencing Among several powerful methods for high-throughput DNA sequencing, the one commercialized by the company Illumina has been used most extensively in cancer genomics studies to date. In this method, DNA fragments to be sequenced are modified with short adaptor sequences. These adaptors enable attachment of single strands of the fragments to the surface of a reaction chamber (or flow cell) by hybridization to complementary nucleotides attached to the flow cell. Through a series of local binding, PCR amplification, and dissociation steps, each of the original fragments can be amplified into a cluster of identical molecules ready for sequencing. Sequencing is performed by the addition of a sequencing primer complementary to the adaptor sequence, DNA polymerase, and fluorescent nucleotides (with each nucleotide labeled with a different fluorophore). The addition of only one nucleotide per sequencing

round is controlled through the use of reversible chain-termination moieties on the fluorescent nucleotides. At the end of each round of sequencing, the flow cell is imaged to record the identity of the last nucleotide added at each cluster. The next round of sequencing follows the quenching of the fluorescent signal by the previously incorporated nucleotides and the removal of the chain termination moiety. The process is continued in this fashion until hundreds of bases of sequence are read out from each cluster. Computational analysis is then used to align the fragments into larger sequences, such as exomes or whole genomes. (From Y. Lu et al. in J.K. Kulski ed., Next Generation Sequencing - Advances, Applications and Challenges. London: IntechOpen, 2016. © 2016 The Author(s). With permission from the authors.)



A graph depicting the Falling cost of genome sequencing, with cost on the logarithmic vertical scale. According to Moore's law, the cost should have dropped steadily from about 1 hundred million dollars in 2001 to about 1 hundred thousand in 2020. In reality, the cost roughly followed Moore's law until about 2007, but then fell more rapidly. In 2020, the actual cost stood at about 1 thousand dollars.

Figure 12.40 Falling cost of genome sequencing. The graph illustrates the dramatic reduction in the cost of sequencing a human genome sample beginning in 2001, shortly after the first draft sequence of the human genome was released. With a series of technological improvements in conventional DNA sequencing technology, the costs of sequencing steadily declined over the next several years. With the advent of massively parallel sequencing technologies (described in Figure 12.41), genome sequencing costs dropped

precipitously beginning in 2007. Continued improvements have led to even more cost reductions, such that by 2021 the cost of sequencing of an entire human genome sample is well under $600. These cost reductions have fueled multiple large-scale cancer genomic studies as well as the widespread use of numerous other sequencing-based genomic technologies. For comparison, the projected decline in sequencing costs according to Moore's law is shown over this period. Moore's law was initially described in relation to the two-fold improvement in computing power observed in the computer hardware industry every two years, and is considered a mark of outstanding technological improvement. The falling cost of genome sequencing over this two-decade period has vastly outperformed Moore's law (Source: https://www.genome.gov/about-genomics/fact-sheets/DNA-Sequencing-Costs-Data).

This technological revolution has influenced many fields of biomedical research, but none more than cancer research. Through large-scale cancer genome and whole-exome sequencing efforts like The Cancer Genome Atlas (TCGA) and the International Cancer Genome Consortium (ICGC), thousands of cancer specimens have been profiled at unprecedented "depths," that is, redundantly, to ensure maximal accuracy. Among the fruits of these labors are measurements of the prevalence of the specific mutations across multiple cancer types; such analyses include surveys of essentially all the cancer genes that we have discussed in this text. In addition, a large number of novel cancer-associated genes have been identified directly through these large-scale cancer genome studies by means of their recurrent involvement in multiple, independently arising tumors and cancer types. By current estimates, nearly 600 genes in the human genome have been found to be recurrently mutated in one or more types of cancer, among them oncogenes and tumor suppressor genes, as well as genes involved in DNA repair and related genome maintenance functions. The mutations that affect these genes range from missense mutations and nonsense mutations to large-scale structural rearrangements. Extensions of these procedures have also enabled analyses of the protein-encoding RNA segments of specific cell types via the process of whole-exome sequencing.

Glossary

next-generation sequencing
: A set of high-throughput methods used to determine a portion of the nucleotide sequence of DNA. These techniques utilize DNA sequencing technologies that are capable of determining multiple DNA sequences in parallel. *Also called* massively parallel sequencing.

chain-terminating nucleotide
: A nucleotide that lacks a 3′-OH group, which is required for the formation of a phosphodiester bond between two nucleotides. The insertion of a chain-terminating nucleotide causes DNA polymerase to cease extension due to the inability to form a new phosphodiester bond with an incoming nucleotide.

The Cancer Genome Atlas
: A project to identify the complete set of DNA changes in many different types of cancer, led by the U.S. National Cancer Institute and the U.S. National Human Genome Research Institute.

International Cancer Genome Consortium
: A multi-national effort to characterize the genetic changes in the genomes of multiple types of human cancer including multiple cases of specific cancer types. *See also* **The Cancer Genome Atlas**; **Sanger Cancer Genome Project.**

whole-exome sequencing
: Method used to determine the nucleotide sequence primarily of the exonic (including protein-encoding) regions of genomic DNA sample.

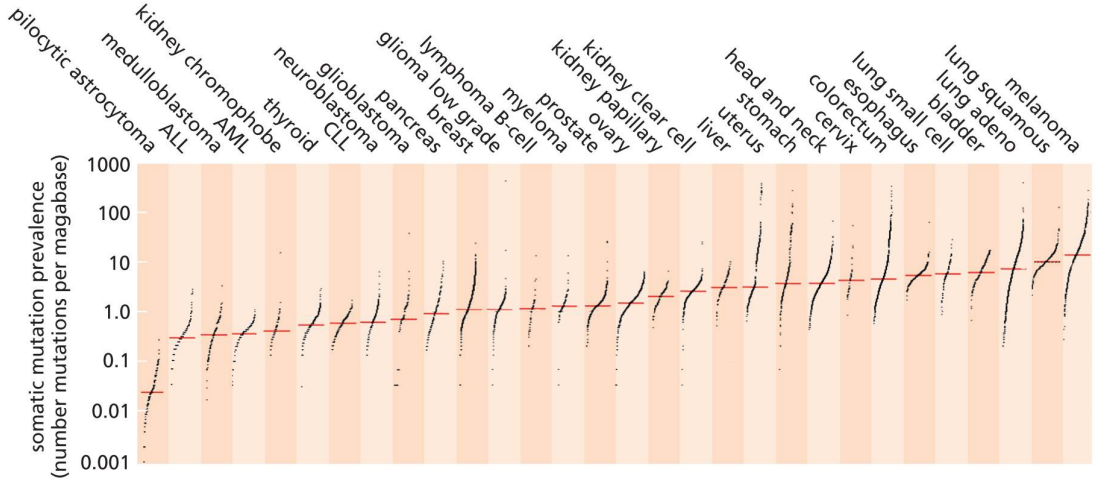
12.13 Genomic analysis reveals that human cancers differ with respect to mutational burden, patterns of mutations, and copy number gains and losses

A number of factors can influence the number of mutations present in the genomes of different types of cancer cells. In cancer genomics studies, tumor mutational burden (TMB) can be expressed either in terms of mutations detected per megabase of DNA sequenced or as the number of protein-altering (also called nonsynonymous) mutations per tumor genome. As shown in **Figure 12.42**, TMB can range from low in certain pediatric cancers with less than one mutation detected per megabase of DNA to very high in adult cancers associated with carcinogen exposure or in those carrying mutations in genes involved in DNA repair (between 10 and to well more than 100 mutations per megabase). The low TMB in cancers of children is likely explained by a combination of the relatively low number of cell divisions that the cell-of-origin of the cancer underwent prior to neoplastic transformation as well as the expected lower lifetime exposure to carcinogens in children compared to adults. (At the same time, it leaves unresolved the question of why pediatric tumors, in contrast to almost all adult tumors, require relatively few mutant driver genes to become neoplastic.)



A graphic listing the somatic mutation prevalence, in number of mutations per megabase, for each of 30 different tumor types. The prevalence is extremely low

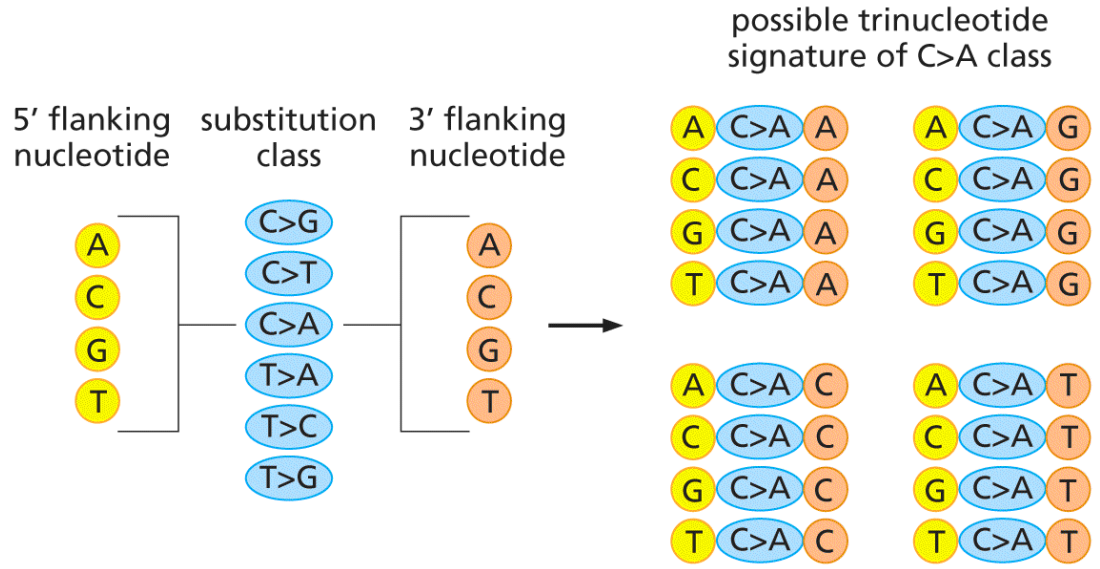
for pilocytic astrocytoma, less than 0.03 on average. For other tumor types, the prevalence ranges from 0.3 for A L L up to about 10 mutations per megabase for melanoma.

Figure 12.42 Large-scale genome sequencing reveals diverse patterns of mutagenesis The results of sequencing of more than 7000 cancer genomes show vastly differing densities of point mutations. These vary by greater than a factor of 1000 from pediatric tumors (pilocytic astrocytoma, *left*) to some of the solid tumors in adults (*right*) having documented exposure to known carcinogens (tobacco smoke and UV radiation), mutations in DNA repair genes, or overexpression of APOBEC enzymes. Each *black* point in the graph represents the number of point mutations per megabase (Mb) in a single cancer genome. The *red* horizontal lines are the median number of mutations in the respective cancer type. ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CLL, chronic lymphocytic leukemia. (From L.B. Alexandrov et al., *Nature* 500, 415–421, 2013. With permission from Nature.)

Underscoring the importance of carcinogen exposure in driving TMB are the mutations observed in smoking-associated adenocarcinoma of the lung, in which the average number of nonsynonymous mutations is approximately 175; in contrast, the genomes of lung adenocarcinomas in never-smokers bear on average approximately tenfold fewer mutations of this type. At the high end of the TMB spectrum are tumors that carry mutations in genes involved in the DNA repair pathways that we discussed above, including the mismatch repair genes, as well as mutations in the proofreading domains of DNA polymerases genes, *POLE* and *POLD*. For example, as mentioned earlier, colon and endometrial cancers that harbor mutations affecting the fidelity of the pol-δ and pol-ε replicative DNA polymerases have “ultra-mutated” genomes with well over 200 mutations per megabase of DNA sequenced. (As we will learn later in Chapter 15, the nonsynonymous mutations have implications for the immune responses to tumors, because these mutations encode, by definition, structurally altered proteins that may function as “neoantigens” capable of provoking robust immune responses.)

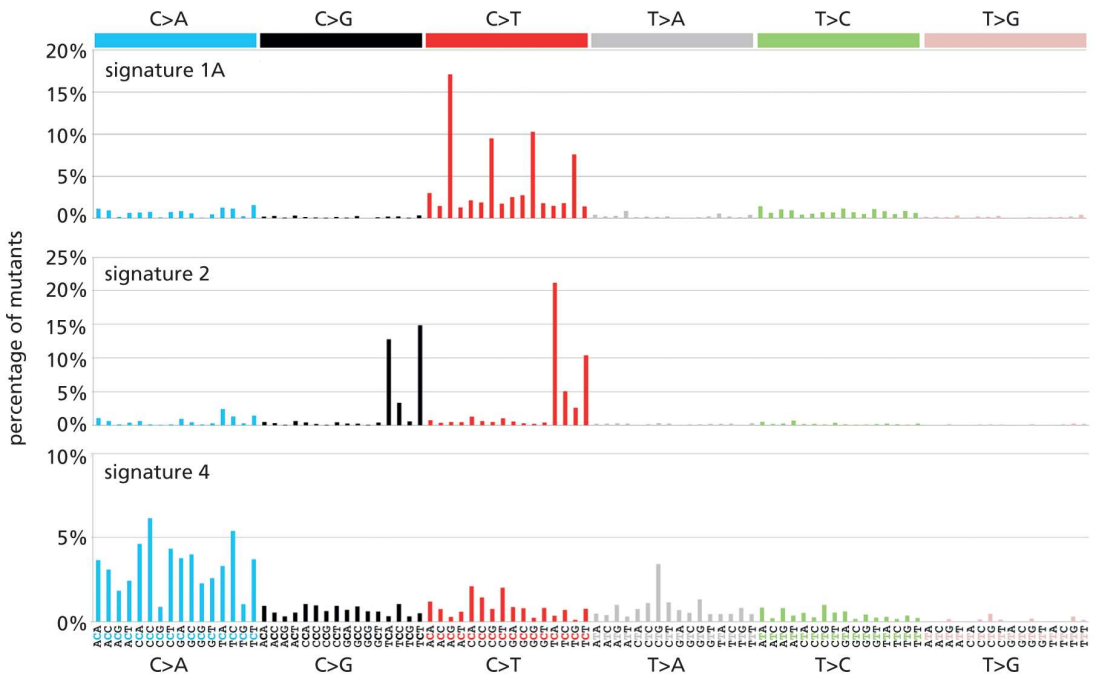
In addition to revealing the TMB in a given cancer or cancer type, in some cases the *patterns* of mutation in cancer genomes—whether they occur in genes or in noncoding regions—as well as the DNA sequence context in which those mutations arose, can be used to infer the nature of the mutagenic processes that were responsible for these mutations (**Figure 12.43**). A clear example of this can be seen in melanomas that arise in areas of sun-exposed areas of skin. Whole-genome or whole-exome sequencing of these cancers clearly shows a “signature” of UV-induced mutations (see Figure 12.43 for examples of mutational signatures), featuring C>T mutations in dipyrimidine sites. As discussed earlier in Section 12.5, these sequences are known to undergo UV-

induced intra-strand photo-cross-linking that, if not repaired, can lead to transition mutations at these sites.



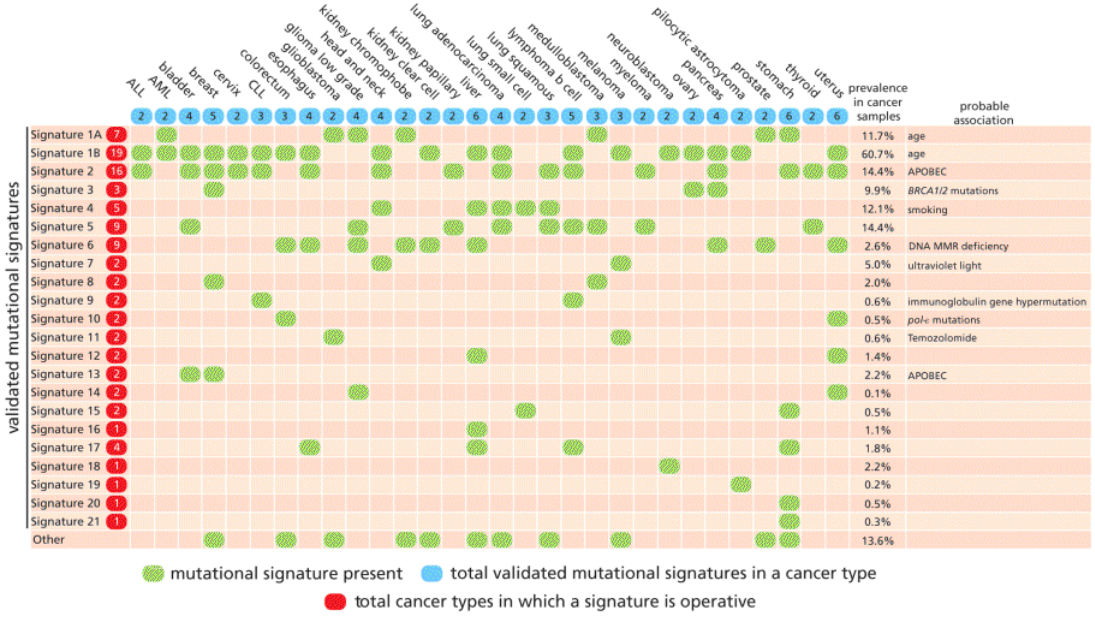
An illustration of the different ways of combining a 5 prime flanking nucleotide on one side and a 3 prime flanking nucleotide on the other side with a substitution class in the middle. Each of the flanking nucleotides can be A, C, G or T. The six substitution classes are C to G, C to T, C to A, T to A, T to C, and T to G. There are a total of 4 times 6 times 4 = 96 combinations; the 16 combinations with C to A in the middle are shown.

(A)



A list of three mutational signatures, named 1A, 2 and 4. A histogram for each one shows the percentage distribution over the 96 different combinations. Signature 1A is characterized by frequent C to T substitutions, especially with G as the 3 prime flanking nucleotide. Signature 2 is characterized by frequent C to T and also C to G substitutions with T as the 5 prime flanking nucleotide. Signature 4 is characterized by frequent C to A substitutions.

(B)



A table with validated mutational signatures listed down the left and different tumor types listed across the top. Cells are filled in or empty to indicate whether a mutational signature is present or absent in a given type of cancer. To the right is a column titled prevalence in cancer samples. Signature 1B, for example, is found in 60.7 percent of cancer samples. For other signatures the percentages are significantly lower. A final column lists probable associations for some signatures. Signatures 1A and 1B are associated with age, signature 4 is associated with smoking, and signature 7 is associated with ultraviolet light.

(C)

Figure 12.43 Mutational signatures in cancer genomes To discern patterns of mutations (mutational signatures) in cancer genomes, one can analyze the frequency of base changes in the context of the flanking 5′ and 3′ bases. (A) In the analysis seen here, only the pyrimidine bases (C,T) of the unmutated, wild-type sequence that were initially present were considered; each of these two initial pyrimidine bases has three possible alternative substitutions (C>A, C>G, C>T, T>A, T>C, T>G). Because there are four possible 5′ flanking bases and four possible 3′ flanking bases (that is, 16 combinations) in each case, there are 3 × 16 or 48 possible mutational signatures for each of these two initial pyrimidine nucleotides, making 96 in all. The 16 possible mutation types for the substitution class C>A are shown here. (B) From the analysis of several thousand cancer genomes, up to 30 mutational signatures have now been observed. This panel shows three signatures that are prominently observed in different types of human cancer. Signature 1A (*above*), which features C>T mutations in sequences where the mutated C residue is followed by a G residue are believed to be caused by the spontaneous deamination of 5-methylcytosine residues in CpG dinucleotides (see Section 12.4). Signature 2 (*middle*) is associated with increased expression of members of the APOBEC family of cytosine deaminases and is associated with a high prevalence of C>T and C>G mutations in particular sequence contexts. Signature 4, (*below*) which is marked by C>A mutations, is associated with exposure to cigarette smoke carcinogens. (C) Different human cancer types show contributions of the different mutational signatures (*green ovals*). The total validated number of distinct mutational signatures for each cancer type are shown in *blue ovals* and the number of cancers that show a particular identifiable signature are shown in *red ovals*. The probable or inferred causes of 11 of the mutational signatures are shown at the *right*. Note that for many of the signatures, the mutagenic mechanisms leading to their formation are not known at present. (From L.B. Alexandrov et al., *Nature* 500: 415–421, 2013. With permission from Nature.)

The genome-wide analyses have confirmed and extended earlier work that focused on sets of frequently mutated genes such as p53, which also showed a predominance of C>T mutations in cancers associated with UV light exposure. Yet another clear signature is seen from genome sequencing of the smoking-associated lung cancers. Here one finds clear evidence of exposure to the guanine alkylating agents that comprise some of the many carcinogens in tobacco products (see Section 12.5). These tumors have a mutagenic signature (Signature 4 in Figure 12.43B and C) featuring a high frequency of C>A transversion mutations. Other cancer types linked to tobacco use, such as squamous cell cancer of the head and neck, also show this mutational signature upon genomic analysis. Hence, mutational signatures in cancer genomes can provide clues to the nature of the etiological agents responsible for tumor development (**Sidebar 12.10**).

Sidebar 12.10 Mutational signatures reveal the likely environmental source of Romanian kidney cancers

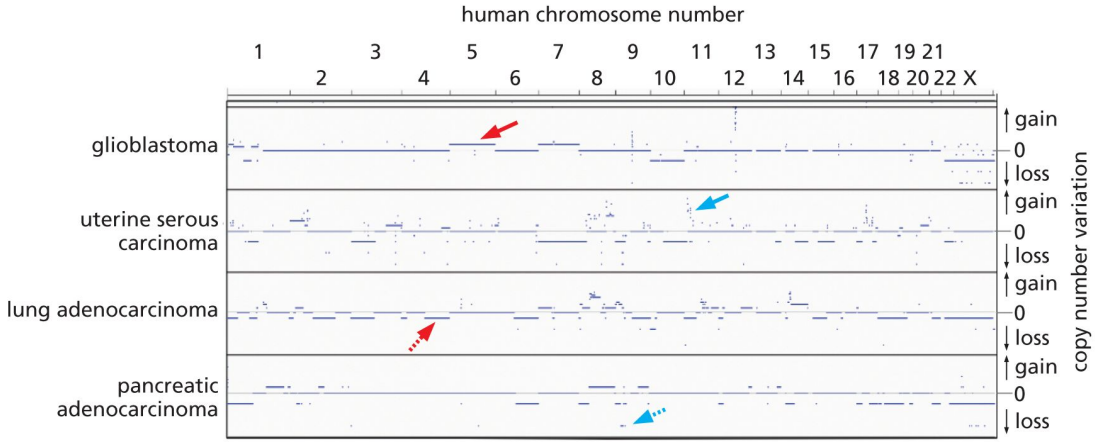
Searching the genomic sequence data from a particular cancer specimen or cancer type for mutational signatures can provide clues to the endogenous mutational processes or exogenous mutagens that might have contributed to tumor formation. A good example of the value of this approach comes from the genomic analysis of renal cell carcinomas (RCC, a form of kidney cancer) from different countries in Europe. Although the patterns of mutations present in these cancers from most countries were similar, a subset of the RCC specimens from Romania carried a distinctive mutational signature with a preponderance of A>T transversion mutations. Further signature analysis showed that these mutations occurred in the sequence C/TpApA/G. Interestingly, this same mutational signature had previously been found in urothelial cancers in parts of Asia, associated with exposure to aristolochic acid (AA), a known carcinogen present in plants from the genus *Aristolochia* used in herbal medicines.

These observations raised the possibility that AA exposure may have also contributed to RCC development in parts of Romania, where *Aristolochia* species endemic to the area may be inadvertently introduced in the food supply. Subsequent studies have shown that the DNA base adduct caused by a metabolic derivative of AA can be observed in the normal kidney of Romanian RCC patients, strongly supporting a causal role for this environmental mutagen in this form of cancer. Ongoing cancer genomic studies are attempting to use mutational signature analysis to identify environmental carcinogens that are responsible for cancers with unexpectedly high prevalence in certain geographic regions, that is, so-called “cancer clusters.”

Mutational signatures in cancer can also provide tell-tale signs of the failure of DNA repair in repair-deficient tumors or the hyperactivity of mutagenic enzymatic

processes. For example, the genome sequences of colon and endometrial cancers harboring mutant mismatch repair genes show numerous short insertion and deletion (indel) mutations in homopolymeric or simple repeat sequences. Breast and ovarian cancers with inactivating mutations in the *BRCA1* or *BRCA2* genes, which are involved in homology-directed repair (see Section 12.9), show high incidence of indel mutations throughout the genome, which likely result from these cancer cells needing to rely on error-prone nonhomologous end-joining (NHEJ) mechanisms to repair double-strand breaks in DNA. Overexpression of members of the APOBEC family of cytosine deaminases (see Sidebar 12.6) occurs in many cancers, including those of the lung and bladder. Their conversion of cytosine residues to uracil occurs preferentially in the sequence context TpCpA/T, leading to C>T and C>G mutations at these sites.

In addition to identifying base substitutions and indel mutations, cancer genome sequencing studies also highlight regions of copy number gain and loss, which are the products of amplifications or deletions of segments of a cancer genome. These so-called copy number variations (CNVs) are revealed by the number of sequence reads from a region of the genome relative to the value expected from a normal diploid (2*n*) genome. CNVs provide clues to the existence of possible oncogenes in regions of gain or tumor suppressor genes in regions of loss. Regions containing CNVs can be limited in length (termed “focal”), in which only one or a small number of genes is affected, or more extensive, in which as much as an entire chromosomal arm can be affected. Whole-chromosome gain or loss can also be recognized by CNV analysis. **Figure 12.44** shows examples of CNVs cancer genomes.



A graphic giving Copy number variations in four different types of cancer. The cancer types are listed down the left, and chromosome numbers are listed across the top, 1 through 22 plus X. For each cancer, a horizontal baseline represents the average number of copies. Deviations above or below the baseline represent copy counts above or below average. Glioblastomas have excess copies of two entire chromosomes, namely 5 and 7, and shortfall counts of chromosome 10. Lung

adenocarcinomas show loss of an entire arm of chromosome 4, as indicated by a continuous below-baseline line segment representing part of chromosome 4. Focal amplification in uterine serous carcinoma is indicated by an above-baseline cluster of dots at the left end of the chromosome 11 segment. Focal deletion in pancreatic adenocarcinoma is indicated by a below-baseline cluster of dots at the left end of the chromosome 9 segment.

Figure 12.44 Copy number variation in cancer Cancer genomes frequently carry regions of copy number variation (CNV), resulting from whole chromosome gain or loss or regional amplification or deletion within individual chromosomes. These CNVs can be detected using a number of methods, including the whole-genome sequencing (WGS) method employed here. WGS data from four different human cancers are depicted with the read counts plotted according to chromosomal location (*top*). The average read count per sample is considered the copy neutral region for this analysis (denoted 0). Regions of copy number gain have read counts greater than the copy neutral value, and regions of copy number loss have read counts less than the copy neutral value. Note that all four cancers have numerous areas of CNV, including whole chromosome gains (*solid red arrow*), loss of an entire chromosome arm (*dashed red arrow*), focal amplification (*solid blue arrow*), and focal deletion (*dashed blue arrow*). (From A. Cherniack and R. Beroukhim; data from https://portal.gdc.cancer.gov/.)

OceanofPDF.com

Glossary

tumor mutational burden
: The total number of mutations found in the genomic DNA of tumor sample, often presented as number per haploid genome or per megabase of genomic DNA.

nonsynonymous
: A nucleotide mutation that alters the amino acid sequence of an encoded protein. Nonsynonymous mutations differ from synonymous mutations, which do not alter amino acid sequences of encoded proteins. *See also* **synonymous**.

indel
: Insertion or deletion mutation.

copy number variation
: Alteration involving the number of copies of a gene or chromosomal region present in a genome, usually the genome of a neoplastic cell that has undergone somatic mutation.

12.14 Cancer genomes contain driver and passenger gene mutations

When familiar genes such as *Kras* or *p53* are found to be mutated in a cancer sample, there is no debate about their causal role in the process of tumor development. However, when a gene that has never been previously associated with cancer is discovered in mutant form in a cancer specimen, it is reasonable to ask whether the mutation was selected for during the development of that cancer (that is, the mutant gene functioned as a driver of tumorigenesis) or whether the mutation might simply have occurred coincidentally and been carried along for the ride together with a selectively advantageous driver mutation (that is, a passenger mutation; see Section 11.6).

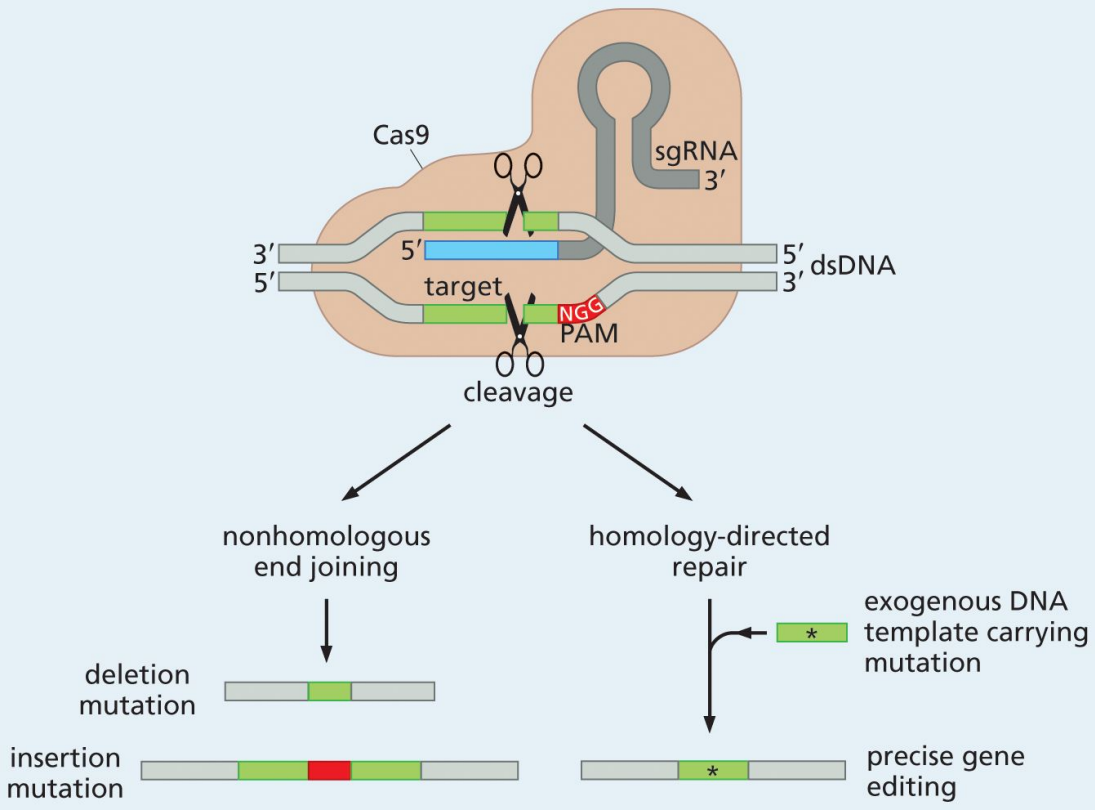
Several criteria can be applied to bolster the claim that a gene is a bone fide cancer driver. First, the frequency of mutation of a particular gene in multiple tumors of a given cancer type or across multiple cancer types can be an indication of direct involvement in the tumorigenic process. If such frequencies significantly exceed those expected simply by chance, one can reasonably conclude that the mutations were selectively advantageous. When calculating these expected frequencies, one must bear in mind that large genes will present a larger target for randomly occurring mutations than smaller ones.

In addition, the *pattern* of mutation in a gene might provide a clue. For example, if the gene in question is predicted to encode a kinase and the mutations detected in cancer specimens are analogous to known kinase-activating mutations in well-described oncogenes, then the case in favor of assigning driver mutation status would be strengthened. Likewise, a novel tumor suppressor gene might be identified based in part on a pattern of recurring loss-of-function mutations as well as evidence of mutations affecting both alleles of the gene in a series of cancer specimens. Ultimately, functional tests, either in cell culture transformation assays (see Sections 3.2 and 3.4.) or in whole animal cancer models (see Sidebar 7.2), are the most direct way to distinguish true cancer driver genes from passengers. The use of CRISPR/Cas9-based genome editing methods has greatly accelerated cancer functional genomics (**Sidebar 12.11**). Although passenger mutations do not contribute to cellular transformation or tumor progression per se, they may still have an impact on tumor development by creating neoantigens, as mentioned earlier and discussed in detail in Chapter 15.

Sidebar 12.11 The CRISPR-Cas9 system has become an important tool in cancer research

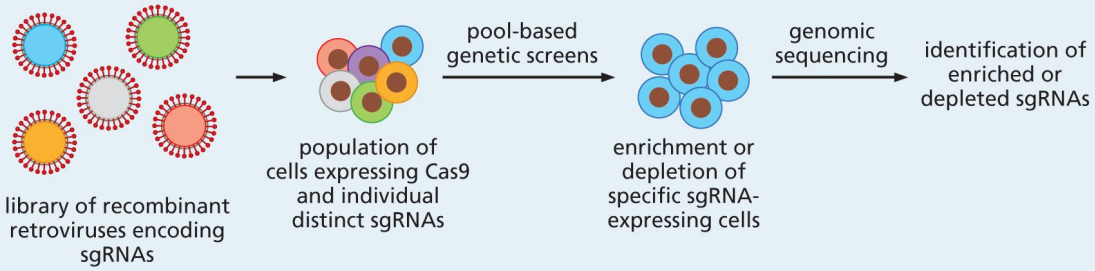
A powerful set of genome-editing tools has emerged in recent years through the application of CRISPR–Cas (clustered regularly interspaced short palindromic repeats–CRISPR-associated systems). This novel technology has been derived from prokaryotic systems that evolved as an adaptive defense mechanism against bacteriophage infection and have now been redeployed to rapidly mutagenize the genomes of cells from a wide array of species; in addition, the CRISPR-Cas technology can now be used to functionally interrogate cancer genes.

The *Streptococcus pyogenes*-derived type II CRISPR–Cas9 system was the first to be modified for use in mammalian cells. This highly versatile system is composed of two components: an RNA-guided DNA endonuclease (Cas9) and a so-called single-guide RNA (sgRNA). The sgRNA molecule binds to the Cas9 enzyme and directs it to a genomic sequence of interest via base pairing to a predetermined target sequence (**Figure 12.45A**). Combining the expression of Cas9 with an sgRNA that is complementary to a target DNA sequence leads to high-efficiency cleavage of the target site in the genome, resulting in a double-strand DNA break. Subsequent repair by the error-prone NHEJ DNA repair pathway (see Section 12.9) can lead to insertion or deletion mutations at the target site, often causing loss of gene function.



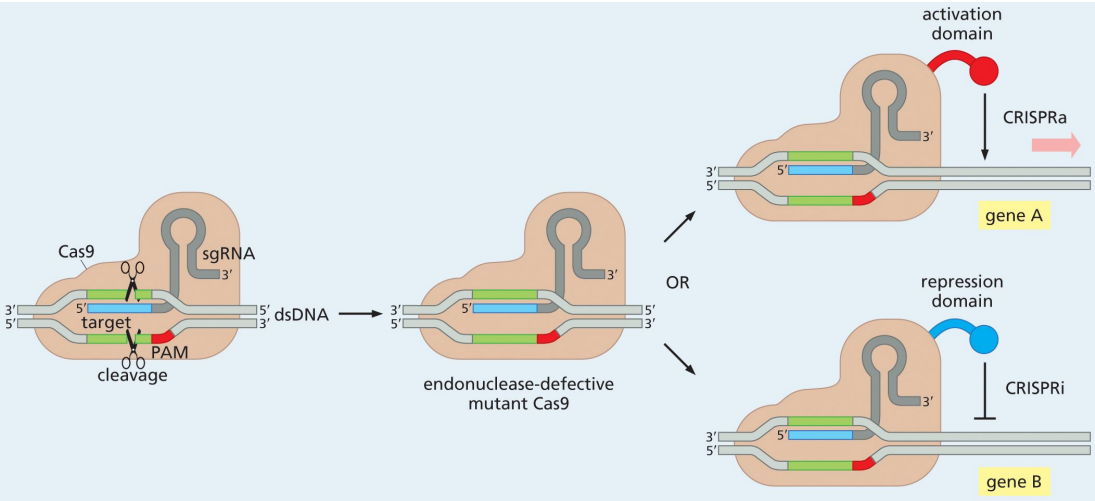
A complex labeled C a s 9 enfolds an s g R N A and also a section of unwound double-stranded D N A, namely a section that matches a section of the s g R N A. Both strands of the D N A are cleaved. One of the two strands is adjacent to a sequence shown as N G G and labeled P A M. If the cleavage is repaired using nonhomologous end joining, the result may be a deletion mutation or an insertion mutation. If the cleavage is repaired using homology-directed repair, the use of an exogenous D N A template carrying a mutation results in precise gene editing.

(A)



A process that begins with a library of recombinant retroviruses encoding s g R N Ayze. This produces a population of cells expressing C a s 9 and individual distinct s g R N Ayze. pool-based genetic screens are used to achieve enrichment or depletion of specific s g R N A expressing cells. Finally, genomic sequencing is used to identify enriched or depleted s g R N Ayze.

(B)



A mutation is introduced that renders C a s 9 endonuclease-defective. This is then shown augmented with an activation domain and affecting CRISPeR A-

mediated activation of gene A or, alternatively, augmented with a repression domain and affecting CRISPeR I-mediated inhibition of gene B.
(C)

Figure 12.45 CRISPR/Cas9-based genome editing, genetic screens, and modulation of gene expression The versatile CRISPR/Cas9 system can be used to precisely modify genomes and broadly modulate gene expression. (A) The *S. pyogenes*-derived Cas9 DNA endonuclease can be localized to a specific DNA sequence through binding to a single-guide RNA (sgRNA) that also forms base pairs via a complementary sequence (*blue*) to a specific target sequence in the genome (*green*). The target sequence must be adjacent to a protospacer adjacent motif (PAM) sequence, a three-nucleotide sequence composed of any nucleotide (N) followed by two G residues (NGG). Cas9-mediated cleavage (*shown as scissors*) of both strands of the target sequence results in a double-strand DNA break. Repair of the break by the error-prone nonhomologous end joining pathway can produce deletion and insertion mutations, which typically cause loss of gene function. With the addition of an exogenous DNA template carrying a mutation (*asterisk*), homology-directed repair can transfer the mutation into (*continued*)the genome. (B) To perform CRISPR-based genetic screens, libraries of recombinant retroviruses are constructed, such that each virus carries a different sgRNA targeting a specific gene (depicted by different colors). These viruses are used to infect Cas9-expressing cells. Subsequent CRISPR/Cas9-mediated mutation leads to the generation of a population of cells with targeted loss-of-function mutations in the corresponding genes. Subjecting these cells to selective conditions causes enrichment or depletion of certain mutant cells. For enrichment-based screens, the identity of selected mutations can be determined following DNA sequencing of the sgRNA portions of the retroviral proviruses present in the remaining mutant cells. For depletion-based screens, one compares the representation of sgRNA sequences in the starting population of cells to that present following growth in the selective conditions; sgRNA sequences that are relatively underrepresented in the final population are indicative of genes in which mutation led to a fitness disadvantage. (C) Cas9 can be rendered endonuclease defective through specific mutations. Such endonuclease-defective mutant Cas9 proteins can still bind to sgRNAs and be targeted to specific sites in the genome. By fusing transcriptional activation or repression domains onto the endonuclease-defective Cas9 proteins and targeting them to the promoter regions of genes of interest via expression of the appropriate sgRNAs, one can affect CRISPR-mediated gene activation (CRISPRa) or inhibition (CRISPRi).

Co-introducing (via transfection) a cloned exogenous DNA template that carries a mutation of interest at the time of the CRISPR-Cas9 cleavage event can enable efficient transfer of the mutation into the genomic site by HDR (see Section 12.9),

thereby allowing the precise introduction of gain-of-function or other mutations into a cell's genome (see Figure 12.45A). In both cell-based models and whole-animal models, these methods have been used to functionally test candidate TSGs and oncogenes identified in various cancer genomic studies.

In addition to facilitating the targeting of mutations to individual genes, CRISPR-Cas9-based systems have also been used to carry out large-scale genetic studies in cell lines. These studies use libraries of sgRNAs (typically encoded by pools of recombinant retrovirus vectors), each of which targets a specific gene and, when used together, target hundreds or thousands of genes in populations of cells (Figure 12.45B). The introduction of these libraries into large populations of cultured cells allows the selective outgrowth of individual cells (and thus clonal populations) that have gained increased fitness in the population; this fitness is defined by certain selective conditions imposed on the populations as whole, such as ability to resist killing by a certain cytotoxic drug.

Mutant cell clones that grow out in these experiments can be isolated and their genomes interrogated by DNA sequencing of the sgRNA-encoding portion of the retroviral proviruses that have integrated into the genomes of the cells in these clones, thereby identifying the genes in which loss-of-function mutations provide a selective advantage under the experimental conditions imposed on these cell populations.

One can also use this method to identify those genes in which mutations lead to a selective *disadvantage* to cells. For example, genes required for cell growth in culture or upon transplantation into animals (termed "essential genes") can be identified in CRISPR-Cas9-based genetic screens by comparing the relative abundance of sgRNA coding sequences in the starting retroviral library to their relative abundance after introduction into cells and a period of passage in culture or growth following implantation *in vivo* (Figure 12.45B). These "drop-out" screens can also be applied to cancer cell lines in an effort to identify genes that are specifically required in the context of a particular cellular genotype (e.g., in the presence of a mutant oncogene or tumor suppressor gene; see Figure 12.45B). Sometimes termed "synthetic lethal" screens, these experiments can identify genetic vulnerabilities in cancer cells of a certain mutant genotype that have the potential to guide the subsequent development of anti-cancer therapeutic drugs.

The CRISPR-Cas9 system has been further modified to be used to *modulate* gene expression rather than cause genetic mutation. Mutant Cas9 proteins engineered to lack endonuclease activity (thus preventing DNA cleavage) have been fused to protein domains that either stimulate or repress transcription (Figure 12.45C). Here sgRNAs serve to guide the Cas9 fusion proteins to promoters of genes of interest in order to increase the transcription of targeted genes [CRISPR-mediated activation (CRISPRa)] or decrease their expression [CRISPR-mediated inhibition (CRISPR)]. As with

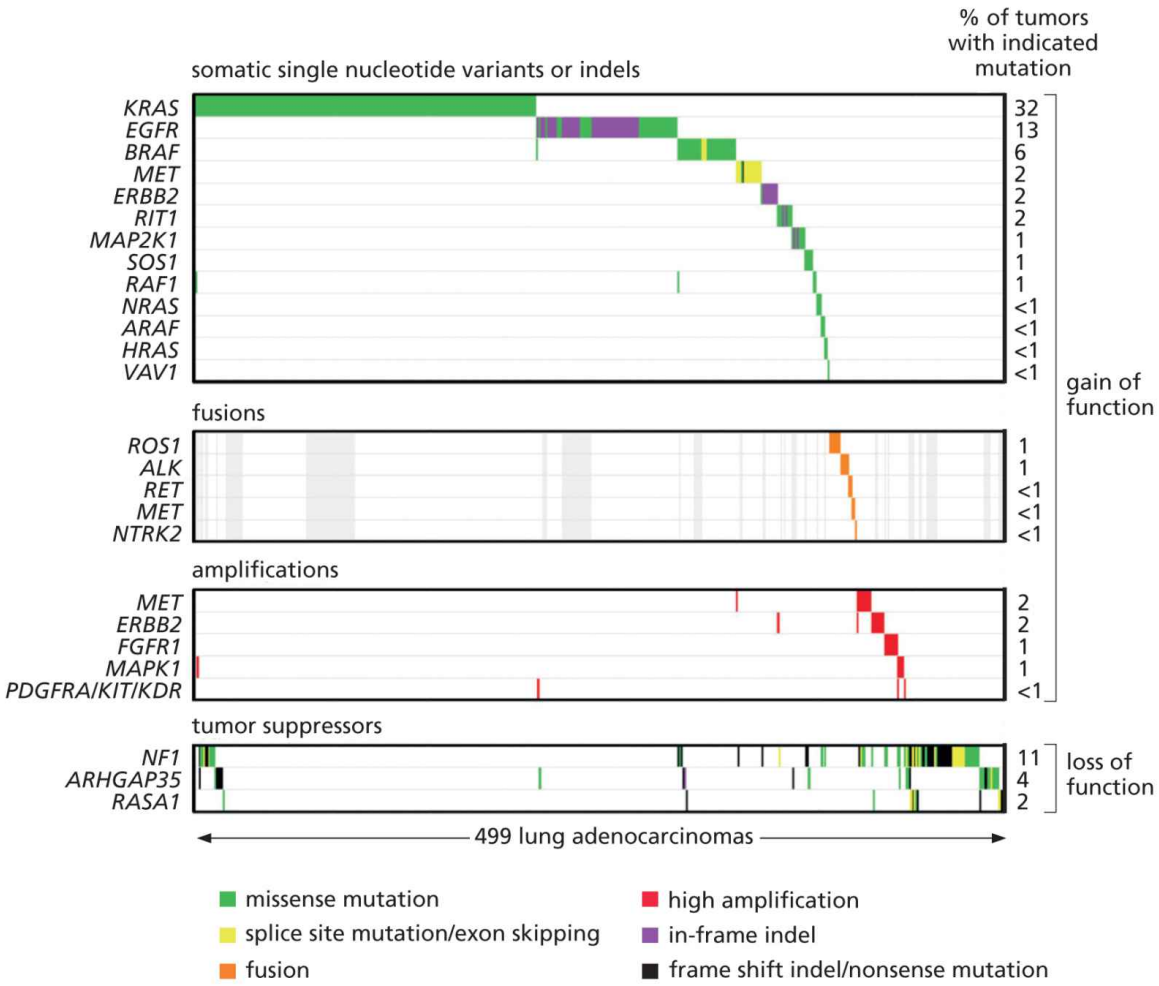
traditional CRISPR-Cas9 strategies described above, CRISPRa and CRISPRi can be used in studies focused on individual genes or in genome-wide screens using sgRNA libraries.

OceanofPDF.com

12.15 Cancer genomic studies reveal both inter-tumoral and intra-tumoral heterogeneity

Surveys of the genomes of multiple tumors of a given cancer type reveal considerable inter-tumoral heterogeneity, such that different tumors display different constellations of mutations of known or presumed driver genes. Some of this heterogeneity is explained by the number of alternative cellular signaling pathways that can be activated or inactivated to promote tumor formation and progression. Thus, “many roads lead to Rome” and different tumors may take somewhat different paths en route to full-fledged malignancy (see Figure 11.11).

As an example, recent studies that analyzed larger numbers of lung adenocarcinomas identified almost 40 genes that were mutated to a statistically significantly extent, including some that were found in just a handful of patients. Scanning the data from this and other large collections of tumors, one can conclude that very few tumors of a given type carry precisely the same combination of driver gene mutations and CNVs. At the mechanistic level, we can rationalize this inter-tumoral diversity by recognizing that within a given cellular regulatory pathway, there are multiple alternative genes that can be altered in order to yield the same pro-tumorigenic phenotype, as discussed in Section 11.3. For example, in the lung adenocarcinoma study cited above, genome sequencing revealed frequent mutation of components of the mitogenic signaling pathway that was described in Chapter 6, including those affecting the EGFR growth factor receptor gene, the K-Ras protein, and the GAP-related gene *NF1*. Because mutation of any one of these genes would be expected to activate this particular pathway, one might expect mutation of one, but not multiple, members of this group of genes within a given patient’s tumor genome. This type of mutual exclusivity of cancer gene mutations is evident in large-scale cancer genomics datasets (**Figure 12.46**), and indeed, these patterns of mutations can help investigators infer functional relationships between genes ostensibly operating in common signaling pathways.



A graphic describing Patterns of cancer gene mutations in 499 lung adenocarcinomas. The mutations are of four types, the first three of which involve gain of function and the last of which involves loss of function. The first type is somatic single nucleotide variants or insertions or deletions. These are mostly missense mutations, although in-frame insertions or deletions and splice site mutation or exon skipping also occur. Mutations of this type occur in the K R A S gene on 32 percent of tumors and progressively less often in 12 other genes. The second mutation type is fusion. This occurs in 5 genes. The third mutation type is high amplification. This occurs in a different set of 5 genes. The last mutation type, which involves loss of function rather than gain, is tumor suppressors. These occur in three genes and are a mix of missense mutations, splice site mutation or exon skipping, and frame shift insertion or deletion slash nonsense mutation.

Figure 12.46 Patterns of cancer gene mutations Large-scale cancer genomic studies often reveal pattens of cancer gene mutations displaying a

high degree of mutual exclusivity. This figure shows data from 499 lung adenocarcinomas, each of which carried an alteration in one or more of 26 genes encoding components of the mitogenic signaling pathway (*listed at left*); the different cancers samples are arrayed *left to right*. The presence of a mutation in a given gene is indicated by a *colored vertical line*. Different classes of mutations are shown in each of the 4 rectangles. The gain-of-function alleles are grouped in the *upper three rectangles*, which affect presumptive oncogenes, while the loss-of-function alleles, which affect presumptive tumor suppressor genes, are grouped in the *lower rectangle*. "Somatic single nucleotide variants" denotes point mutations, whereas "indels" indicates insertions or deletions. The specific types of mutation are denoted according to the color scheme at bottom. Within each rectangle the tumor samples with the most frequent mutant allele are arrayed to the *left* and the least frequent to the *right*. Note the high degree of mutual exclusivity involving mutations in this class of genes; that is, most tumors have only one mutation that activates oncogenes. Essentially all tumors lacking an identified oncogene-activating mutation carry instead a loss-of-function mutation in a tumor suppressor gene that normally negatively regulates the mitogenic signaling pathway (*lowest rectangle*). The mutual exclusivity is not absolute, however, as can be seen in the subset of tumors that have mutations in both an oncogene (*upper three rectangles*) and a tumor suppressor gene (*lowest rectangle*). (Adapted from J.D. Campbell et al., *Nature Genet.* 48:607–616, 2016. With permission from Nature.)

In addition to this inter-tumoral heterogeneity, genome sequencing studies have revealed extensive intra-tumoral heterogeneity, the product of clonal diversification occurring during the course of the multi-step formation of a single tumor, as we discussed in Section 11.6. By sampling distinct sectors of a tumor, cancer genome studies have revealed that some mutations are shared by most or all cells within the tumor. Such mutations are likely to have arisen early in disease progression and were under continued selective pressure to be maintained throughout the entire subsequent course of multi-stage tumorigenesis. These mutations are sometimes referred to as "truncal mutations" because they can be viewed as arising in the trunk of an evolutionary lineage tree that illustrates the genetic relationships of the cells forming the tumor. In contrast, some mutations can be found in only one sector of the tumor—an indication that they mark separate branches of an evolutionary tree (see Figures 2.17C and 11.16C). Moreover, the fine structure of such trees—the individual twigs—can also be

identified through the analysis of individual cancer cells isolated from tumors using single-cell DNA sequencing.

For an individual patient, the sequencing of their tumor DNA (taken from a surgical resection or even a biopsy) can identify mutated genes that may be appropriate for particular forms of targeted therapy. As discussed in Chapter 17, an increasing number of such therapies, involving both small-molecule drugs and monoclonal antibodies, have been developed to counteract the effects of specific mutant oncogenes. The use of these therapies can be tailored to those patients whose tumor carries a mutant form of a specific gene and sometimes even a particular mutation harbored by that gene. In all cases, drug targeting in response to the discovery of a truncal mutation and derived mutant gene product is most likely to yield a longer clinical response, whereas drug treatments that respond to one or another mutant branch are unlikely to elicit long-term responses, if any at all.

Another important application of cancer genomic studies is tracing the clonal origins of late-stage cancer colonies, that is, metastases, back to the primary tumor. This concept was introduced in Chapter 11, and we will return to it again in Chapters 14 and 17. For example, by comparing the genome or exome sequence of a series of metastatic lesions from a patient with the lineage information derived from the clonal architecture of their primary tumor, one can often identify a specific subclone within a primary tumor that seeded a given metastasis as well as the clonal relationships between distinct metastatic lesions present in the same patient. Some of the mutant alleles are present in one metastasis but not others and are therefore referred to as “private” (that is, not shared) mutations. Finally, similar cancer genomics-based analyses can be used to determine the clonal origins of a relapsed cancer following initial therapy. By comparing the sequence of a relapsed sample with the lineage information from an individual’s initially diagnosed primary tumor, it is often possible to identify the subpopulation of cells within the primary tumor that eventually gave rise to the cells that created the clinical relapse. We return to this subject in Chapter 17.

12.16 Synopsis and prospects

Genome instability has been inherent in life since the first cells appeared 3.5 billion years ago. In the intervening time, living organisms have continually struck a balance between too little and too much instability in their genomes. If they went too far in suppressing the rate at which mutations accumulated, Darwinian evolution, which depends directly on the continued generation of genetic diversity, would have ground to a halt. Conversely, if they allowed mutation rates to increase too much, their ability to reproduce and even their viability would have been seriously compromised. The relatively low level of genomic instability that operates in our cells—specifically those carrying the germ line—represents a compromise between these two conflicting needs.

This balance between too little and too much genetic instability does not need to be struck in the individual cells of our somatic tissues. In these, any genetic instability—mutability, as we have called it—is undesirable because it opens the door to neoplasia. The need to avoid neoplasia would seem to explain why evolution has worked hard to ensure that the genomes of our somatic cells are so stable.

Multiple layers of defense mechanisms operate to hold somatic mutation rates to extremely low levels. At the biological level, they are embodied in the organization of stem cells and their differentiated progeny. At the biochemical level, an array of enzymes and a variety of low–molecular-weight biochemical species are deployed to confront and neutralize mutagens before they succeed in striking the genome. And should damage be inflicted, either because mutagens have slipped through the outer defenses or because of errors in DNA replication, then a large group of DNA repair enzymes—the caretakers—lie in wait, always alert to structural aberrations in the double helix and its nucleotides. More often than not, these enzymes deal very effectively with incurred damage and succeed in restoring the DNA to its pristine state, erasing any sign that damage was ever sustained. In addition, a complex array of proteins ensures that mitosis and meiosis occur only when the chromosomes are aligned properly at the metaphase plate, thereby sustaining the euploid karyotype.

Our perception of DNA and its much-touted stability is changed by an understanding of these caretakers and their multiple roles in maintaining the genome. Previously, we depicted DNA as a rock-solid, unchanging entity within the cell, a unique island of stability sitting amid countless other molecules that are constantly forming and being degraded. Now, we realize that this portrayal was simplistic and an illusion. Like all other molecules in the cell, DNA is vulnerable to many types of damage. Its apparent stability reflects nothing more than a dynamic equilibrium, an ongoing battle between the forces of order and chaos. Any stability that chromosomal DNA does exhibit, and it

is considerable, represents a stunning testimonial to the elaborate array of caretakers that are always on watch, ready to fix even the most minor lesion in the double helix.

The implications of this dynamic equilibrium for cancer are simple and clear: if a breakdown of genomic integrity is an essential ingredient in forming human tumors, it can result most readily from weakening of the ever-vigilant repair machinery and its controllers.

Our initial encounter with the breakdown of genomic stability came in Chapter 9, where we learned that the p53 tumor suppressor protein is occasionally called the "guardian of the genome," because cells lacking p53 function acquire a variety of genetic defects at an elevated rate. In large part, this increased mutability, which includes alterations in DNA sequence as well as changes in karyotype, does not reflect p53's role in directly maintaining the genome. Instead, the loss of p53 function creates an environment that is permissive for the survival of mutant cells. In the present chapter, we changed our focus by posing a different question, one that goes beyond p53 inactivation: If p53 loss permits mutant (and highly mutable) cells to survive, how, precisely, do the mutations acquired by these cells arise in the first place?

These mutations occur frequently during tumor progression, and elevated mutability is increasingly accepted as an important element of cancer pathogenesis. As discussed in Section 11.4, a departure from DNA's highly stable state may be essential for the formation of human cancers. This notion derives from calculations of the rates at which mutations accumulate in normal cells and an estimate of the number of genetic alterations that are needed in order for tumor progression to reach completion.

Without such increased mutation rates—so the thinking goes—the time intervals between clonal successions (see Section 11.4) would be far too long. Actually, the readings from the last chapter and this one suggest at least two alternative ways by which clonal successions can be accelerated during multi-step tumor progression. Tumor promoters (including endogenous processes such as inflammation) can compress the time between clonal successions; alternatively, acceleration can be achieved by the destabilization of the genome, as described here. Because the two complex processes often work hand in hand, mathematical modeling of tumor progression becomes very difficult.

We now realize that mathematical analyses of multi-step tumor formation depend on so many quantitative assumptions that their major predictions represent little more than an inspired speculation. As is almost always the case in biology, observations of living systems speak more loudly than theorizing: recent high-throughput sequencing analyses of tumor cell genomes indicate enormous variability in the rates with which various types of tumors accumulate mutations as they pass through multi-step tumor progression. Although increased mutability clearly accelerates the rate of tumor

progression (thereby leading to increased tumor incidence), it is clear that certain tumors arise in the absence of large numbers of mutations, as discussed below.

Cancer stem cells (CSCs) are present in many and perhaps all tumors. Their presence complicates our understanding of how mutations accumulate within tumor cell genomes. Because of their ability to self-renew, the lineages of CSCs within tumors are likely to persist long after their more differentiated descendants have entered into post-mitotic states or died; accordingly, CSCs are likely to serve as the long-term repositories of the tumors' genetic information. Hence, advantageous mutations must sooner or later be introduced into the CSC pools in order to ensure transmission to future generations of cancer cells.

This scenario is complicated because SCs in general, and CSCs in particular, are present in relatively small numbers within normal and neoplastic tissues. Because the likelihood that a population of cells will sustain a mutation is directly proportional to the size of this population, pools of CSCs are relatively unlikely (mathematically) to directly acquire the mutations that drive tumor progression forward. This situation creates a dilemma that is at present unresolved: specialized, still-undiscovered mutagenic mechanisms may destabilize the genomes of CSCs. Alternatively, and more likely, most advantageous mutations strike the genomes of transit-amplifying/progenitor cells within tumors, and the latter cells then introduce their advantageous mutations back into the CSC pool by spontaneous dedifferentiation (**Supplementary Sidebar 11.6**).

Unfortunately, all discussions of cancer cell mutability rest on shaky foundations. Measurements of mutability—number of mutations sustained per cell generation—depend on knowledge of the number of successive cell generations through which a cell lineage has passed since its initiation. At present, we have only very limited information on this critically important parameter (see, for example Figure 10.21A), undermining any attempts at demonstrating heightened mutability definitively.

These discussions of mutation rates generally focus on the submicroscopic changes in genome structure created by defective BER and NER—lesions that are far too small to affect the karyotype of cancer cells. However, as we read in this chapter, cell genomes are also affected by changes occurring on a far larger scale—changes that scramble overall chromosome structure and thereby alter the karyotype of a cell. Such karyotypic alterations are found in the cancer cells from the great majority of solid tumors. In Section 10.4, we read that telomere erosion may be responsible for much of this instability through its ability to trigger breakage–fusion–bridge cycles. Surely, yet other molecular mechanisms will one day be found to contribute to the karyotypic chaos frequently encountered in cancer cells.

Between the minute lesions left behind by imperfect BER and NER and the large-scale rearrangements generated by telomere collapse are genomic changes resulting from the process of replication stress, in which the unbalanced mitogenic signals operating in many cancer cells cause uncoordinated firing of replication origins and frequent replication fork collapse of the sort depicted in Figure 12.8. The repair of these collapsed replication forks is often imperfect, providing an explanation for many of the local amplifications and deletions that are present in the genomes of solid tumors (see Figure 12.44). Strikingly, signs of replication stress, in the form of activated DNA repair proteins, are already apparent relatively early in multi-step tumor progression (for example, in dysplastic tissues), long before frankly neoplastic growths have emerged.

Although there seem to be common underlying biochemical principles governing how diverse types of human cells are transformed to a neoplastic state (see Section 11.9), the genetic routes taken by various cells throughout the body to reach this state bear little resemblance to one another, at least as gauged by measurements of copy number change.

Independent of its origins, increased mutability forces us to confront another reality: the resulting disruption of cancer cell genomes is a double-edged sword, because it places these cells at great risk. Frequent errors in DNA replication and in chromosomal segregation make these cells especially vulnerable to death because of lethal, unrepaired defects in their genomes. Indeed, it is possible that much of the attrition of cancer cells during each cell generation (see Figure 10.4D) occurs because of frequent genomic catastrophes that are incompatible with continued cell survival. Hence, cancer cells must weave a fine course between too much and too little mutability, and certain cancer cell types may actually benefit from maintaining their genomes in a relatively stable configuration.

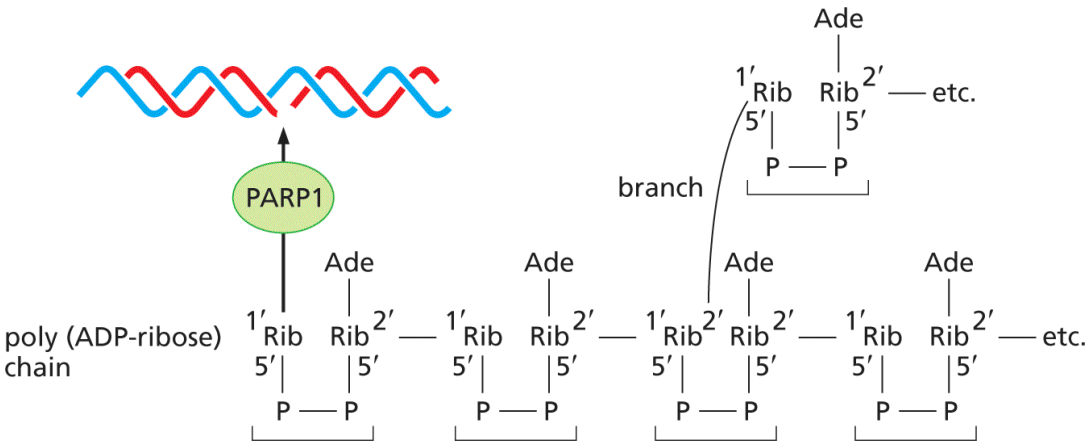
Actually, cancer cells may be exposed to a second danger because of their defective DNA repair apparatus: they may be especially susceptible to certain forms of chemotherapy. We already encountered one example of this in the vulnerability of many gliomas to killing by temozolomide, an alkylating chemotherapeutic. Those tumors that shut down expression of their *MGMT* gene during their initial formation, ostensibly because doing so increases mutability and accelerates tumor progression, pay a price later, because they have lost the ability to remove the toxic methyl groups added to their DNA by this drug (see Section 12.7).

Another example of such increased vulnerability comes from breast and ovarian tumors that have lost BRCA1 or BRCA2 function. The resulting loss of an ability to repair covalent inter-strand cross-links, which depends on homology-directed repair (HDR), makes certain ovarian carcinomas especially sensitive to killing by platinum-based chemotherapeutics (see Section 17.2). Consistent with this, ovarian cancer

patients carrying germ-line *BRCA1* or *BRCA2* mutations have longer progression-free survival following platinum therapy than do those identically treated patients with sporadic (that is, nonfamilial) tumors in which BRCA1/BRCA2 function is usually intact.

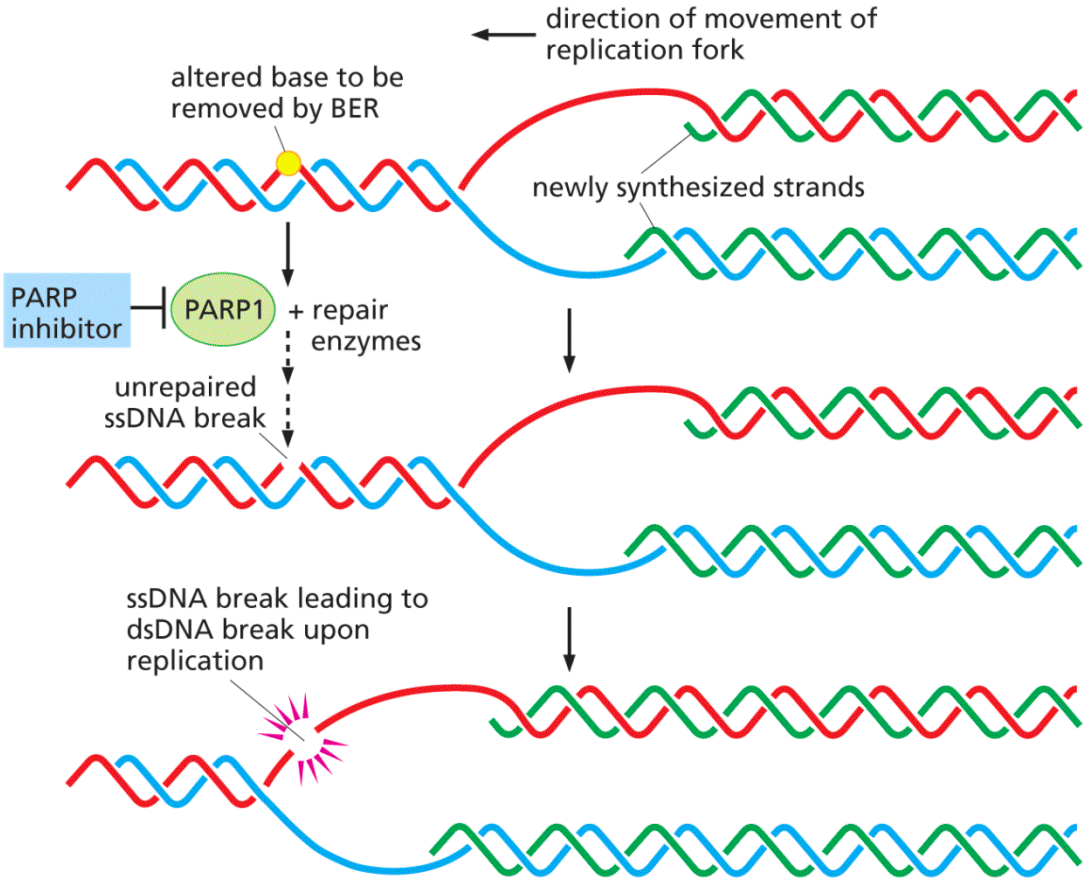
A more subtly crafted therapeutic strategy derives from examining in great detail the mechanisms of base-excision repair (BER) and homology-directed repair (HDR). As we learned earlier, a relatively small number of double-strand breaks (DSBs) occur in each cell cycle because of the fragility of the replication fork (see Figure 12.8); the repair of these lesions usually depends on HDR. In fact, an alternative and far greater threat comes from the thousands of mutant bases that are created every day by endogenous processes, notably oxidation; the resulting DNA lesions are healed by BER. As described earlier (see Figure 12.20A), BER generates single-nucleotide gaps (through both BER pathways) and thus single-strand breaks (SSBs) that must be filled by a DNA polymerase and then sealed by a DNA ligase.

DNA repair enzymes involved in BER are recruited to SSB sites by the actions of PARP1 [poly-(ADP ribose) polymerase-1]. This enzyme binds to these breaks and proceeds to ADP-ribosylate itself and possibly neighboring proteins as well; **Figure 12.47A**. The resulting poly-ADP tails thereafter serve as docking sites for recruiting the repair enzymes needed to fix the SSBs; hence, when the PARP1 enzyme is inhibited pharmacologically, SSBs persist. These unrepaired SSBs generate a far more serious problem—DSBs—when a replication fork passes through during a subsequent S phase (see Figure 12.47B).



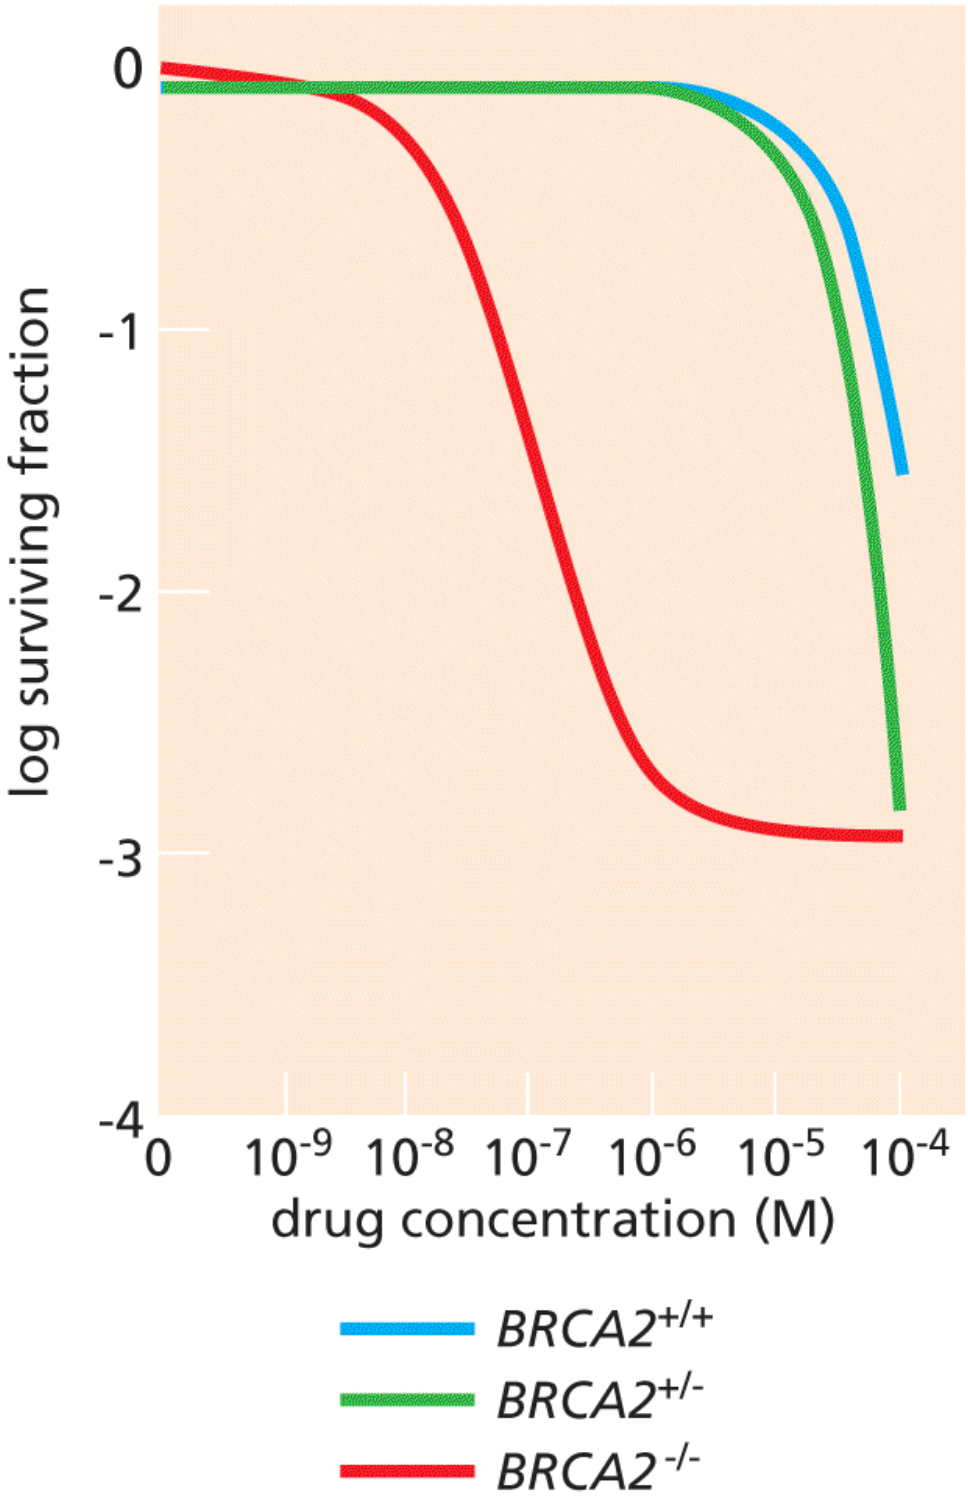
A PARP 1 attaches to a point where one strand of a double-stranded D N A has broken. Attached to back end of the PARP 1 is a chain of repeating A D P-ribose elements. Each A D P-ribose is a short chain consisting of a ribose with a 1 prime end and a 5 prime end, followed by a phosphate, followed by another phosphate, followed by a ribose with a 5 prime end and a 2 prime end

followed by an adenine. The 1 prime ribose end of each element attaches to the 2 prime ribose end of the element before. Through attachment to both the first and the second ribose of an element, branching may occur.
(A)



A replication fork in progress. On the part of the double-stranded original D N A that has yet to be unwound, there is an altered base to be removed by B E R A PARP inhibitor blocks the action of PARP 1 and repair enzymes that together would heal the resulting break, and so the break remains unrepaired. When the replication fork reaches the break in the single strand, the result is a break of double stranded D N A.

(B)



A line graph with surviving fraction on the logarithmically scaled vertical axis and increasing drug concentration on the logarithmically scaled horizontal axis. Three lines show that B R C A 2 plus plus and B R C A 2 plus minus cells only begin to die when the concentration exceeds 10 to the minus 6

moles per liter. By contrast, B R C A 2 minus minus cells begin to die as the concentration approaches 10 to the minus 8 moles per liter.
(C)

Figure 12.47 Killing of BRCA2-negative cells by an anti-PARP drug The reliance of BRCA1- and BRCA2-negative human breast cancer cells on a redundant HR pathway mediated by poly-(ADP ribose) polymerase-1 (PARP1) makes these cells especially vulnerable to killing by an anti-PARP drug. (A) PARPs constitute a family of related enzymes that act by generating repeating branched polymers of as many as 200 residues (*brackets*) each. These residues are attached both to the PARP enzymes themselves (*green oval*) and to other proteins involved in effecting biochemical responses (*not shown*); these chains may be branched as shown here. In the case of PARP1, it binds to ssDNA breaks (SSBs) and ADP-ribosylates itself; its poly-ADP chains then attract a series of repair enzymes that may be ADP-ribosylated by PARP1 and thereafter proceed to complete various steps of base excision repair (BER). (B) Such SSBs are created routinely by oxidized bases, which are usually removed by BER. Here, an oxidized base (*yellow*) should be excised and the DNA repaired through the actions of PARP1 and recruited repair enzymes. However, in the presence of a PARP1 inhibitor, these other enzymes are not recruited, BER cannot proceed to completion, and the resulting SSB will be converted to a double-strand DNA break (DSB) when a replication fork moves through during the next S phase. This break can be efficiently restored to a wild-type configuration only through homology-directed repair (HR), which is defective in BRCA1- and BRCA2-mutant cells. Failure to repair a DSB will often lead to cell death. (C) Cultured mouse ES (embryonic stem) cells of three genotypes were treated with KU0058948, a PARP1 inhibitor. The $BRCA2^{+/+}$ (*blue*) and $BRCA2^{+/-}$ (*green*) ES cells were killed only by very high drug concentrations, whereas the $BRCA2^{-/-}$ ES cells were killed by the drug at concentrations almost 1000-fold lower (*red*). (C, from H. Farmer et al., *Nature* 434:917–921, 2005. With permission from Nature.)

All this suggests an interesting therapy: shut down the PARP enzyme in *BRCA1*- or *BRCA2*-mutant cells with a pharmacological inhibitor. Resulting SSBs will be converted to DSBs during replication, and these DSBs, which are usually repaired by HDR, will not be repairable in cells lacking HDR function (from loss of BRCA1 or BRCA2 function; see Figure 12.47B). Lethal DSBs will then accumulate in large numbers, triggering cell death. Indeed, PARP1 inhibitors have been employed successfully in the clinic for patients with ovarian and breast cancers.

The scenario of acquired genetic instability seems to create a logical quandary: almost all the genetic alterations that occur during tumor progression appear to confer some

immediate growth or survival benefit on the cells that acquire them. Many of the earlier chapters in this book documented the specific growth advantages resulting from each of these alterations. As described in a previous chapter, these dynamics cause one to speculate that tumor progression is a process that is analogous to Darwinian evolution (see Section 11.4). However, unlike many traits acquired by cancer cells, the trait of increased genomic instability does not provide an immediate payoff—no marked advantage in proliferation or survival. Instead, acquisition of this trait represents a "long-term investment"; that is, a benefit will only be realized by the distant descendants of this cell.

We can understand this long-term advantage in the following way. Cell clones that have acquired some of the initial genetic alterations leading to cancer seem to arise with great frequency throughout the body's tissues. Nearly all remain in a dormant, premalignant state for an entire human lifetime, unobtrusive and unthreatening, because their stable genomes preclude the acquisition of the additional mutations that would render these cell clones truly dangerous. On rare occasions, however, a cell in one or another of these already-initiated clones acquires an alteration in one of its caretaker genes. Now, for the first time, this cell and its descendants have the opportunity to tinker with their genomes by testing new combinations of genetic elements and new sequences, some of which will allow them to resume their advance down the long road of tumor progression. By opening a floodgate of genetic changes, clones of would-be cancer cells are destined, over the long term, to prosper, while their brethren, lacking this instability, are likely to remain unchanged and indolent for decades.

As we learned in this chapter, a variety of familial cancer syndromes are attributable to the inheritance of mutant forms of genes specifying important components of the DNA repair apparatus. Genomic instability or a tendency toward genetic instability is already implanted in all the cells of such genetically afflicted individuals. In these cases, genetic instability is not an acquired attribute—unlike the situation operating in the most human cancers.

On some occasions, such as those arising in the many subtypes of xeroderma pigmentosum (XP), both copies of a critical DNA repair gene are inherited in defective form. This nullizygous state leaves all the cells in the skin without the means to cope with the UV-induced formation of pyrimidine dimers. In other cases, such as hereditary non-polyposis colon cancer (HNPCC), an individual inherits a defective gene copy of a mismatch repair gene, and the remaining copy is then discarded in various somatic cells through a loss-of-heterozygosity (LOH) event.

The familial cancer syndromes that have been identified to date, including those involving heritable defects in DNA repair, reflect the actions of strongly penetrant germ-line alleles. Such alleles ensure that individuals carrying them will, with high

likelihood, manifest obvious disease at some point in their lifetimes. However, the known familial cancer syndromes may well represent only the small tip of a very large iceberg. Thus, a variety of less penetrant, mutant alleles of the genes involved in genome maintenance may be widespread in the human gene pool. Each of these alleles may confer only a slightly increased risk of cancer, but one that is not readily apparent when studying individual families and their susceptibilities to various types of cancer. Consequently, a significant portion of many commonly occurring types of human tumors, such as breast cancer (see, for example, **Supplementary Sidebar 12.12**), may be associated with inheritance of these still-unknown germ-line alleles.

Our thinking about the family cancer syndromes associated with inheritance of defective caretaker genes is confounded by one major mystery: the majority of these diseases involve only a very narrow subset of tissues in the body, even though we have every reason to believe that the services of affected caretakers are required ubiquitously. Why, for example, do inherited mismatch repair defects have such a strong preference for causing tumors in the intestinal tract? The puzzle is drawn even more starkly in the case of breast cancer. By one account, inherited defects in at least seven genes that are involved, directly or indirectly, in the maintenance of genomic integrity generate substantially increased risks of mammary tumors in humans. These include the *BRCA1* and *BRCA2* genes, two genes encoding BRCA1-associated proteins (*BARD1* and *BACH1*), *CHK2*, *p53*, and *ATM* (which specifies one of the kinase sensors that activate the p53 alarm following DNA damage; see Section 9.7).

Of course, this is not the first time that we have encountered a puzzle of this sort. Recall, for example, the behavior of inherited mutant alleles of the retinoblastoma gene, *Rb*. This gene specifies a protein, pRb, that appears to function in almost every cell type in the body as the critical controller of advance through the cell cycle, yet children who inherit defective *Rb* alleles are predisposed peculiarly to a rare eye tumor when they are very young and to bone tumors as adolescents (see Sections 7.3–7.5).

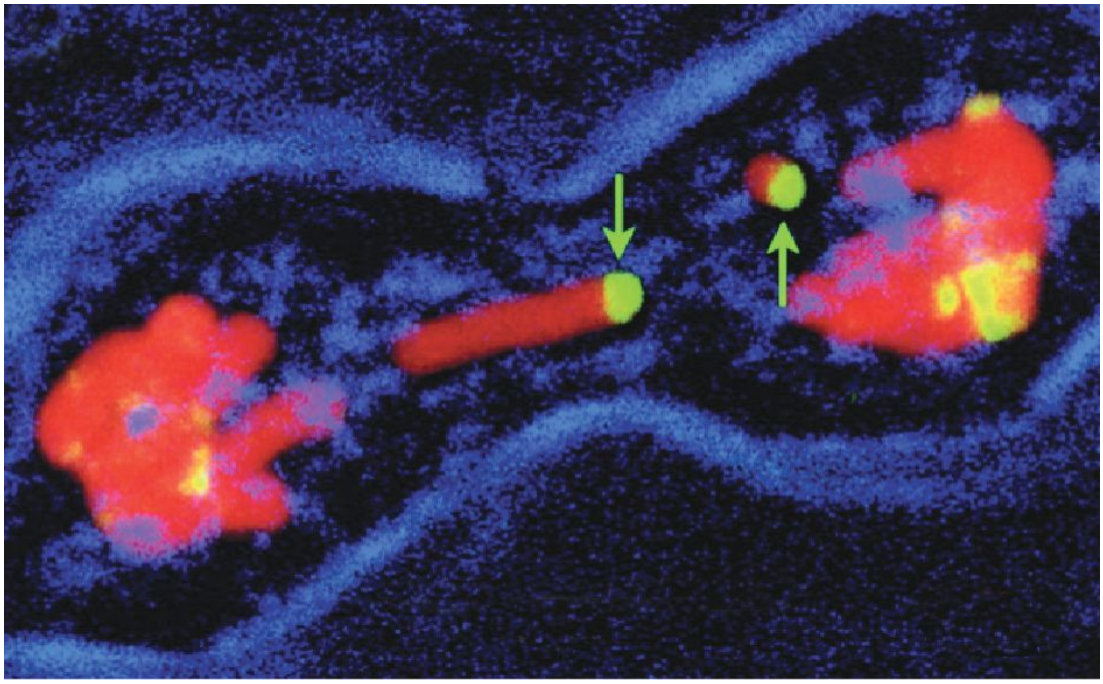
To date, our perceptions about the genes that are responsible for mammalian genome maintenance have been shaped largely by bacterial and yeast genetics. These disciplines have yielded a wealth of genes that are essential for genome maintenance in these microbes and, by extension, in our own genomes as well. For example, the resonance between yeast genetics and its harvest of mismatch repair genes and the HNPCC syndrome led to the rapid enumeration of six human genes and proteins that are responsible for this type of genome maintenance.

Importantly, microbial genetics may have netted only a portion of the genes in the human genome that are responsible for maintenance of its integrity. How large, then, is the universe of human caretaker genes and proteins? The sequencing of the yeast genome begins to give us a feeling for this number. Recent estimates indicate that this genome consists of approximately 5600 distinct genes. Of these, 153 are classified as

being involved in DNA replication and repair, and 88 seem to be involved exclusively with repair. Many of the genes encountered in this chapter are metazoan inventions, which suggests that the size of the cohort of human genes involved in these processes is likely to be much larger. Indeed, by 2001, more than 130 DNA repair genes had already been identified in the human genome; by 2004, the number approached 150, and it reached 176 in 2012. Hence, genes and proteins that play critical roles in the maintenance of the genome and thus in the suppression of cancer are being discovered continually, some in very unexpected places (**Sidebar 12.12**).

Sidebar 12.12 Histones function to reduce cancer risk

For many decades, histones and the nucleosomes that they form were depicted as static structural components of chromatin that serve to package and compact the chromosomal DNA. Beginning in the 1990s, it became clear that covalent modification of histones is critical in making regions of chromatin more or less hospitable for transcription (see Section 1.8). Even more recently, histones have been found to play a dynamic role in DNA repair. H2AX is a variant of the abundant H2A histone that is present in virtually all nucleosomes. H2AX constitutes about 15% of the H2A-like histones in cells and substitutes for H2A in some nucleosomes (see also Figure 1.16). When a double-strand break is sustained in chromosomal DNA, H2AX molecules (but not the other histones) become phosphorylated, primarily by the ATM and ATR kinases, on a specific serine residue located four amino acid residues from the carboxyl-terminal end; such phosphorylated H2AX is observed in a large chromosomal region (involving as much as 2 megabases of DNA) flanking the break (**Figure 12.48**). (These two kinases are also responsible for phosphorylating and thereby mobilizing p53; see Figure 9.12.) The phosphorylated H2AX (usually termed γ-H2AX) attracts DNA repair proteins, such as BRCA1 and NBS1, as well as at least four others that aid in the task of rejoining the DNA ends (see also Figures 12.28 and 12.31).



A fluorescence microscopy image of a cell approaching the end of the cell division process. The cell contains two widely separated nuclei, not yet fully self-contained, which appear bright red. As the cell's dark blue outline reveals, the cell is peanut-shaped due to a narrowing in the middle, where it is about to cleave in two. However, a loose fragment of thickened D N A lies across this cleavage zone. It is red but has a bright green end. Another, much shorter loose fragment of D N A also appears as red with a green end.

Figure 12.48 γ-H2AX and double-strand DNA breaks The creation of dsDNA breaks by various mechanisms results in the phosphorylation of H2AX histone (a variant form of histone H2A), yielding γ-H2AX. Like H2A, H2AX participates in the formation of nucleosomes. Chromosomal regions as large as two megabases that flank a dsDNA break are found to carry copies of γ-H2AX. In the absence of γ-H2AX , critical DNA repair proteins, including NBS1 and BRCA1 (see Figure 12.31), fail to be recruited to the site of dsDNA breaks. In the image shown here, cells of the Indian muntjac, used because of their small number of chromosomes, have been irradiated with a low dose (0.6 Gy) of X-rays. Late anaphase cells were then stained for γ-H2AX (*yellow-green, arrows*) and for chromosomal DNA (*red)*. The outlines of the dividing cell are seen in blue. Note the staining of γ-H2AX at the broken ends of a chromosome. (From E.P. Rogakou et al., *J. Cell Biol*. 146:905–916, 1999. With permission from Rockefeller University Press.)

Mice that have lost the H2AX gene (because of germ-line inactivation) are viable but stunted in growth. Their cells are unable to execute homology-directed repair (HDR;

see Section 12.9) and are prone to accumulate structurally abnormal chromosomes. Mice lacking both the H2AX and p53 proteins are highly prone to both hematopoietic and solid tumors. Even mice lacking one copy of the H2AX gene in the context of p53 deficiency show significantly increased rates of lymphomas.

These responses illustrate how highly complex the DNA repair process is, and how defects in any of its individual components—many still unidentified—open the door to the appearance of cancer. Provocatively, the human H2AX gene maps to a chromosomal region (11q23) that frequently undergoes loss of heterozygosity and/or deletion, creating the possibility that this gene and encoded histone are frequently shed by human cells en route to malignancy.

This area of cancer research is also having a profound effect on our understanding of another, seemingly unrelated biological process—aging. At least ten distinct premature aging syndromes—each a form of progeria—have been traced to inherited defects in one or another component of the DNA repair system. Individuals suffering from these syndromes often show many of the phenotypes of the aged by the time they reach adolescence. These clinical effects of defective DNA repair provide compelling indications that much of the normal aging process will one day be traced to genetic damage that we accumulate in our stem cells throughout life; their progressive attrition seems to lead to the inability of tissues to renew themselves, yielding precisely the changes observed in the aged. Consequently, cancer and aging may be found to share a common root—the progressive deterioration of our genomes as we get older. And both cancer development and aging may one day be forestalled by treatments and lifestyles that protect our genomes from the ongoing attacks that they suffer, decade after decade, deep within our cells.

The nature and pace of cancer research has changed markedly over the past decade as a result of a series of technological developments in the area of cancer genomics. We have discussed the importance of these approaches to developing comprehensive mutational landscapes of most types of human cancer, including single nucleotide mutations, small-scale indel mutations, larger-scale mutations, and copy number variation. Today, whole-exome and whole-genome analysis of cancer specimens from human patients and pre-clinical models are routinely performed, allowing a remarkably complete view of accumulated genomic alterations associated with tumor development. As discussed in this chapter, understanding the patterns of mutations across the genome in different types of cancer can provide important insights into the etiological factors that influence tumor development, including exposure to exogenous carcinogens as well as defects in DNA damage repair pathways. In Chapter 17, we discuss the use of human cancer genomic studies in guiding the use of specific therapies that are targeted against particular mutant genes. Increasingly, oncologists

order genome sequence analyses for their patients' cancers precisely for this purpose, and this practice is expected to become routine in the not-too-distant future.

Mutations in protein-coding genes—whether they be in cancer drivers or passengers—can produce neoantigens that distinguish the cancer cells bearing these mutations from normal cells, making them visible to components of the adaptive immune system and, in turn, possible targets for attack by various types of immunotherapy, as described in Chapter 16. This provides the rationale for ongoing, extensive efforts to use cancer genome analyses of a patient's tumor DNA to predict which mutations would be expected to yield "strong antigens" that are highly likely to attract the attention of the immune system and, in turn, might be exploited to produce therapeutic cancer vaccines. We will revisit some of these issues in Chapter 16. At the same time, the vulnerabilities of cancer cells arising from acquired defects in their genome maintenance machinery are being explored with the hope of spawning an entire new generation of anti-cancer therapeutic strategies.

Glossary

replication stress
: A physiological cell state that occurs when the normal coordination of DNA synthesis is perturbed, often in response to stalled replication forks, resulting in, among other consequences, the collapse of replication forks arising because of breakage of the persisting ssDNA and the resulting formation of dsDNA breaks. *See also* **replication fork**, **stalled replication fork**.

progeria
: Syndrome in which an individual undergoes premature or accelerated aging.

OceanofPDF.com

Key concepts

- The structural integrity and thus low mutability of DNA depends on a large and complex set of biological and biochemical mechanisms that work to ensure that somatic mutations accumulate in tissues at very low rates.
- Some of the mechanisms depend on the organization of tissues, in which the long-lived cells (the stem cells) are protected from genetic damage while the short-lived cells (the transit-amplifying and differentiated cells) are vulnerable to such damage but are soon discarded.
- Misincorporated bases generated by errors in DNA replication can contribute to the burden of accumulated mutations. The numbers of these alterations are held down by the low error rates of DNA polymerases together with an array of error-correcting proteins, such as those involved in mismatch repair. Inherited defects in mismatch repair proteins can lead to increased susceptibility to certain types of cancer, notably hereditary non-polyposis colon cancer.
- Cell genomes are under continuous attack by a variety of chemically reactive molecules, many of them deriving from the cellular process of oxidative phosphorylation and the resulting reactive oxygen species that are generated as by-products of this process. Cell genomes may also suffer spontaneous chemical alterations, which affect DNA bases at a low but significant rate.
- In addition, the genomic DNA of cells can be attacked by mutagenic molecules of foreign origin. Such xenobiotics and their chemically reactive derivatives may come from pollutants and, to a far greater extent, from commonly consumed foodstuffs.
- Cells attempt to detoxify many of these compounds before they can attack genomic DNA. However, the side products of these reactions may actually be more reactive and mutagenic than the initially introduced molecular species.
- If the attacking mutagenic agents succeed in damaging DNA, an elaborate array of proteins involved in base-excision and nucleotide-excision repair lies in wait in order to remove most damaged bases.

Inherited defects in base-excision repair proteins can lead to various types of cancer susceptibility.

- Other types of DNA damage include double-strand DNA breaks, which can be created by X-rays or, more commonly, by accidental DNA breakage at replication forks.
- Double-strand DNA breaks can be repaired in the G_1 phase of the cell cycle by nonhomologous end joining or in the S and G_2 phases by homology-dependent repair. Inherited defects in double-strand DNA repair can explain the breast and ovarian cancer susceptibility among patients inheriting mutant *BRCA1* or *BRCA2* germ-line alleles.
- Genomes may be scrambled by mechanisms that affect the karyotype of cells. One class of such alterations includes those that affect chromosomal structure, including the translocations that are created by the fusions of unrelated chromosomal arms to one another. Such fusions seem to be commonly triggered by eroded telomeres and collapsed replication forks, both of which generate double-strand DNA breaks.
- Changes in chromosome number are also common in cancer cell genomes and appear to facilitate the accumulation of genes in proportions that favor the proliferation and survival of these neoplastic cells. Many of these changes derive from defects in the mitotic apparatus and its regulators, notably the centrosomes and proteins involved in connecting spindle fibers with chromosomal kinetochores.
- The advent of high-throughput genome sequencing technologies has allowed in-depth analysis of cancer genomes and a comprehensive understanding of the array of mutations that contribute to tumor development.
- The specific nature of mutations in cancer genomes and the sequence context in which they occur can provide clues to possible carcinogen exposure or defects in DNA repair processes that contributed to tumor development.

Thought questions

1. What types of evidence suggest that karyotypic alterations of cell genomes are not absolutely essential for neoplastic transformation?
2. When calculating the rates of mutation required for multi-step tumor progression to reach completion, what parameters must one know in order for such a calculation to accurately describe the actual biological process?
3. How does our understanding of defective DNA repair processes in tumor cells make possible the development of new anti-cancer therapeutic strategies?
4. In which ways do the defectiveness of p53 function and resulting defects in apoptosis and DNA repair facilitate the forward march of tumor progression?
5. What evidence implicates mutagenic chemicals originating outside the body in the pathogenesis of human cancers? How can one gauge their contribution to human carcinogenesis compared with that of mutagens and mutagenic processes of endogenous origin?
6. How do defects in various cell cycle checkpoints allow for accelerated rates of the accumulation of mutations?
7. How do the biological properties of stem cells help to reduce the rate at which tissues accumulate mutant genes?
8. How does the existence of cancer stem cells affect the calculations of the rate at which mutations must be accumulated in order to allow multi-step tumor progression to advance?
9. How does the genetic heterogeneity in the human gene pool affect the functioning of various types of biological defenses that have been erected to prevent the accumulation of mutant alleles in human somatic cells?
10. How does mutual exclusivity in cancer gene mutations in a given cancer type inform the functional relationships between genes in a biological pathway?
11. What does the observation of extensive inter-tumoral heterogeneity in cancer gene mutations for a given cancer type imply with respect to the nature of the pathways required to cause oncogenic transformation?

12. How can cancer genomics allow scientists to investigate intra-tumoral heterogeneity in cancer?

Supplementary Sidebars

Supplementary Sidebar 12.1 Hematopoiesis is a model for the organization of many kinds of tissues

Our understanding of the organization of a variety of self-renewing tissues derives in large part from the study of the organization of hematopoiesis (**Figure S12.1**). Experiments performed in the 1960s and 1970s led to a number of concepts that remain deeply embedded in our thinking to this day. Among them are the following:

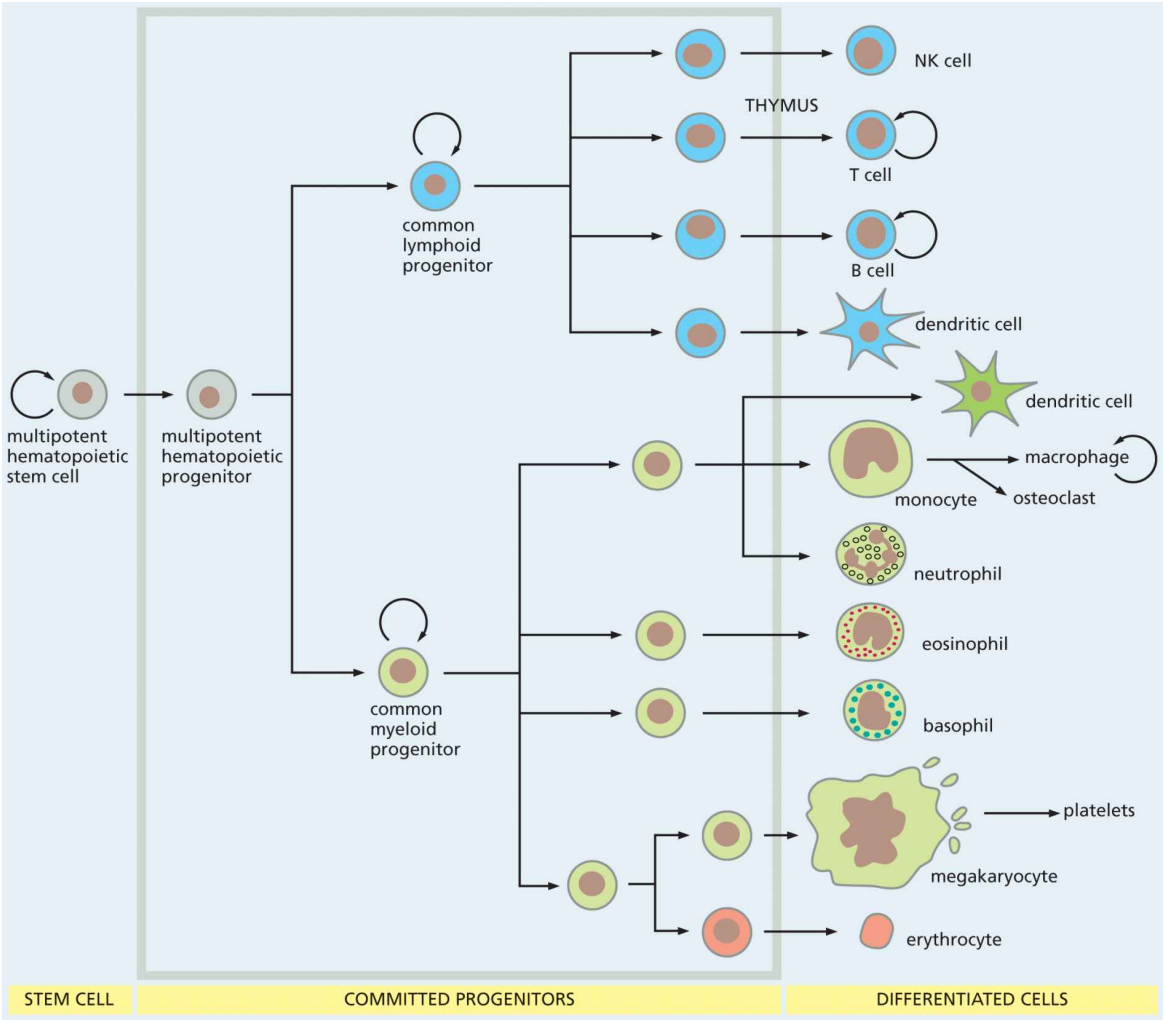

Figure S12.1 Hematopoietic differentiation Our current understanding of hematopoietic cell differentiation teaches a number of lessons. (1) It indicates that a single cell type—the multipotent hematopoietic stem cell (HSC; *left*)—is capable of generating virtually all of the cell types in the blood and in the immune system. (2) It shows that a single stem cell type can spawn multiple types of "committed" stem progenitor cells, in this case, the two stem cell types that are committed to generating lymphoid and myeloid cell types. (3) It shows that self-renewal ability (*curved arrows*) is not confined to a single stem cell type in a tissue; instead, in certain tissues such as this one, "committed progenitors" (i.e., the common lymphoid and myeloid progenitor cells shown here) assume the role of the stem cells in these two major hematopoietic lineages; note as well that some of their descendants have self-renewal capability. The fact that a patient suffering from CML (chronic myelogenous leukemia) often exhibits several distinct differentiated lymphoid and myeloid cell types carrying the Ph^1 chromosome (and a *BCR-ABL* translocation) provides strong indication that this abnormal chromosome was initially formed in some multipotent HSC or progenitor and that this mutant configuration was eventually introduced into the multipotent hematopoietic stem cell compartment. (From B. Alberts et al., Molecular Biology of the Cell, 7th ed. New York: W.W. Norton, 2022.)

---

1. A primitive, relatively undifferentiated cell type can spawn progeny that ultimately generate multiple distinct differentiated cell types.
2. These primitive cell types reside long-term within a tissue and, upon dividing, ensure that at least one of their daughters remains a stem cell, while the other may exit the stem cell state and begin a process of differentiation. The generation of two phenotypically distinct daughter cells is termed *asymmetric division*.
3. This generation of a daughter cell that is indistinguishable from its mother represents the process of *self-renewal*, guaranteeing that the pool of stem cells in a tissue is not depleted by such cell divisions.
4. The non-stem cell daughter that arises following division of a stem cell may not immediately undertake to differentiate, but instead may participate in a succession of symmetric cell divisions, generating more cells like itself. Such cells, which are often termed either *transit-amplifying* or *progenitor* cells, may increase exponentially, ensuring that a single cell division of the original mother cell—the stem cell—yields dozens if not hundreds of progenitor cell progeny. Therefore, the stem cell need only occasionally pass through a cycle of growth and division, minimizing the likelihood that the

genome of this cell and its stem cell descendants will be susceptible to the genetic accidents that accompany active cell division.

5. After a certain number of divisions, the progenitor cells may then generate fully differentiated progeny that undertake the work of the tissue. Because these differentiated cells often have entered into a post-mitotic state, most of the mitotic activity in a tissue is often associated with the transit-amplifying/progenitor cell population.

The model presented in Figure S12.1 was strongly supported by experiments in which a mouse that had been lethally irradiated, thereby depleting its hematopoietic cells, could be rescued from otherwise-inevitable death by implanting hematopoietic stem cells. These experiments demonstrated, among other things, that all the cells in the hematopoietic tissues of such a rescued mouse might derive from a single engrafted stem cell, proving that this stem cell was multipotent, in that its progeny could enter into multiple distinct states of differentiation and thereby generate multiple differentiated cell types.

Supplementary Sidebar 12.2 Oxidation products in urine provide an estimate of the rate of ongoing damage to the cellular genome

By recent estimates, the genomes of some human cells suffer as many as 10^3 oxidative hits a day, about tenfold less than the rate at which depurination of bases occurs. The resulting oxidized bases are largely but not totally removed and replaced with the appropriate normal bases. (Rat cells suffer about tenfold more oxidative hits per cell per day in their genomes than do human cells because they have about a sevenfold greater metabolic rate.) Any unrepaired oxidative lesions will accumulate with time, especially in the genomes of cells that are not mitotically active.

The most frequently observed nucleotide product of oxidative damage is 8-oxo-dG. It seems that the DNA repair apparatus fails to remove 1 to 2% of this oxidized nucleotide fails. Oxidants may oxidize the nucleotide precursor of dG prior to its incorporation into DNA and the resulting oxidized nucleoside triphosphate may then be incorporated instead of dGTP into the DNA. Alternatively, oxidants may attack the guanine base after its incorporation into DNA. The 8-oxo-dG excised from DNA is largely excreted in the urine.

The importance of oxidized dGTP (that is, 8-oxo-dG triphosphate) is indicated by the fact that a specialized enzyme—MTH1 (mammalian MutT homolog 1)—is

employed by mammalian cells to degrade this oxidized DNA precursor; mice lacking MTH1 develop tumors at a 3 to 4 times higher rate than their wild-type counterparts. Under standard conditions of tissue culture, early-passage human fibroblasts will usually proliferate for several dozen population doublings before entering senescence (see Section 10.1). However, when expression of the MTH1 enzyme was suppressed in these cells by expression of an shRNA (see **Supplementary Sidebar 1.5**), almost all of them entered into senescence within a single population doubling (approximately one day). This indicated that these cells were poised under these conditions of culture to enter senescence rapidly and were saved from this fate by the continuous actions of this detoxifying enzyme. Interestingly, when these cells were propagated in an environment of 3% oxygen (rather than the 21% usually present in tissue culture incubators), then this rapid entrance into senescence was avoided. This lower oxygen tension more closely approximates the conditions experienced by cells within our tissues (see also **Supplementary Sidebar 10.3**).

Unfortunately, studies of the importance of DNA oxidation products have been subject to a number of artifacts, including the inadvertent oxidation of DNA and nucleosides *in vitro*. On one occasion, aliquots of one DNA preparation were sent to 21 laboratories in Europe for measurement of 8-oxo-dG content; the results yielded estimates ranging over a factor of more than 200. The estimates of the numbers of oxidized bases in cell genomes have fallen dramatically in recent years. Nonetheless, the newer, more conservative estimates place the steady-state number of 8-oxo-dG residues in the DNA isolated from an average human cell at about 3000. This steady-state level is comparable to the level of chemically altered bases that are formed in the DNA of target tissues of laboratory animals that have been exposed to high, carcinogenic doses of compounds such as aflatoxin and heterocyclic amines.

Supplementary Sidebar 12.3 How does red meat cause colon cancer?

A number of epidemiological studies have linked high red meat consumption to increased risk of colon, pancreatic, and rectal cancer (and, to a lesser extent, to cancers of the breast, lung, and urinary bladder). However, it has not been possible to associate these risks specifically with the heterocyclic amines (HCAs) that are generated by cooking meats at high temperatures (that is, by frying or grilling). Attempts to make such an association are complicated by inter-individual differences in the metabolism of HCAs, by complex metabolic conversions undertaken by bacterial flora (see below), and by the possibility that

other components of meat and fat, including other compounds generated by cooking, may play important contributory roles in the observed increased cancer risk.

It is clear, for example, that an HCA such as PhIP (see Figure 12.16A), which is produced in substantial amounts when cooking meats and fish at high temperatures, is capable of inducing G-to-T transversions and deletions of a single G from the sequence GGG—mutations of the sort that are found in many *p53* alleles carried by human colon cancer cells. However, such a correlation hardly proves causation, and the specific causes of these and other mutations in colon cancer genomes remain to be demonstrated. More recent work indicates as much as a twofold increased risk of prostate cancer in men who consumed large amounts of grilled or barbecued red meat. Consequently, although HCAs are clearly carcinogenic, their actual contributions to human cancer incidence are still the subject of great debate.

Complicating this analysis are the repeated observations that processed meats are especially carcinogenic and are associated with even higher incidence of colorectal cancer than red meats in general. These processed meats include bacon, various types of sausage and hot dogs, and packaged sandwich meat. Common to these various processed meats is the presence of sodium nitrite, which is added by meat companies as a preservative and to provide a bright red (and thus fresh) appearance to these meat products. Sodium nitrite can, in turn, generate nitrosamines. Thus, $NaNO_2$ + R_2NH (cellular amines) → $R_2N—N—O$ (nitrosamine) + heat → $R—N_2^+$ (diazonium ion) + DNA bases → DNA adducts. Importantly, the nitrite concentrations used to preserve red meats in the United States have decreased over the past three decades and ascorbic acid has been added to inhibit the first of the reactions described above (termed nitrosation), clearly lessening but not eliminating the carcinogenicity of nitrite preservatives. Once again, compelling evidence of a direct connection between an agent—nitrites—with human cancer incidence is lacking, even though the connection between processed meats and cancer drawn from epidemiology is clear and undeniable.

There are additional confounding effects that complicate our ability to establish direct connections between foodstuffs and cancer incidence because, by some estimates, between 500 and 1000 distinct bacterial species reside in the human colon. The mix of bacterial species varies from one individual to another, being affected by genetic background, by diet, and possibly even by immune state. Each of these microbial species has its own set of enzymes that convert chemical

species in the fecal matter, including xenobiotics (compounds that are not naturally produced in the body) such as HCAs, into a vastly complex collection of metabolites. Each of these metabolites, in turn, has its own particular set of chemical reactivities. Hence, the mechanisms of mutagenesis in the colon are extraordinarily complex and contrast starkly with the mechanisms operating in the skin, where many carcinogenic mutations can be traced directly and unequivocally to the actions of ultraviolet photons and the pyrimidine dimers that they generate. Finally, it is worth noting a totally independent and unrelated hypothesized mechanism of cancer induced by red meat, which involves the consumption of a particular sialic acid isoform. This isoform gets incorporated into glycoproteins expressed in various human tissues. Because the sialic acid isoform is perceived as foreign by the human immune system, it can induce low-level, continuous inflammation. Such inflammation, as described in Section 11.15, creates tissue microenvironments that favor the inception and outgrowth of various neoplasms.

Supplementary Sidebar 12.4 Allelic variation in genes encoding metabolic enzymes can affect cancer susceptibility and response to therapy

Alleles of many genes involved in the metabolism of carcinogens and procarcinogens have been linked to cancer risk. For example, a connection between the glutathione *S*-transferase enzymes and cancer susceptibility is suggested by epidemiologic studies. In one such study, the allelic configurations of two separate GST-encoding genes, termed *GSTT1* and *GSTM1*, were examined in a normal control population and in individuals suffering from myelodysplastic syndrome (MDS), a hyperproliferative disorder of the bone marrow that often progresses to acute myelogenous leukemia (AML). Of the patients suffering from MDS, 46% carried two null alleles (which encode no enzyme) of *GSTT1*; this genetic state was present in only 16% of the control population. (In the case of the related *GSTM1* gene, homozygosity of the null allele was found in comparable proportions of the two populations.) Calculations indicated that individuals inheriting two null alleles of the *GSTT1* gene run more than a fourfold increased risk of myelodysplastic syndrome over those who carry at least one functional allele of the gene. These observations suggest that the T1 isoenzyme of glutathione *S*-transferase is involved in some way in detoxifying the compounds that provoke MDS. (An alternative interpretation, which is less likely but nonetheless difficult to exclude at present, is that the *GSTT1* gene is closely linked on the chromosome to a second gene that predisposes an individual to MDS.)

In fact, cells use a broad spectrum of enzymes to modify potential carcinogens in a variety of chemical ways, including the attachment of acetyl, glucuronic acid, glutathione, and sulfate groups; many of these chemical modifications aid in the detoxification and eventual excretion of these compounds. Because of heterogeneity in the human gene pool, the level of expression of many of the enzymes responsible for these detoxification reactions varies greatly among individuals. These differences may, in turn, strongly influence the biological responses of an individual to potentially carcinogenic compounds. For example, a study of 416 lung cancer patients and 446 healthy control individuals determined that persons of a certain genotype had a twofold increased risk of lung cancer; these susceptible individuals carried a particular allele of the cytochrome-encoding *Cyp1A1* gene and null alleles of the gene specifying glutathione *S*-transferase M1 (GSTM1).

Another study focused on breast adenomas among women who consumed more than 27 ng per day of the heterocyclic amine MeIQx (2-amino-3,8-dimethylimidazo[4,5-f]quinoxaline; see Figure 12.16A) by eating large quantities of burnt meat. Women who expressed high levels of *N*-acetyltransferase 1 (NAT1, an enzyme that can help to convert heterocyclic amines into active mutagens) were reported to experience a sixfold increased rate of adenomas, whereas those with much lower levels of NAT1 showed only a twofold increased risk. In both cases, adenoma frequency was compared with the incidence of adenomas in a third group of women who had low levels of MeIQx in their diet. These correlations suggest that enzymes can influence cancer incidence in two ways: some enzymes affect the rate at which a number of potentially mutagenic compounds are detoxified, whereas others (inadvertently) convert otherwise-nonreactive compounds into chemically reactive mutagens.

In fact, these enzymes intersect with the disease of cancer in yet another way, because they can also function to detoxify chemotherapeutic drugs, thereby blunting the effects of treatment. A particularly dramatic example of this effect was observed upon comparing the clinical responses of breast cancer patients who carried functional alleles of the *GSTM1* and *GSTT1* genes with those of a group of women who had only null alleles at both genetic loci. All of these women were treated with a combination chemotherapy regimen (involving cyclophosphamide, Adriamycin, and 5-fluorouracil) plus radiation. Of those women who had functional *GSTM1* and *GSTT1* alleles, almost all succumbed to their disease within six years of treatment. In contrast, of those women with a double-null genotype at both genetic loci, about two-thirds were still alive eight years after treatment. (This parallels the responses of glioblastoma patients to the

cytotoxic drug temozolomide as described in Section 12.7; their responsiveness to this chemotherapeutic agent is strongly influenced by the level of the MGMT repair enzyme that their cells express.)

In all of the cases cited in this sidebar, the different responses were correlated with specific alleles. It is important to remember, however, that these are only correlations and not proofs of causality. In each case, it is possible, in principle, that the alleles being studied are genetically closely linked to yet other alleles that are the true causes of the observed increased or decreased cancer incidence of patients.

Supplementary Sidebar 12.5 Oxidation removes methyl groups from DNA bases

Another mechanism cells use to deal with methylated bases involves homologs of the bacterial AlkB DNA repair protein, which work by oxidizing methyl groups that have become attached to bases. The oxidized methyl groups are then shed as formaldehyde molecules from the rings of all four DNA bases; similarly, AlkB enzymes also cause the larger ethyl group to be released as acetaldehyde. (Aficionados of DNA repair portray these enzymes as “burning off” the unwanted alkyl groups!) In fact, methylation of DNA bases may occur frequently during the lives of cells through the actions of *S*-adenosylmethionine, the methyl donor that participates in the biosynthesis of many molecules in the cell. Its highly reactive methyl group may accidentally become diverted to methylate a variety of cellular macromolecules, including the bases of DNA (see Figure 12.12C).

Bacterial AlkB (and quite possibly its mammalian homologs) has also been found to be capable of removing more complex base adducts. For example, the inadvertent oxidation of unsaturated lipids, yielding lipid epoxides and peroxides, occurs at high rates in inflamed tissues (see Sidebar 12.3); these highly reactive chemical groups can generate complex adducts with DNA bases (see Figure 12.19D) that are highly mutagenic. Indeed, such adducts have been found in tissues of patients with ulcerative colitis, a condition known to progress, with significant frequency, to carcinomas (cited in Table 11.5). A direct role in cancer pathogenesis of the human homologs of AlkB, termed hABH2 and hABH3, has not yet been demonstrated.

Supplementary Sidebar 12.6 Following base excision repair, DNA is restored by a series of steps

After an aberrant base is removed by a DNA glycosylase in the process of BER, the base-free sugar that results is then cleaved by a second enzyme, an endonuclease named APE (apurinic/apyrimidinic endonuclease) that is specialized to cut the strand carrying the base-free deoxyribose, doing so on the 5′ side of this sugar; a third enzyme, termed an AP lyase, then cleaves on the 3′ side, liberating the base-free sugar. The resulting single-strand gap in the DNA is repaired by a DNA polymerase, often polymerase β. The single-strand nick that results is finally closed by a DNA ligase, which rejoins adjacent nucleotides through the formation of phosphodiester bonds between them, thereby reconstructing the normal chemical structure of DNA. An occasionally used variant form of base excision repair, termed “long patch repair,” involves the excision of 4 to 7 nucleotides adjacent to the damaged base followed by a filling of the resulting gap.

Supplementary Sidebar 12.7 A convergence of bacterial, yeast, and human genetics led to the discovery of hereditary non-polyposis colon cancer genes

The route through which the genetic basis of HNPCC was discovered is quite fascinating. By following the co-inheritance of HNPCC susceptibility in a number of afflicted families and the inheritance of a set of chromosomal markers scattered throughout the human genome, geneticists discovered two distinct genetic regions that seemed to be associated with disease susceptibility. In some families, HNPCC susceptibility co-segregated with genetic markers from human Chromosome 2p16, whereas in a second set of families, this susceptibility seemed to be inherited together with markers from chromosomal region 3p21.

At the same time, astute observation of the types of genetic aberrations found in a subset of sporadic colon carcinomas noted that stretches of A’s (for example, A_7) often were expanded or compressed (that is, were replaced by A_6 or A_8) in the genomes of colon carcinoma cells; thereafter, more complex microsatellite sequences [for example, $(CA)_8$] were also found to undergo expansion or shrinkage (see Section 12.3). Such microsatellite instability (MIN) was found to be rampant in the cancer cells of individuals suffering from HNPCC.

Other researchers noted that these changes in DNA sequence were strikingly similar to the alterations that accumulated rapidly in *E. coli* that bore mutant versions of either of two genes—*mutS* or *mutL*—involved in mismatch repair (MMR; see Section 12.3); yeast carrying mutations in the homologous genes showed identical genome-wide aberrations. This similarity led some scientists to investigate whether human homologs of these or other known mismatch repair genes were affected in HNPCC patients, leading rapidly to the confirmation that, indeed, a human *mutS* homolog (named *hMSH2*) mapped to human Chromosome 2p16 and a human *mutL* homolog (*hMLH1*) mapped to 3p21. Eventually, members of one set of HNPCC families were found to transmit mutant germ-line alleles of *hMSH2*, whereas those belonging to a second set of HNPCC kindreds carried mutant germ-line alleles of *hMLH1*.

Supplementary Sidebar 12.8 Homology-directed repair requires a homologous sequence

Homology-directed repair (abbreviated HDR or simply HR) is thought to depend on the ability of a DNA helix suffering a double-strand break (DSB) to consult the related, still-intact homologous sequences present in another chromosome, doing so in order to reconstruct a repaired helix whose sequences are indistinguishable from those that existed prior to the DNA damage. In fact, the reference sequences are almost invariably carried by the other chromatid that arises following DNA replication during the S phase of the cell cycle. (This other helix carried in the other chromatid has presumably not suffered damage during this period.) This mechanism dictates that HDR is limited to those phases in the cell cycle—S and G_2—when replication has generated such a second reference helix. Conversely, HDR is thought not to occur in the G_1 phase of the cell cycle, a phase when such homologous chromatids are not yet present. The machinery that underlies HDR depends on a series of proteins (**Figure S12.2**), some of which are found in defective form (or are absent) in certain human cancers. This leads to the notion that defects in HDR, because they leave behind unrepaired, still-damaged DNA, are highly mutagenic and that this increased mutagenicity explains the increased cancer risks of women who, for example, bear mutant forms of either the BRCA1 or BRCA2 proteins. This conclusion is still not fully substantiated, because proteins like BRCA1 have multiple alternative functions, many not connected directly with DNA repair.

Figure S12.2 Detailed roles of DNA repair proteins in homology-directed repair of double-strand DNA breaks After a double-strand break (DSB) occurs in DNA, this lesion is recognized and bound by the heterotrimeric MRN complex, composed of MRE11, RAD50, and NBS1 (also termed nibrin because of its involvement in Nijmegen breakage syndrome) (see Figure 12.31). This MRN complex recruits CtIP (CtPB-interacting protein) and, while acting in complex with BRCA1 and BARD1, undertakes exonuclease activity to generate two 3′-overhanging single-strand (ss) DNA ends. These ssDNA ends are rapidly coated by RPA (replication protein A; *green*). BRCA1, acting through PALB2, then recruits BRCA2, and the latter loads RAD51 (*orange*) onto the ssDNA, thereby displacing the previously bound RPA protein. This RAD51 protein acts as a recombinase and then facilitates strand invasion into the undamaged homologous region of the sister chromatid, which depends on unwinding the double-helical DNA of the sister chromatid; RAD51 also participates in the search for binding to the proper complementary sequence in the sister chromatid (termed a "homology search"). A displacement (D-) loop is produced when the 3′ ssDNA forms double-helical complexes with the DNA strands of the sister chromatid. This permits DNA polymerases to perform strand elongation from the 3′ ends of the inserted ssDNA by using the complementary ssDNA strands of the sister chromatid as templates. The result is the formation of a complex structure, termed a Holliday junction (HJ), between the two chromatids. The two HJs can be resolved in either of two ways, resulting in either cross over or lack-of-cross over when the two, now-intact sister chromatid helices separate from one another. Other variations of this basic scheme may operate in certain circumstances. (Adapted from P.J. O'Donovan and D.M. Livingston, *Carcinogenesis* 31:961–967, 2010. With permission from Oxford University Press.)

Supplementary Sidebar 12.9 BRCA1 has diverse functions

As BRCA1 function is studied in ever-increasing detail, its mechanisms of action become increasingly confusing, if only because additional distinct biochemical functions are ascribed to this very large protein and its physically associated partners. For example, BRCA1 associates with a number of transcriptional regulators, localizes to centrosomes during mitosis, and has been found at the outer edges of cultured cells growing in monolayer, where it helps to regulate cell motility. It is also clear that female cells lacking BRCA1 function are unable to properly inactivate one of the two X chromosomes in their somatic cells (see

Figure S1.1). We still do not understand how these other functions intersect with BRCA1's DNA repair functions and contribute to the strong tendency of mutant germ-line *BRCA1* (and *BRCA2*) alleles to generate almost exclusively female cancers.

In the eyes of some investigators, the contributions of BRCA1 loss to cancer development may be overshadowed by yet another of its activities unrelated to DNA repair: BRCA1 carries in one of its domains a function that leads to monoubiquitylation of histone H2A. (BRCA1 acts as an adaptor protein and thus as an E3 subunit of a ubiquitin ligase complex, in which an unknown E2 subunit performs the actual enzymatic modification of H2A; see **Supplementary Sidebar 7.5** for additional details related to the enzymatic steps related to ubiquitin addition.) This H2A monoubiquitylation results in the formation of heterochromatin, notably the *constitutive heterochroma tin* that is shut down in virtually all somatic cell types. In the absence of this heterochromatinization, a variety of repeat sequences that are normally shut down now become expressed, leading to widespread genetic destabilization as a downstream effect. The relatively recent discovery of this BRCA1 function reveals how poorly we understand why and how BRCA1 loss leads to breast, ovarian, and prostate carcinoma development.

Supplementary Sidebar 12.10 HPV deregulates centrosome number and induces aneuploidy

Primary human cells (that is, those that have been propagated in culture for only a short period of time after removal from living tissue) in which the human papillomavirus (HPV) E7 oncoprotein is expressed show a deregulation of centrosome number, often leading to supernumerary centrosomes beyond the two that are normally present in cells poised to enter mitosis. Recall that the E7 oncoprotein binds to cellular pRb (the retinoblastoma protein), inactivates it functionally, and accelerates its degradation (see Section 8.5). Significantly, a mutant form of the HPV E7 oncoprotein that fails to bind to pRb also fails to induce the appearance of extra centrosomes. Together, these strands of evidence suggest that one of the consequences of loss of pRb function is a deregulation of centrosome duplication. Because the centrosomes play a central role in organizing the mitotic spindles, this deregulation may soon lead to dramatic fluctuations in chromosome number (see Figures 12.38 and 12.39). Indeed, precisely such chromosomal instability is observed in lines of human cervical

carcinoma cells, almost all of which express the early region of the HPV genome, which carries the genes encoding the viral E6 and E7 oncoproteins.

An equal contribution to aneuploidy may be made by the HPV E6 protein (see Sidebar 9.5) and other agents that disrupt p53 function, because cells lacking the services of this important tumor suppressor protein seem particularly susceptible to acquiring aneuploid genomes. Thus, the HPV E7 oncoprotein destabilizes centrosome number, whereas the E6 oncoprotein, through its actions on p53, causes cells to tolerate any centrosome abnormalities that may eventually arise. And in a large variety of other human cancers that are not caused by viral infection, cells that have lost p53 function through other mechanisms also show relatively high rates of instability in their chromosome number. The precise signaling connections between p53 function, mitotic checkpoint controls, and the monitoring of chromosomal number remain obscure.

Inactivation of pRb regulation may confer immediate proliferative advantage on an incipient, HPV-infected cancer cell by inactivating the control that governs passage through the R-point transition (see Section 8.2). In the longer term, additional advantages may accrue to the descendants of this cell because centrosome number will become destabilized, leading in turn to derangement of mitotic spindles and resulting in destabilization of karyotype. The changes in chromosome number that ensue may yield constellations of growth-promoting and growth-retarding genes in proportions that expedite tumor progression.

Supplementary Sidebar 12.11 Rare alterations in genes encoding chromatid assembly and separation proteins in tumorigenesis

To date, only a small proportion of human tumors have been found to carry mutations in the human homologs of yeast genes known to be involved in chromatid assembly and separation during mitosis. Some examples are provided in **Table S12.1**. Unlike the ATM gene, which is well documented because of its role in ataxia telangiectasia (see Table 12.1), mutant germ-line alleles of the genes in this table have rarely been found associated with increased cancer risk. The functions of some of these critical mitosis-regulating genes may be lost through methylation of their promoters (see Section 7.7), but this loss of function remains largely undocumented. In fact, only a small proportion of the large cohort of human genes involved in mitotic functions has been explored to determine whether the functioning of these genes is compromised during the course of tumor progression.

Table S12.1 Mutated, methylated, and overexpressed genes in cancer cells that perturb chromosomal stability

Gene/Complex	Function of gene product	Consequence of alteration in cancer cells
Bubr1/Bub1[a]	spindle assembly checkpoint	progress through mitosis, even in the presence of microtubule inhibitors[a]
Mad1[b]	spindle assembly checkpoint	large-scale aneuploidy
Mad2[, c]	spindle assembly checkpoint	premature entrance into anaphase,[d] aneuploidy
Securin	attachment of sister chromatids	nondisjunction of chromosomes[e]
cohesin complex	attachment of sister chromatids	aneuploidy
Aurora-A, -B	separation of chromatids at anaphase	premature entrance into anaphase[d]
Chfr[e]	spindle assembly checkpoint	nondisjunction[f], chromosome loss
14-3-3σ	DNA damage checkpoint	segregation of unrepaired chromosomes

Gene/Complex	Function of gene product	Consequence of alteration in cancer cells
Rb	cell-cycle regulator	aneuploidy
Apc[g]	regulation of proliferation	mitotic defects, cytokinesis failure

One example of such mitotic control genes is the gene encoding the CHFR (checkpoint with forkhead and RING finger domains) protein, which normally prevents advance from prophase into metaphase in the event that the spindle microtubules and centrosomes are not properly arrayed. The gene encoding this checkpoint protein, which is normally expressed ubiquitously in human cells, has been found to be fully repressed as a result of promoter methylation in 3 of 8 randomly chosen human cancer cell lines and in 7 out of 37 lung cancer biopsies. In mice, activated germ-line alleles of the *Chfr* gene collaborate with knocked-out *Mlh1* alleles (see Section 12.8) to generate dramatically increased tumor incidence rates.

Another key regulator of entrance into M phase is the 14-3-3σ protein. When genomic DNA is damaged, p53 induces synthesis of 14-3-3σ, which proceeds to trap cyclin B–Cdc2 complexes in the cytoplasm (see Section 9.10); by sequestering these cyclin–CDK complexes, 14-3-3σ succeeds in blocking entrance into M phase, thereby holding mitosis in abeyance until damaged chromosomal DNA has been repaired. The gene encoding 14-3-3σ has also been found to be frequently methylated in common cancers, including those of the lung, breast, stomach, and liver. The resulting loss of 14-3-3σ must surely contribute to the aneuploidy observed in these kinds of cancer cells.

These two examples, involving the CHFR and 14-3-3σ proteins, only begin to plumb the depths. There are clearly many other, undiscovered caretaker and checkpoint genes that play critical roles in stabilizing DNA sequences or ensuring normal karyotype and in this way determine whether or not tumor progression will proceed slowly or move ahead rapidly (see **Supplementary Sidebar 12.12**).

Supplementary Sidebar 12.12 Breast cancer studies indicate that common cancers are often caused by inherited defects in caretaker genes

We tend to think that cancers caused by inherited defects in certain genes represent a small fraction of the total cancer burden in the population. The breast cancer families afflicted with mutant BRCA1 or BRCA2 germ-line alleles come to mind here. In fact, the incidence of many commonly occurring cancers, such as breast cancer, may be greatly influenced by heritable genetic factors that strongly increase susceptibility to this disease. An epidemiologic study conducted in Britain of breast cancer incidence in sets of identical twins concluded that a significant proportion, and possibly the majority, of these tumors occur in women who are genetically predisposed to this disease. The genetic factors, whatever their nature, are complex and not strongly penetrant; that is, none, acting on its own, strongly affects disease frequency. Some of these factors could be alleles of DNA repair genes that yield sub-optimal function.

This suspicion comes from biological studies of the normal cells of breast cancer patients and their close relatives. Here is one tantalizing hint among many: in one research study, the lymphocytes of 40% of breast cancer patients showed an abnormally high tendency to develop aberrant karyotypes following exposure to X-rays; only 5 to 10% of individuals in the normal, control population showed this peculiar hypersensitivity. Significantly, the first-degree (close) relatives of the breast cancer patients were far more likely to have these hypersensitive lymphocytes than people in the general population (**Figure S12.3**). These relatives had no obvious disease phenotypes yet clearly carried alleles of caretaker genes that compromised genome maintenance; such still-unidentified genes are highly likely to have played major roles in causing the breast cancers in their families.

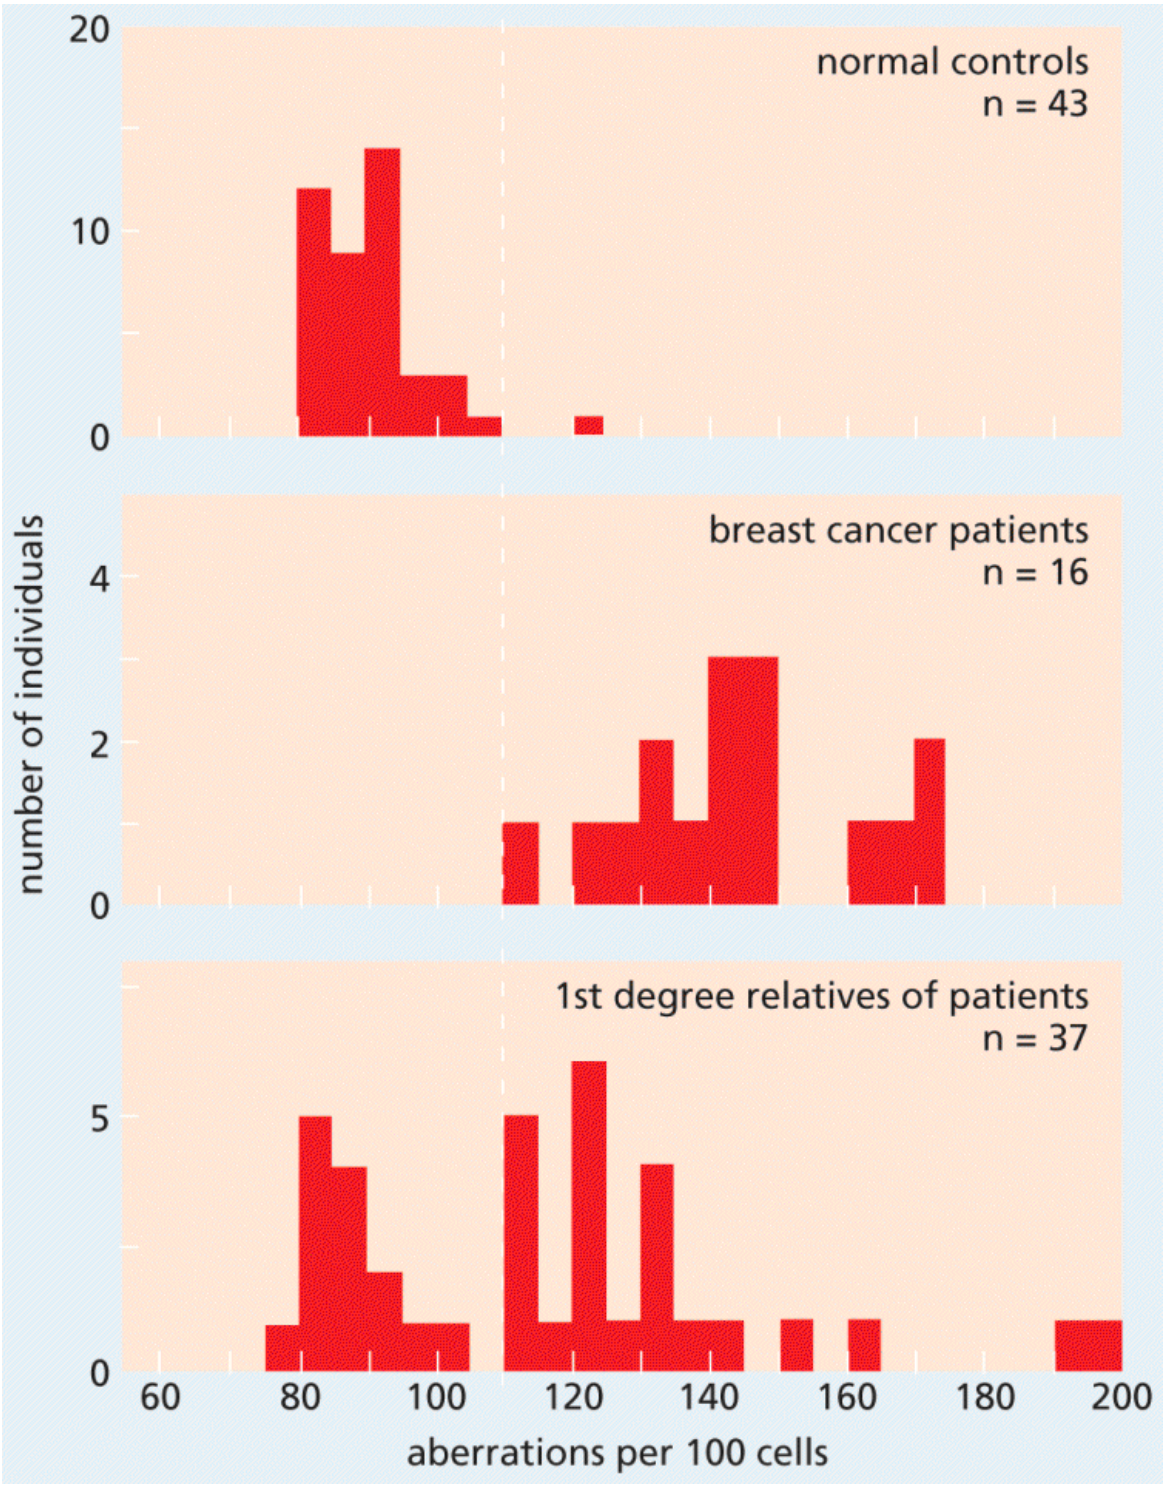

Figure S12.3 DNA repair in lymphocytes of breast cancer patients and their relatives The ability of the DNA repair system to respond to X-ray–induced damage by restoring normal karyotype is one measure of its functioning. In the experiments described here, cultured lymphocytes from

various individuals were exposed to a sublethal dose of radiation (0.5 Gy) and the number of karyotypic aberrations present in 100 irradiated lymphocytes was scored shortly thereafter by trapping cells in metaphase with Colcemid, a microtubule antagonist. (Because the lymphocytes were not associated with the breast cancers and not affected by the somatic mutations that culminated in breast carcinomas, their behavior presumably reflects the germ-line-inherited genetic determinants of DNA repair.) Lymphocytes from healthy individuals (normal controls) developed 80–100 aberrations per 100 irradiated cells, whereas the lymphocytes from breast cancer patients developed 110–165 aberrations per 100 cells. Significantly, the first-degree (close) relatives of these patients showed either normal or greatly reduced ability to repair these breaks, the latter indicating the effects of strongly penetrant alleles of fully unknown genes that are transmitted in the families of the breast cancer patients. (From S.A. Roberts et al., *Am. J. Hum. Genet.* 65:784–794, 1999. With permission from Elsevier.)

Another striking finding comes from a study of 1071 breast cancer patients who had a familial history of the disease but carried normal BRCA1/BRCA2 alleles; in this case, researchers looked at the configuration of another gene implicated in DNA repair but not known to contribute to inborn susceptibility to breast cancer —*CHK2*; this gene encodes a kinase that is activated after X-ray–induced DNA damage and is responsible for activating, in turn, p53, among other targets (see Section 9.7). The DNAs of these patients were compared with those of 1620 healthy controls. In the patient group, 5.1% of the women and 13.5% of the men (who suffered from male breast cancer, an especially aggressive disease) had inherited a faulty version of CHK2 compared with 1.1% of the individuals in the control group. Observations like these suggest that mutant alleles of a number of other genes involved in genome maintenance will one day be discovered to be influential in determining breast cancer susceptibility and, quite possibly, a tendency to develop other common types of cancer.

Glossary

multipotent
: Referring to the ability of a stem cell to differentiate into multiple distinct cell types. *See also* **totipotent**, **pluripotent**.

xenobiotic
: (n., adj.) A chemical species that originates outside of the body of an organism and is foreign to its normal metabolism.

myelodysplastic syndrome
: Hyperproliferative condition of cells of the myeloid lineage in the bone marrow which often progresses to acute myelogenous leukemia.

ligase
: An enzyme that covalently joins two molecules together; in the context of DNA, ligases join the 3′ end of one ssDNA to the 5′ end of another other via a phosphodiester linkage.

heterochromatinization
: The process whereby euchromatin is converted to heterochromatin, notably that occurring during the process of X-chromosome inactivation.

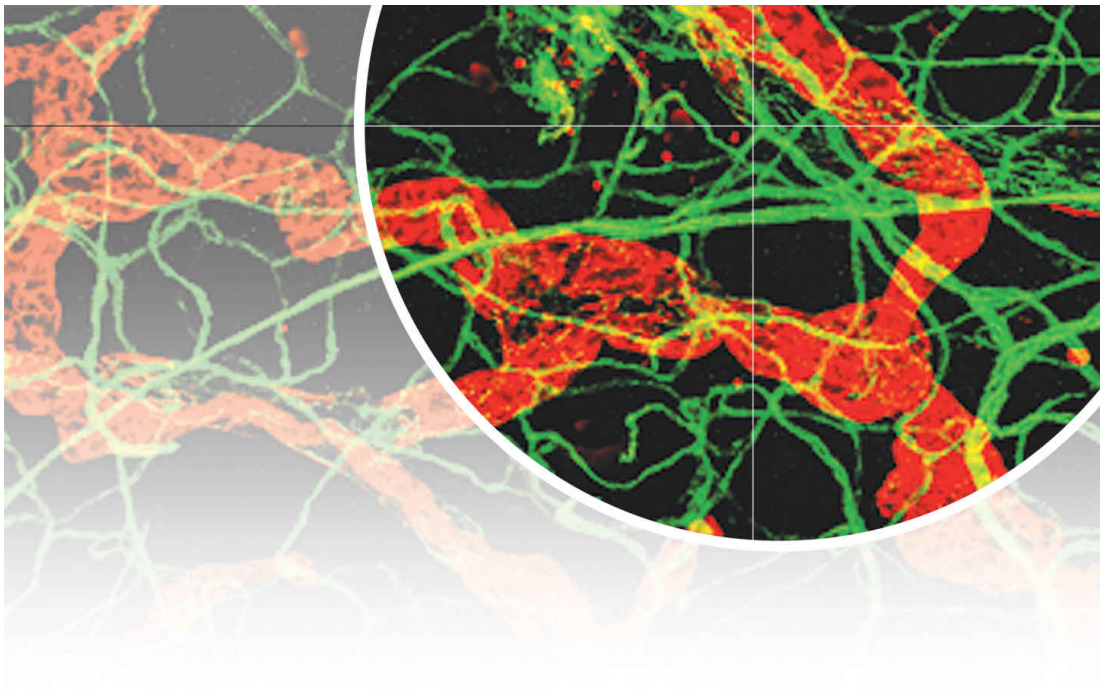
Chapter 13

Dialogue Replaces Monologue: Heterotypic Interactions and the Biology of Angiogenesis



A fluorescence microscopy image of blood capillaries, shown in green, and larger, less numerous lymph ducts, shown in red-orange.

Simple ideas are wrong. Complicated ideas are unattainable.

Paul Valéry, poet, 1942

Tumors: wounds that do not heal.

Harold Dvorak, 1986

A simple and powerful conceptual paradigm pervades most of the previous discussions in this book: cancer is a disease of cells, and the phenotypes of cancer cells can be

understood by examining the genes and proteins within them. The origins of this idea are clear, being traceable directly back to bacterial and yeast genetics. These two research specialties thrived because they were well served by the postulate that cell genotype determines all aspects of cell phenotype. Indeed, virtually all the attributes of individual bacterial and yeast cells could be shown to derive directly from the genes that these microorganisms carry in their genomes.

Applying this concept to metazoans and their tissues has had obvious advantages for biologists. Metazoan organisms are complex almost beyond measure, and this complexity has frequently prevented researchers from extracting simple and irrefutable truths about organismic function. In response, many researchers, notably molecular biologists, cell biologists, and biochemists, embraced the credo of reductionist science: when working with complex systems, the best way to arrive at solid and rigorous conclusions is to take apart these systems into simpler, more tractable components and study each separately. Although the lessons learned may relate only to small parts of very large systems, at least these lessons are solid and definitive and will not require substantial revision each time a new generation of researchers revisits these complex systems and their component parts.

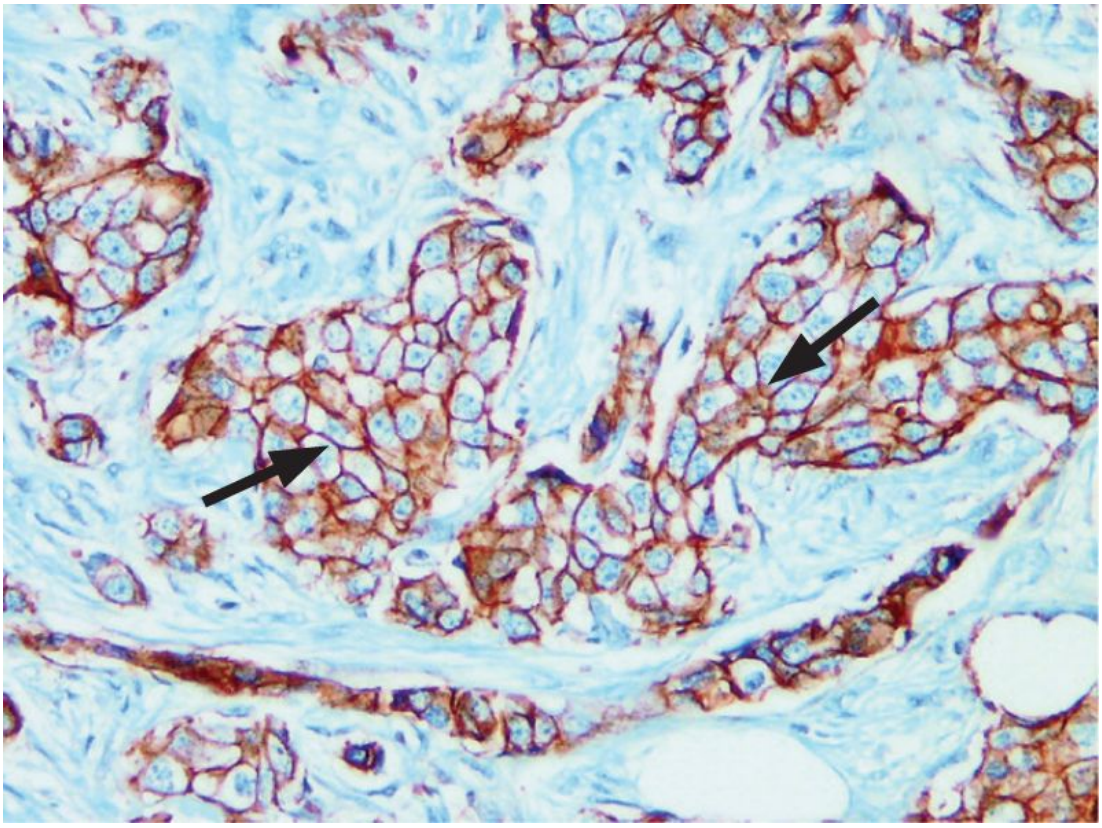
Such reductionism has allowed many areas of cancer research to thrive. Witness the progress described in the early chapters of this textbook: when the first proto-oncogene was discovered three-quarters of the way through the twentieth century (see Sections 3.8 and 3.9), almost nothing was known about the genetics and molecular biology of cancer. By the end of the century, information was available in abundance about how cancers begin and progress to highly aggressive, malignant states. Much of this avalanche of information came from taking the reductionist paradigm to its limits—disassembling normal and neoplastic tissues into component cells and the cells into component molecules.

In the case of cancer research, the reductionist pact was extended in another direction as well: all of the traits of a tumor can be traced directly back to the behavior of its constituent cancer cells. Their behavior, if well understood, could be used to deduce that of the tumor as a whole.

By the end of the twentieth century, it became increasingly clear that many of the traits of tumors could not in fact be traced directly back to individual cancer cells and the genes they carry. The grand simplifications agreed upon a generation earlier by cancer researchers had begun to lose their utility. Increasingly, evidence turned up that cancer is actually a disease of tissues, in particular, the complex tissues that we call tumors.

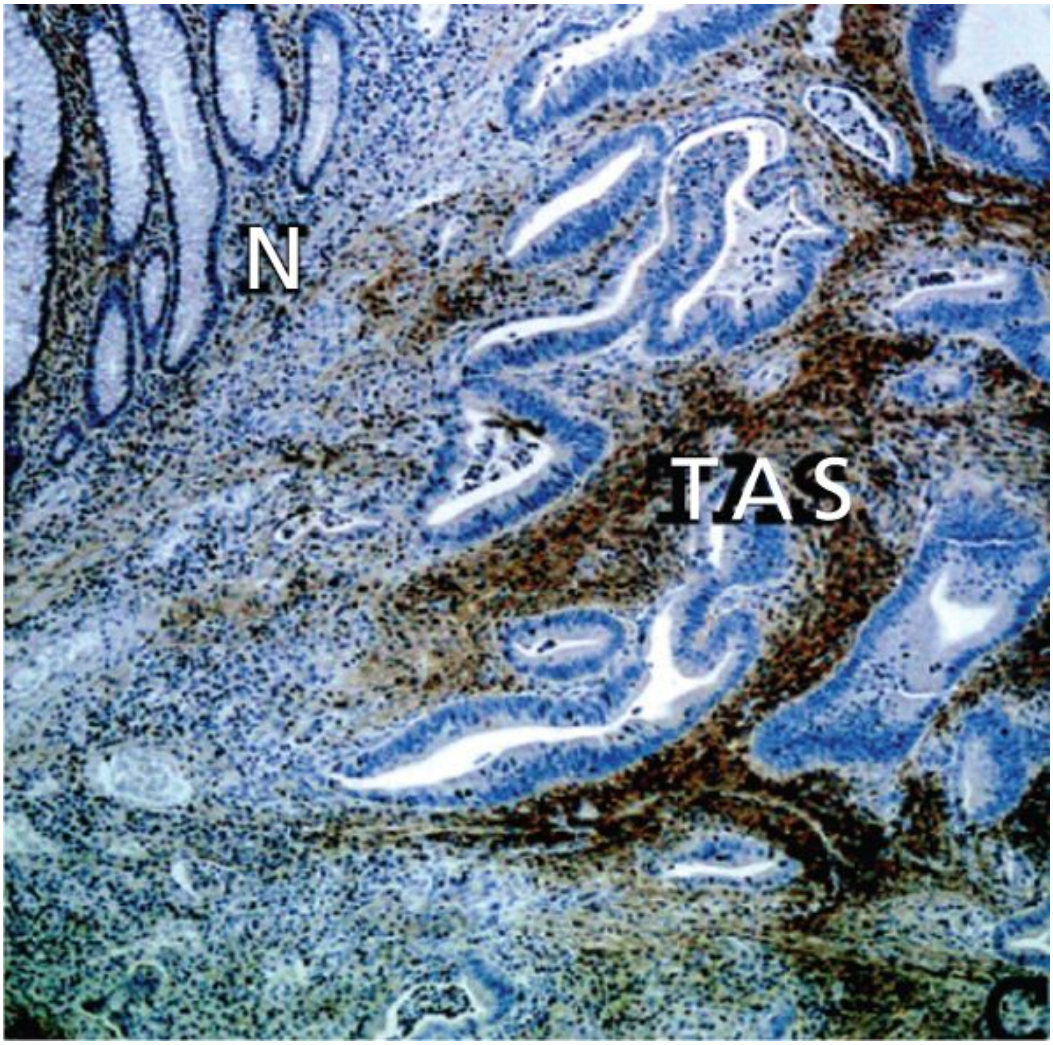
The reductionists' way of thinking had, all along, denied certain realities that clinical oncologists and pathologists confronted on a daily basis, namely, that carcinomas—which constitute more than 80% of the human cancer burden—derive from epithelial

tissues of very complex microscopic structure. Histopathological characterizations of these epithelial tumors reveal that they are composed of a number of distinct cell types (**Figure 13.1**).



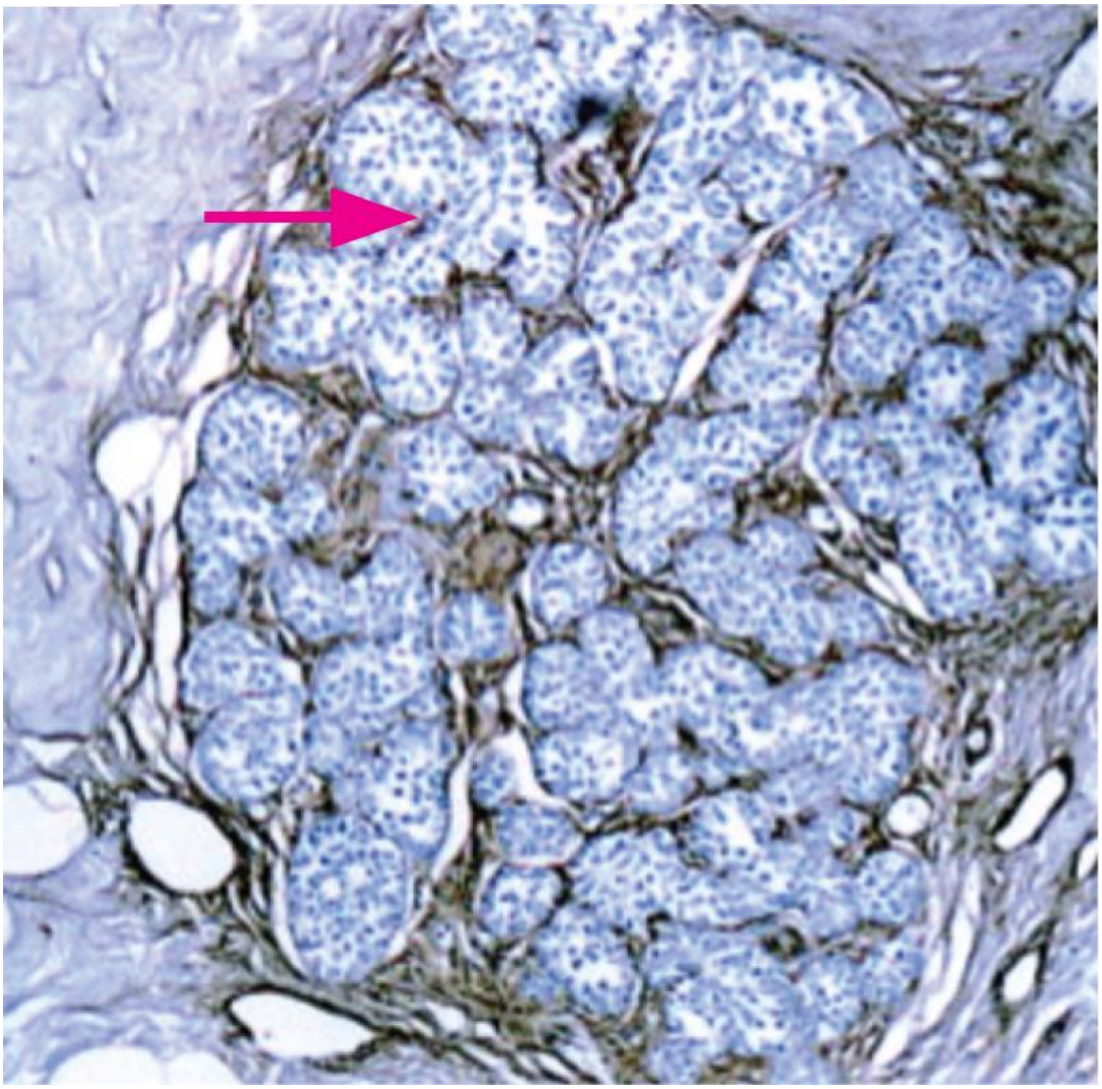
A histology image. Scattered clusters of brown cells with light blue nuclei are surrounded by light blue cells with light blue nuclei.

(A)



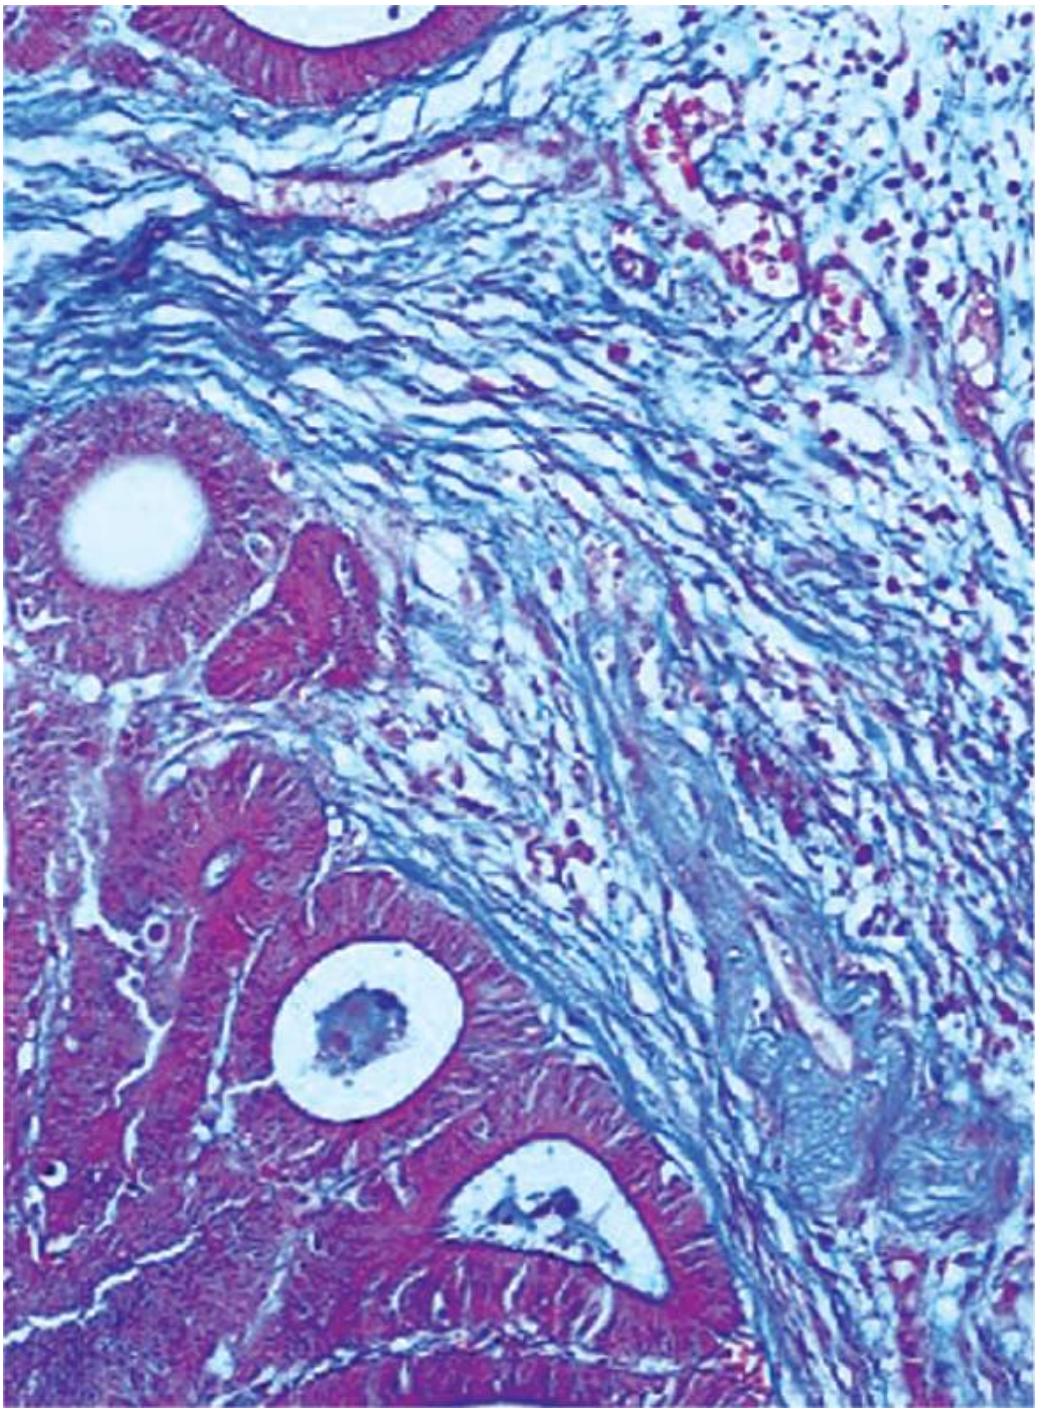
A histology image. The left part of the image, labeled N, is filled with cells stained medium blue and blue-green. On the right is a region labeled T A S, containing ducts lined with borders of cells stained deep blue. The cells between the ducts are stained dark brown.

(B)



A histology image. A mass of what looks like adipose tissue consists mostly of clumps of light blue and white cells. The thin spaces between the clumps are dark brown.

(C)



A histology image. There are large clumps of magenta cells with white centers in the bottom left, while the rest of the space is occupied by flowing light blue cells with small magenta dots.

(D)

Figure 13.1 Stromal components of several commonly occurring carcinomas
As is shown here, a variety of common carcinomas contain significant proportions of both epithelial cancer cells and recruited stromal cells. (A) A high-grade invasive ductal carcinoma of the breast, in which the membranes (*arrows*) of the epithelial cells are stained *brown*, and the nuclei of the stromal cells are *light blue*. (B) A colon carcinoma (*right side*) and normal colonic mucosa (N, *left side*), in which fibroblast-like cells in the tumor-associated stroma (TAS) are immunostained *dark brown* for PINCH (a protein associated with the cytoplasmic tails of integrins), and the nuclei of epithelial cancer cells lining ducts are *light blue*. (C) A lobular carcinoma *in situ* of the breast showing small clusters of cancer cells (*light blue nuclei*, arrow) surrounded by thin layers of stromal fibroblasts that have been immunostained for PINCH antigen (*dark brown*). (D) An adenocarcinoma of the stomach in which the cancer cells (*purple*, *lower left)* are adjacent to extensive stroma, which has been stained for collagen (*blue).* (A, from A. Gupta, C.G. Deshpande and S. Badve, *Cancer* 97:2341–2347, 2003. B and C, from J. Wang-Rodriguez et al., *Cancer* 95:1387–1395, 2002. D, from S. Ohno et al., *Int. J. Cancer* 97:770–774, 2002. All with permission from John Wiley & Sons.)

One's first instinct is to dismiss the non-neoplastic cells forming the tumor stroma as distracting contaminants that confound rather than illuminate one's understanding of the biology of tumors. To do so now seems increasingly unwise. Recent research results make it clear that non-neoplastic cells, notably the stromal cells of carcinomas, are active, indeed essential collaborators of the neoplastic epithelial cells within tumor masses, having been recruited and then exploited by the cancer cells. The biology of these recruited cells now appears to be almost as important as that of the neoplastic cells in enabling the growth of tumors.

Consequently, the disease of cancer is far more than cancer cells talking to themselves in endless monologues. We know, instead, that in most tumors, the neoplastic cells are in continuous communication with non-neoplastic host cells. In this chapter, we focus largely on these nearby signaling channels and explain how they affect the fate of incipient tumors and thus the course of clinical cancer development. At the same time, realizing the presence of non-neoplastic stromal cells in the life of a tumor, we can refine our vocabulary: "carcinoma cells" are neoplastic and cancerous, whereas "tumor cells" includes both the neoplastic and non-neoplastic cells within a mass (**Sidebar 13.1**).

Sidebar 13.1 Tumor cells assemble complex signaling networks

This depiction of the interactions of cancer cells with host tissues only responds to those interactions operating within the boundaries of individual tumors, that is, between the neoplastic cells and the nearby tumor-associated stroma. In fact, an equally important set of interactions should be included in these discussions: tumor cells often release signals that perturb distant tissues in the host, thereby leading to systemic changes in host physiology. (Accordingly, such signaling represents *endocrine* signaling channels rather than the *paracrine* signaling that operates between nearby cells within individual tissues.) By calling in host cells from various reservoirs in the body—largely the bone marrow—tumors can affect their own ability to invade and metastasize and even evade elimination by components of the host immune system, a topic that is covered in depth in Chapters 15 and 16.

Tumors can affect distant tissues, yielding a set of responses termed paraneoplastic syndromes. Thus, some neuroendocrine tumors release hormones that profoundly perturb normal systemic physiology. Other tumors carry antigens that provoke the synthesis of strong auto-reactive antibodies; once formed, the resulting antibodies can then attack a variety of tissues throughout the body, including the brain, yielding in the latter case diverse neurological symptoms. Indeed, these symptoms are often first indication of a previously undiagnosed tumor.

OceanofPDF.com

Glossary

reductionism
: A scientific philosophy and research strategy that involves the study of individual, relatively simple components or subsystems of complex systems rather than the systems as a whole.

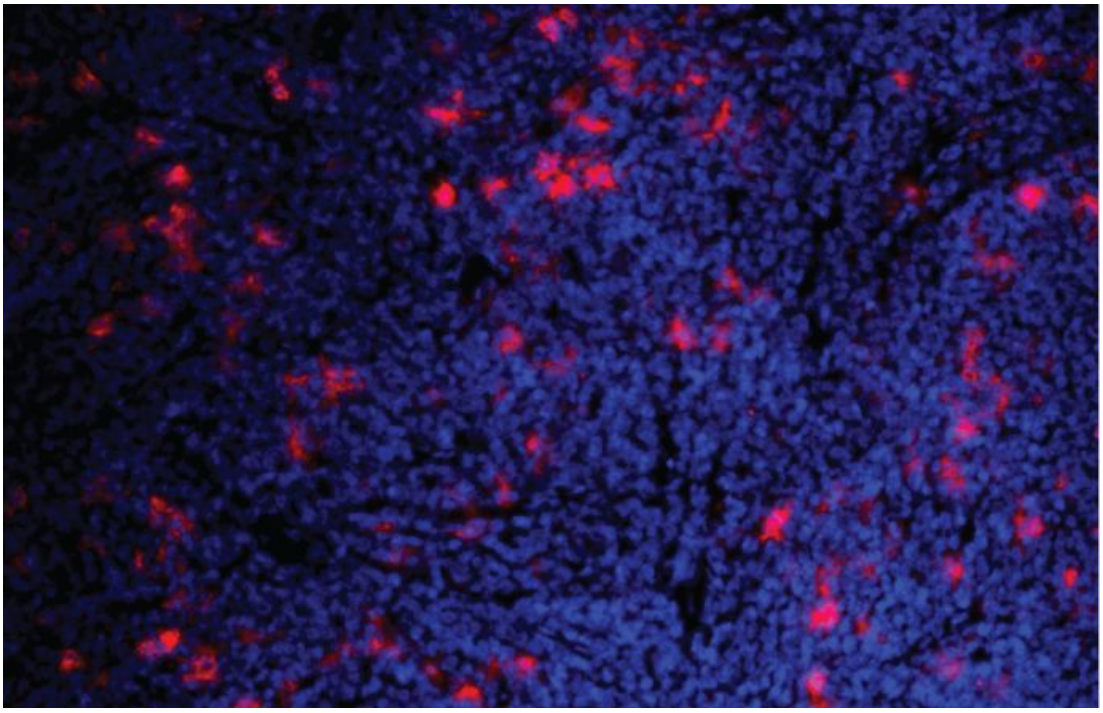
paraneoplastic
: Referring to a biological effect evoked in the body by a tumor at a site in the body that is located some distance from the tumor itself and is apparently not directly involved in the pathogenesis of the tumor.

OceanofPDF.com

13.1 Normal and neoplastic epithelial tissues are formed from interdependent cell types

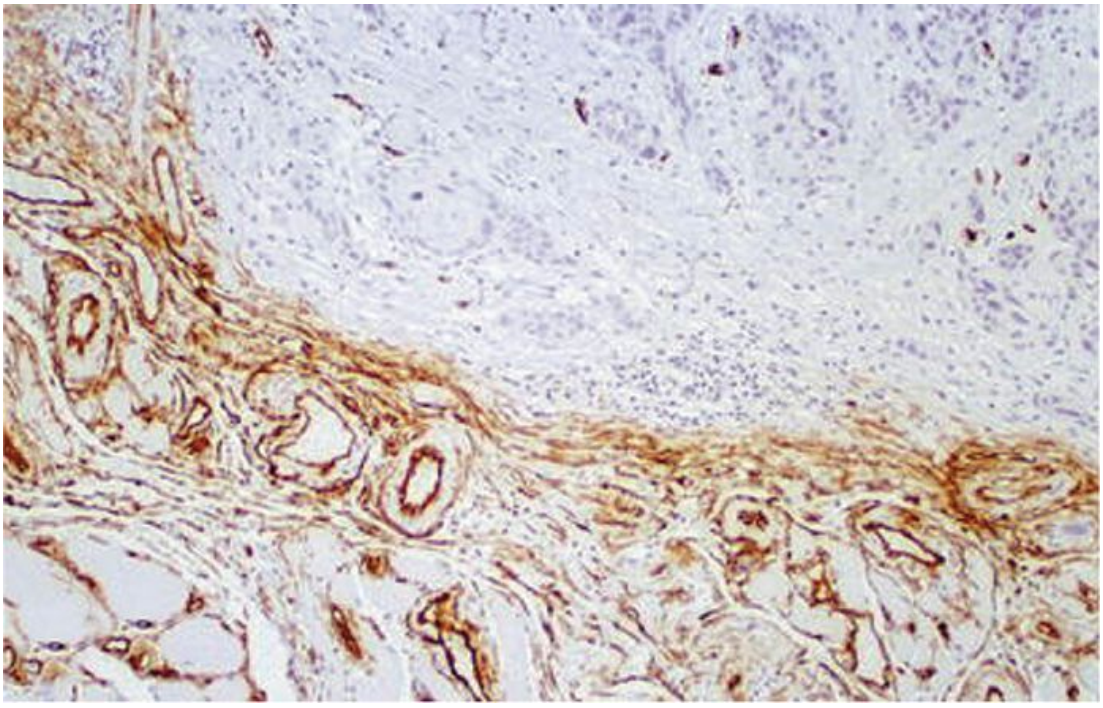
In fact, even cursory examinations under the microscope indicate that most carcinomas are as complex histologically as the normal epithelial tissues from which they have arisen. In some cases of commonly occurring carcinomas, such as those of the breast, colon, stomach, and pancreas, the non-neoplastic cells, which together constitute the tumor stroma, may account for as many as 90% of the cells within the tumor mass.

The true complexity of the stroma of epithelial cancers becomes apparent only at high magnification under the microscope **Figure 13.2**. In addition to the neoplastic epithelial (that is, carcinoma) cells, a number of stromal cell types populate the tumor. These stromal cells include fibroblasts, myofibroblasts, endothelial cells, pericytes, adipocytes, macrophages, lymphocytes, and mast cells; not shown are the extensions of neurons that thread their way through the bulk of tumor masses. Because most of these cell types constitute only a relatively small proportion of the stroma of many tumors, their presence, when viewed microscopically, becomes apparent only through use of immunostaining with antibodies that bind cell type–specific antigens. Use of immunostaining allows the localization of some of these cell types, as seen in Figure 13.2. Often the stroma of a tumor is depicted as the tumor microenvironment (TME, TMEN), with the implication that this collection of cells, having been recruited in various ways to the tumor-associated stroma, thereafter conditions the surroundings of the neoplastic cells and thereby influences growth of the tumor as a whole in various ways.



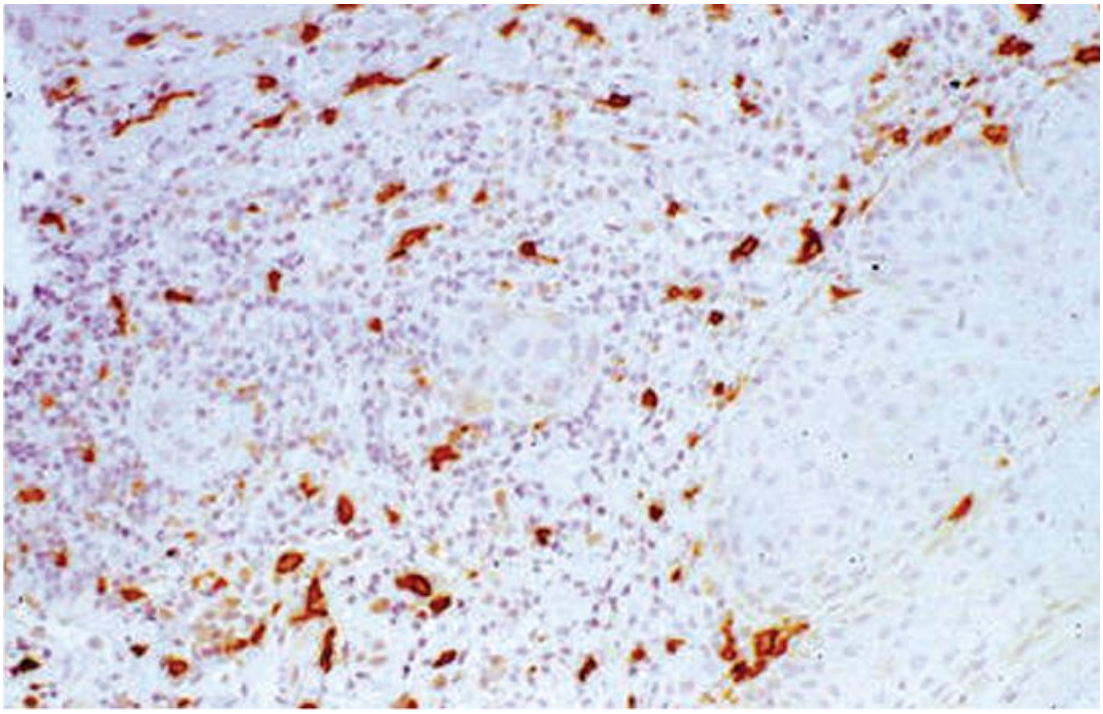
A fluorescence microscopy image. Interspersed among many densely packed dark blue patches are scattered bright red patches.

(A)



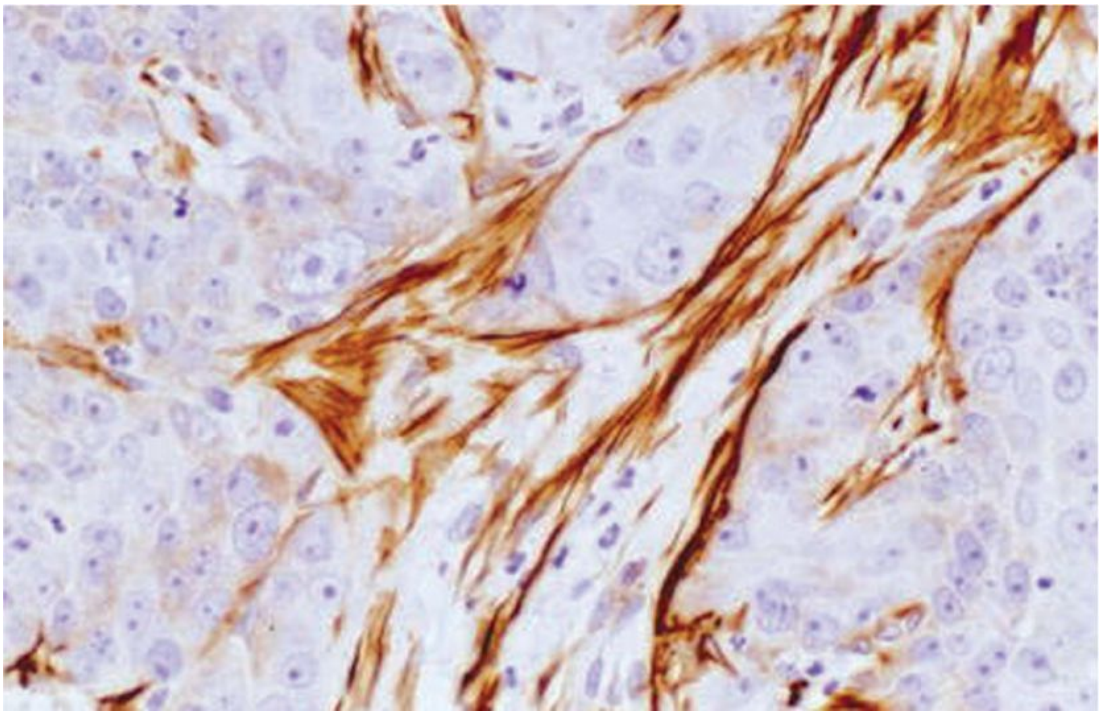
A histology stain. Cells in the lower part of the image have a brown, swirled pattern. Cells in the upper part of the image are pale blue and scattered.

(B)



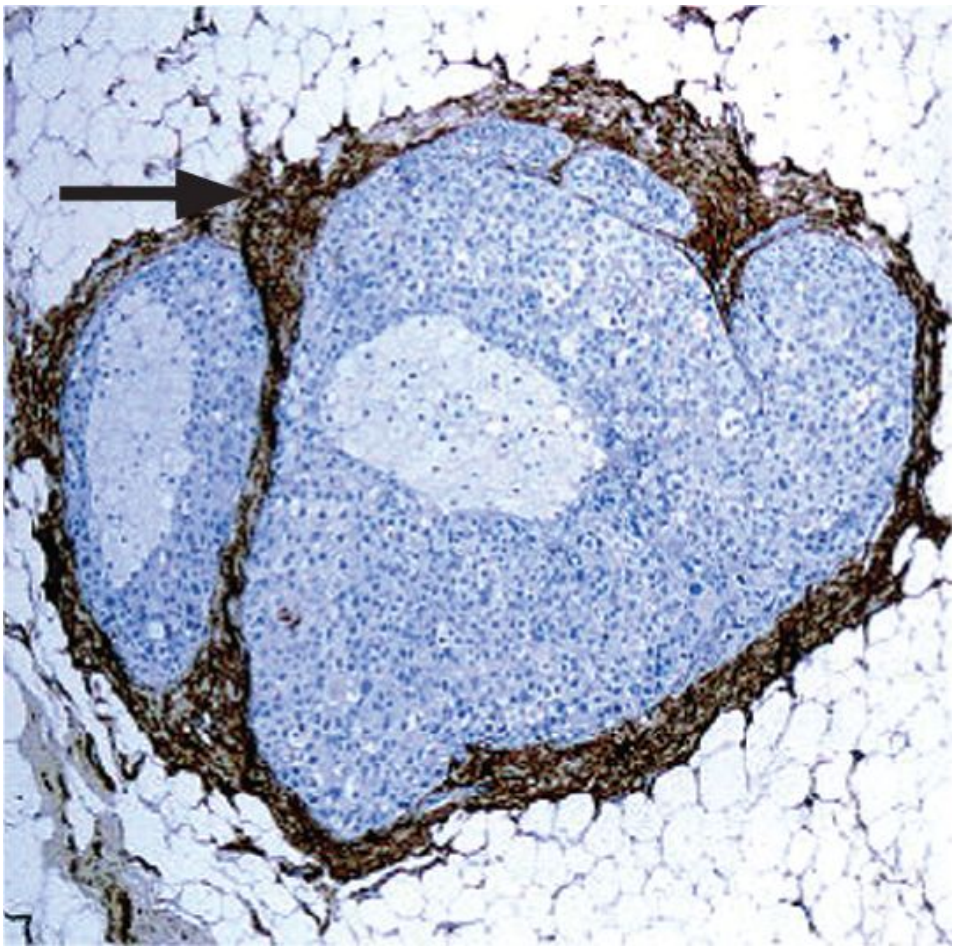
A histology stain. Most of the nuclei are stained a pale bluish pink, but dark brown flecks dot the image.

(C)



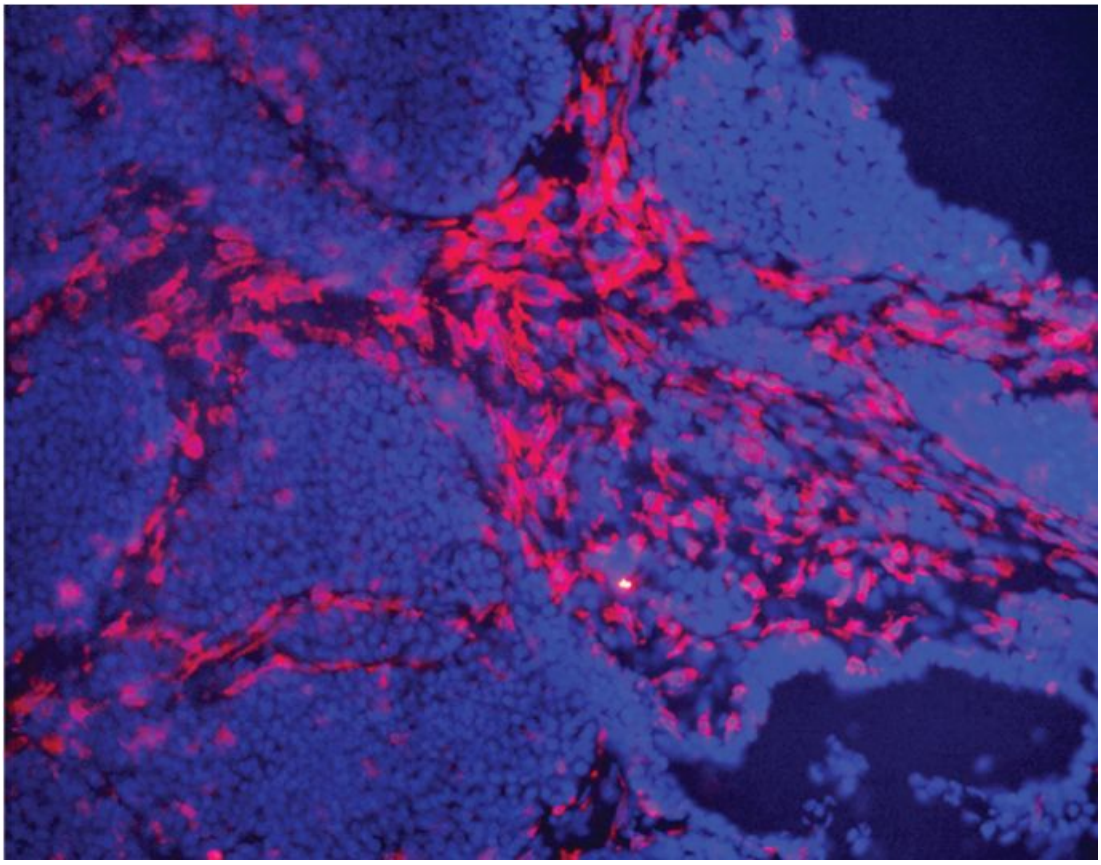
A histology stain. Most of the nuclei are stained a pale bluish pink, but dark brown streak-like fibers run diagonally across the image.

(D)



A histology stain. Two small regions of cells stained light blue are surrounded by larger regions of cells stained darker blue. These two larger regions, in turn, are encased as one in a sheath of cells stained gray-black. This clump of tissue is surrounded by large cells stained pale blue.

(E)



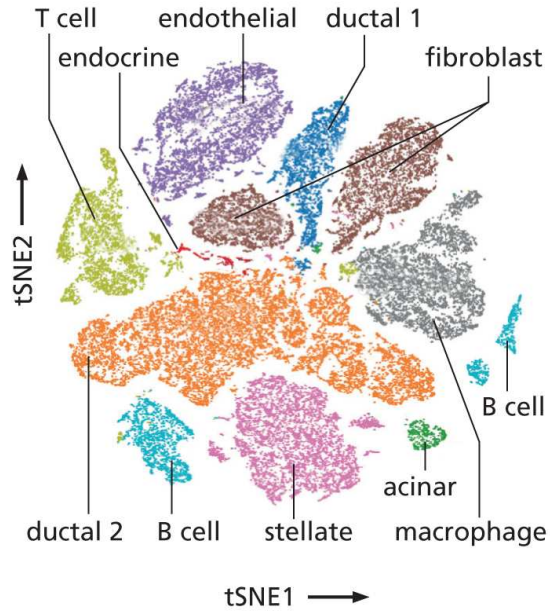
A fluorescence microscopy image. Clumps of dark blue and bright red streaks flow throughout the image in curved lines and patterns over a lighter blue background.

(F)

Figure 13.2 A variety of distinct cell types in the stroma of carcinomas Various antibodies can be used to immunostain specific mesenchymal cell types in the stroma of carcinomas. (A) CD4 antigen–positive T lymphocytes, often termed helper T cells (*red*), are scattered among mouse mammary carcinoma cells (*blue-purple nuclei*). The stroma of squamous cell carcinomas of the oral cavity, pharynx, and larynx may contain (B) CD34 antigen–positive fibrocytes (*brown*), (C) CD117 antigen–positive mast cells (*brown*), and (D) α-smooth muscle actin–positive myofibroblasts (*brown*). (E) The stroma of a ductal carcinoma *in situ* of the breast (DCIS) shows PINCH antigen–positive fibroblasts (*dark brown*; see Figure 13.1B) arrayed in a ring immediately around the carcinoma (*arrow*) and surrounded, in turn, by adipocytes (*light blue rims*). (F) Macrophages (*red*), which have been recruited to a mouse mammary carcinoma, play critical roles in tumor invasiveness and angiogenesis. (A and F, from D.G. DeNardo et al., *Cancer Cell* 16:91–102, 2009. With permission from Elsevier. B, C, and D, from P.J. Barth et

al., *Virchows Arch*. 444:231–234, 2004. With permission from Springer. E, from J. Wang-Rodriguez et al., *Cancer* 95:1387–1395, 2002. With permission from John Wiley & Sons.)

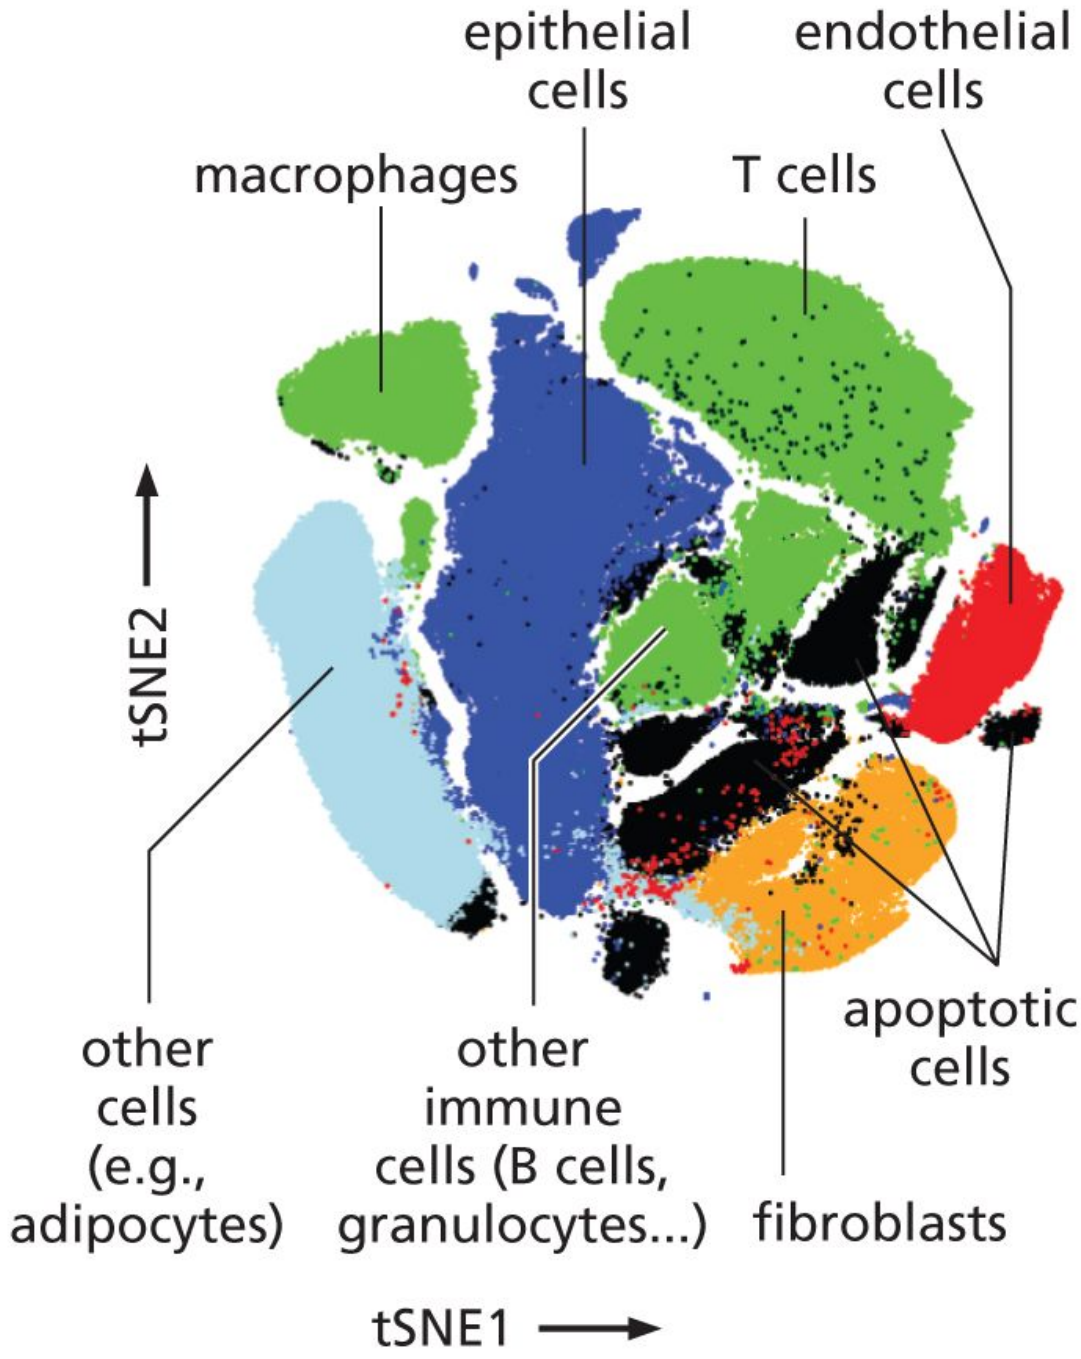
This impression of cellular complexity provided by Figure 13.2 is reinforced by the techniques of typing multiple antigens expressed in single cells as well as single-cell RNA sequencing (scRNAseq) in which distinct cell types are identified by the antigens or the transcriptomes that they express (**Figure 13.3**).



cell type	no. of cells	percentage
ductal cell 1	2,646	6.30%
ductal cell 2	11,315	26.95%
acinar cell	512	1.22%
endocrine cell	459	1.09%
endothelial cell	5,134	12.23%
fibroblast	5,802	13.82%
stellate cell	5,282	12.59%
macrophage	4,802	11.44%
T cell	3,616	8.61%
B cell	2,416	5.75%

A two dimensional map of the different cell types within a tumor, with a horizontal t S N E 1 axis and a vertical t S N E 2 axis. At the center of the tumor is a large mass of ductal type 2 cells, representing about 27 percent of the tumor. Other cell types include ductal 1, acinar, endocrine, endothelial, fibroblast, stellate, macrophage, T cell, and B cell.

(A)



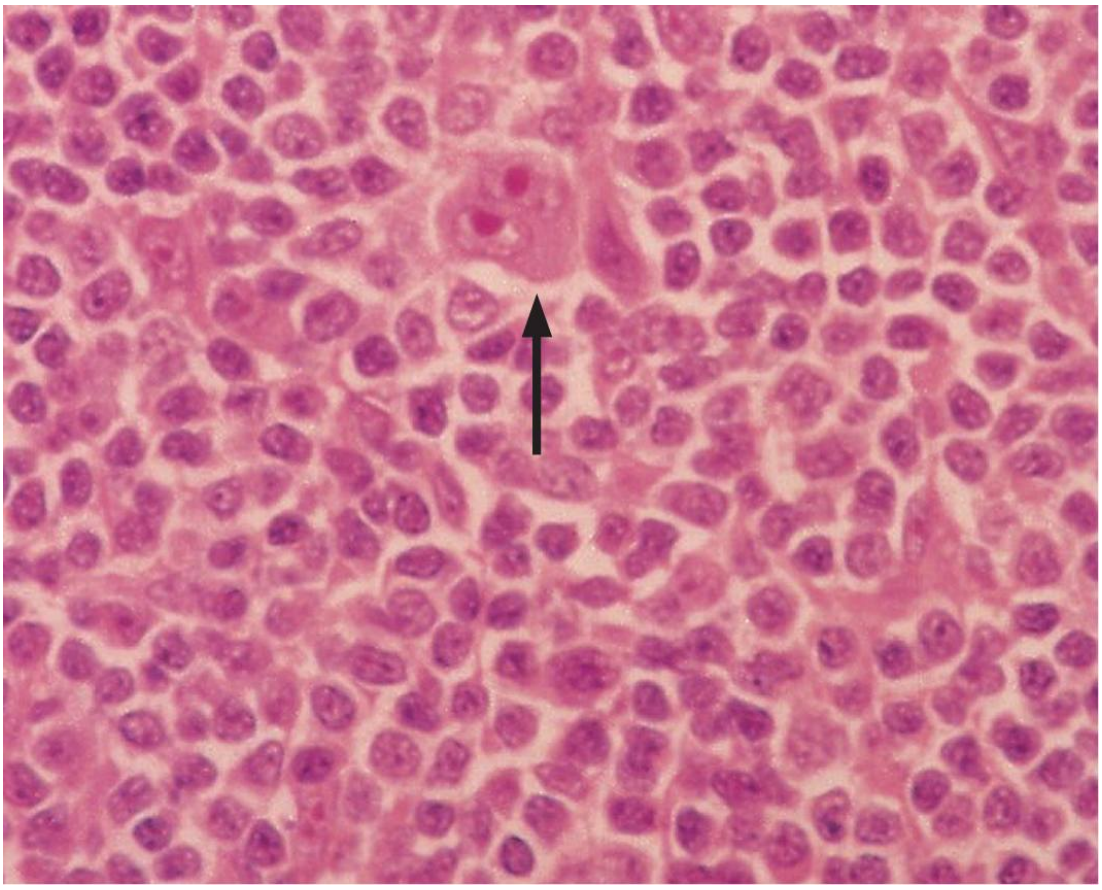
A two dimensional map of the different cell types within a tumor, with a horizontal t S N E 1 axis and a vertical t S N E 2 axis. Epithelial cells and T cells account for the largest percentages of the tumor. Other types include endothelial, macrophage, apoptotic, fibroblast, immune cells such as B cells and granulocytes, and other cells such as adipocytes.

(B)

Figure 13.3 Analyses of single cells enables surveys of the cellular complexity within tumors Techniques have been developed to analyze both the RNA and protein contents of single cells, making it possible to survey the entire contents of a tumor mass cell by cell. Results in both cases are plotted in 2 dimensions using the t-distributed stochastic neighbor embedding (t-SNE) algorithm, which allows multidimensional data to be plotted in 2 or 3 dimensions. (A) The intra-tumoral cellular heterogeneity has been surveyed here in a sample of a human malignant pancreatic adenocarcinoma, in this case from 57,530 individual cells whose RNA transcripts were analyzed by the procedure of single-cell RNA-seq (scRNAseq). In this analysis, two subtypes of pancreatic epithelial cells lining the ducts (ductal cells) are distinguished, as well as a class of acinar exocrine cells that are responsible for generating and secreting the digestive enzymes made by the pancreas. The endocrine cells include the components of the pancreatic islets that are described in a mouse model of pancreatic islet cells carcinogenesis in Figure 13.35. (B) The expression of 73 distinct protein species in 58,000 human breast tumor cells was examined by using cognate monoclonal antibodies to detect individual protein species followed by mass spectrometry to identify the representation of the individual antigen species that were assigned, in turn, to specific cell types. (A, J. Peng, B.F. Sun, C.Y. Chen et al. *Cell Res*. 29:725–738, 2019. With permission from Nature. B, from J. Wagner, M.A. Rapsomaniki, S. Chevrier et al. *Cell* 177:1330–1345, 2019. With permission from Elsevier.)

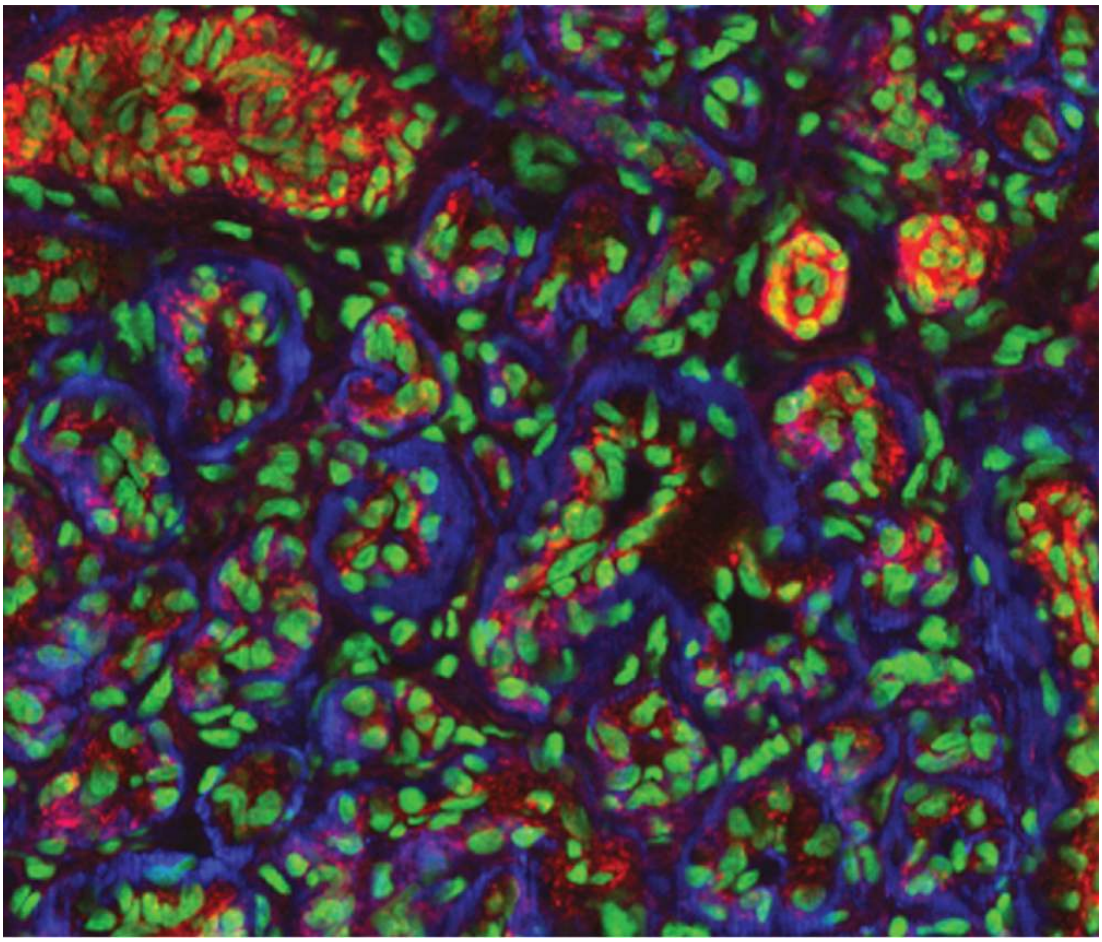
An additional dimension of complexity comes from the great variations in the proportions of various bone marrow–derived cell types within the stroma of different tumor types. As we will see in this chapter and the next, some of these cells are active participants in processes such as tumor cell invasiveness and metastatic spread; yet others may be dispatched by the immune system to eliminate tumor cells. In light of the important functions that these infiltrating cells can exert, we can imagine that they may contribute in major ways to the distinctive traits exhibited by various types of carcinomas.

[These examples fail to illustrate the great range of variations that are encountered in various types of non-carcinomatous human tumors. At one end of the spectrum is another solid tumor—Hodgkin's disease—a lymphoma in which non-neoplastic cells account for 99% of the cells in a tumor mass (**Figure 13.4A**). At the other end are tumors such as the hemangioma, a relatively common benign tumor of the endothelial cells (Figure 13.4B), in which neoplastic cells form the great bulk of the tumor mass. In what follows, we focus largely on carcinomas, in which the epithelial and stromal cells are often present in comparable numbers.]



A pink histology image in which a single, large abnormal cell is surrounded by several hundred smaller normal cells.

(A)



A fluorescence microscopy image in which hundreds of green nuclei appear against a background of blue and red.

(B)

Figure 13.4 Extreme variations in the ratio of neoplastic cells to stroma (A) In certain tumors, normal, non-neoplastic cells may constitute the great majority of living cells. An extreme form of this is illustrated here by Hodgkin's disease, a lymphoma in which as many as 99% of the cells are recruited normal lymphocytes, which surround a rare neoplastic Reed–Sternberg cell (*arrow*). (B) At the other end of the spectrum are tumors such as the benign hemangioma shown here, in which neoplastic endothelial cells (*green nuclei*) form the great bulk of the tumor mass, which is demarcated by basement membranes (*blue-purple*) and occasional capillaries (*red*). (A, from A.T. Skarin, Atlas of Diagnostic Oncology, 4th ed. Philadelphia: Elsevier Science Ltd., 2010. With permission from Elsevier. B, from M.R. Ritter et al., *Proc. Natl. Acad. Sci. USA* 99:7455–7460, 2002. With permission from National Academy of Sciences, U.S.A.)

Most of the diverse cell types forming the tumor-associated stroma are members of several mesodermal cell lineages that generate both connective tissue and various types of immunocytes in the blood and immune tissues, and therefore are biologically very different from the epithelial cells whose transformation drives the growth of carcinomas. (In the case of nonepithelial tumors such as sarcomas, where the cancer cells are themselves of mesodermal origin, the boundaries between the neoplastic cell compartment and the non-neoplastic cells within the tumor mass have never been clearly delineated.)

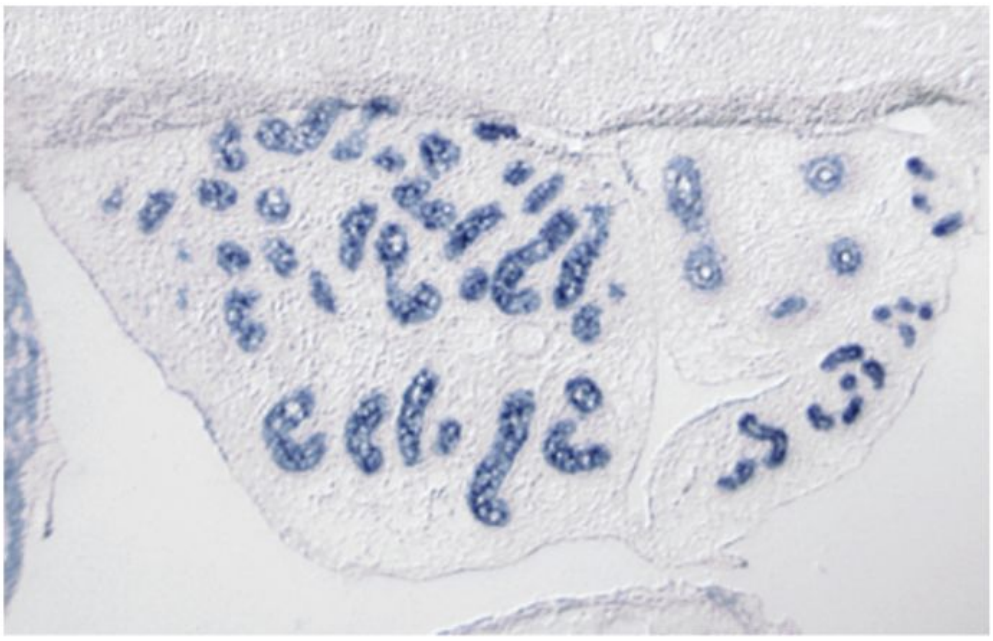
In the absence of other information, we might explain the presence of these various stromal cell types within a carcinoma in two ways. They might represent the remnants of cells that resided in the stroma of a tissue before tumor development began. During the subsequent expansion of the tumor cell population, groups of cancer cells may have inserted themselves between these preexisting normal stromal cell layers, thereby generating the richly textured tissues that are seen when most carcinomas are examined microscopically.

The alternative explanation for the presence of these numerous stromal cells is more intriguing and is likely to be the correct one for the great majority of tumors as suggested above. The rationale behind this second model depends on our current understanding of how normal, architecturally complex tissues develop and maintain their structure and function. In such tissues, the proper proportions of the various component cells must depend on the continuous intercommunication between them. These interactions involve multiple distinct cell types, each following its own particular differentiation program. Such communication between dissimilar cell types is termed heterotypic signaling and is used by each cell type to encourage or limit the proliferation of the other types of cells nearby.

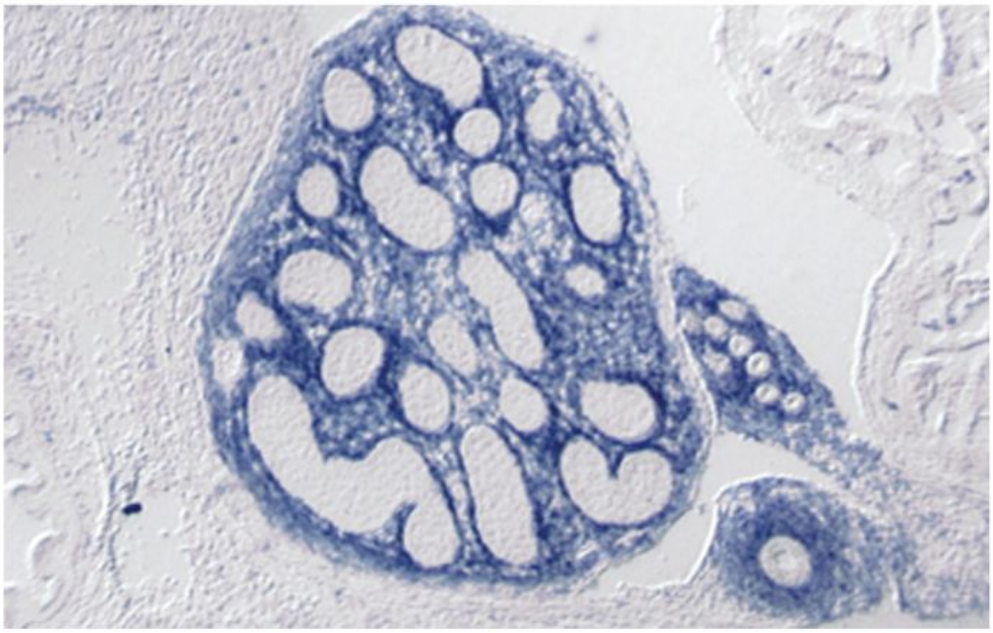
Extending this thinking, we might speculate that many of the heterotypic interactions operating in normal tissues continue to play important roles in the biology of the tumors arising in these tissues. This would suggest that, like normal epithelial cells, carcinoma cells continue to control the populations of stromal cells near them, perhaps by recruiting the latter from nearby normal tissues and distant bone marrow, and then encouraging their proliferation. Operating in the other direction, stromal cells also influence epithelial cell proliferation and survival in the tumor mass.

In normal tissues, these heterotypic signaling channels depend in large part on the exchange of (1) mitogenic growth factors, such as hepatocyte growth factor (HGF), transforming growth factor-α (TGF-α), and platelet-derived growth factor (PDGF); (2) growth-inhibitory signals, such as transforming growth factor-β (TGF-β); and (3) trophic factors, such as insulin-like growth factor-1 and -2 (IGF-1 and -2), which favor cell survival. Although these factors are secreted into the extracellular space, they usually act over short distances between nearby cells (**Figure 13.5**) and their

localization within the interstitial spaces between cells is likely to be critically important to their functions (**Supplementary Sidebar 13.1**).



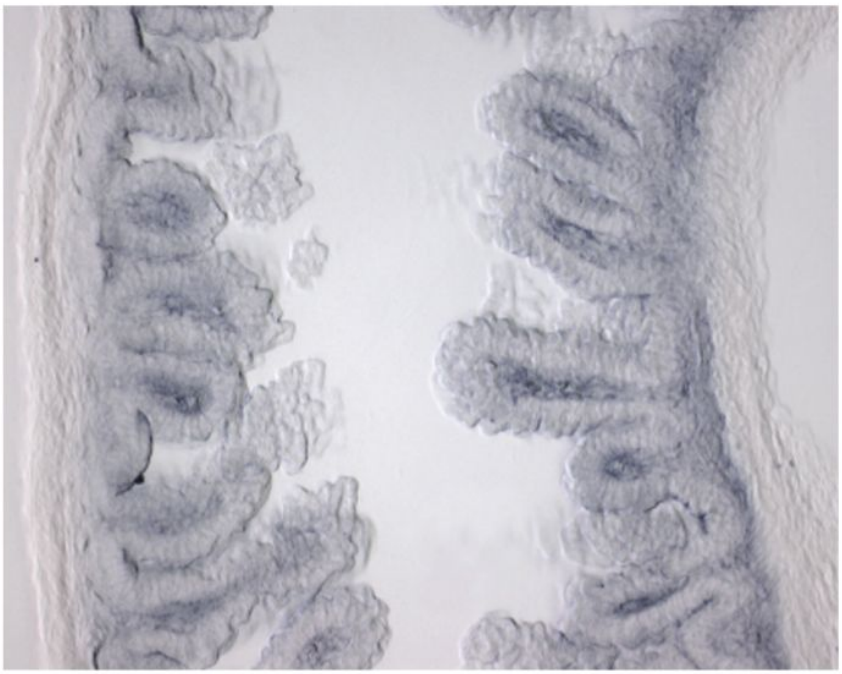
PDGF-A (ligand)



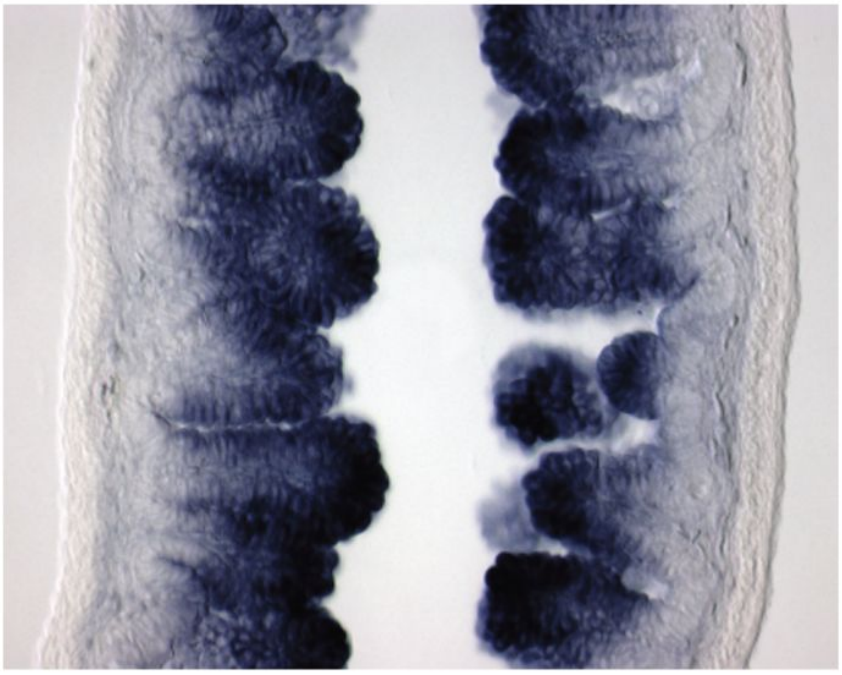
PDGF-Rα (receptor)

A micrograph, labeled P D G F-A (ligand), of a trapezoidal piece of white embryonic mouse testes tissue with blue, wormlike structures in the left portion and along the right edge. There are also rounded structures in the center right portion. Below that is a micrograph, labeled P D G F-R alpha (receptor), of a pear-shaped blue structure with many white holes.

(A)



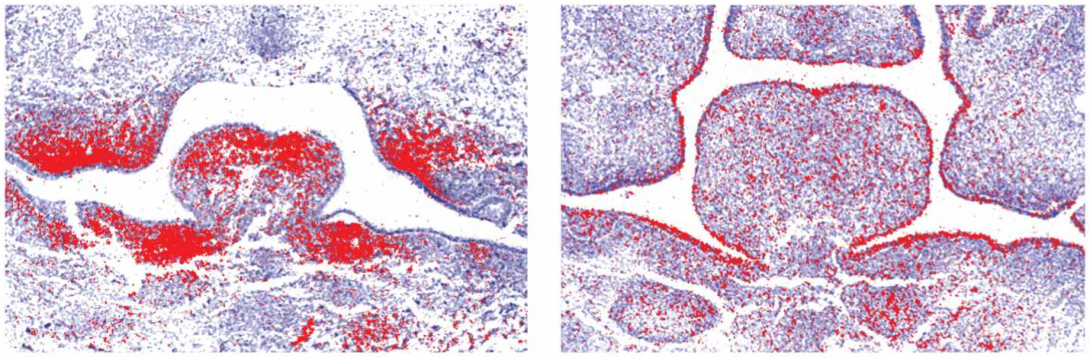
HGF/SF (ligand)



Met (receptor)

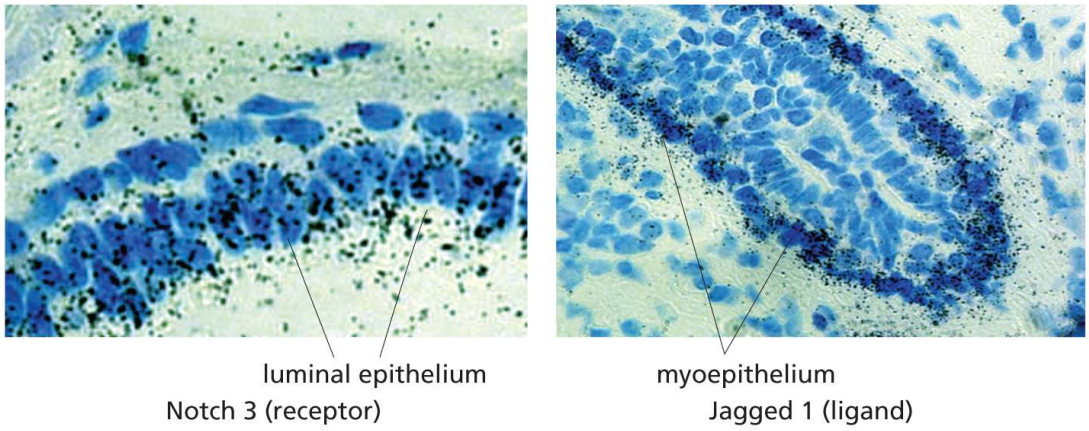
A micrograph, labeled H G F slash S F (ligand), of a section of embryonic mouse intestine. The villi are pale gray and border the left and right sides of the image. Below that is a micrograph, labeled Met (receptor), that is similar to the first one except that the villi are stained a deep indigo.

(B)



Two cross sections of a embryonic mouse's oral cavity. In the first image, labeled F G F10 (ligand), the deep tissues are bright red. In the second image, labeled F G F-R2b (receptor), the surface layer of tissue is bright red and the deep tissues are now light blue.

(C)



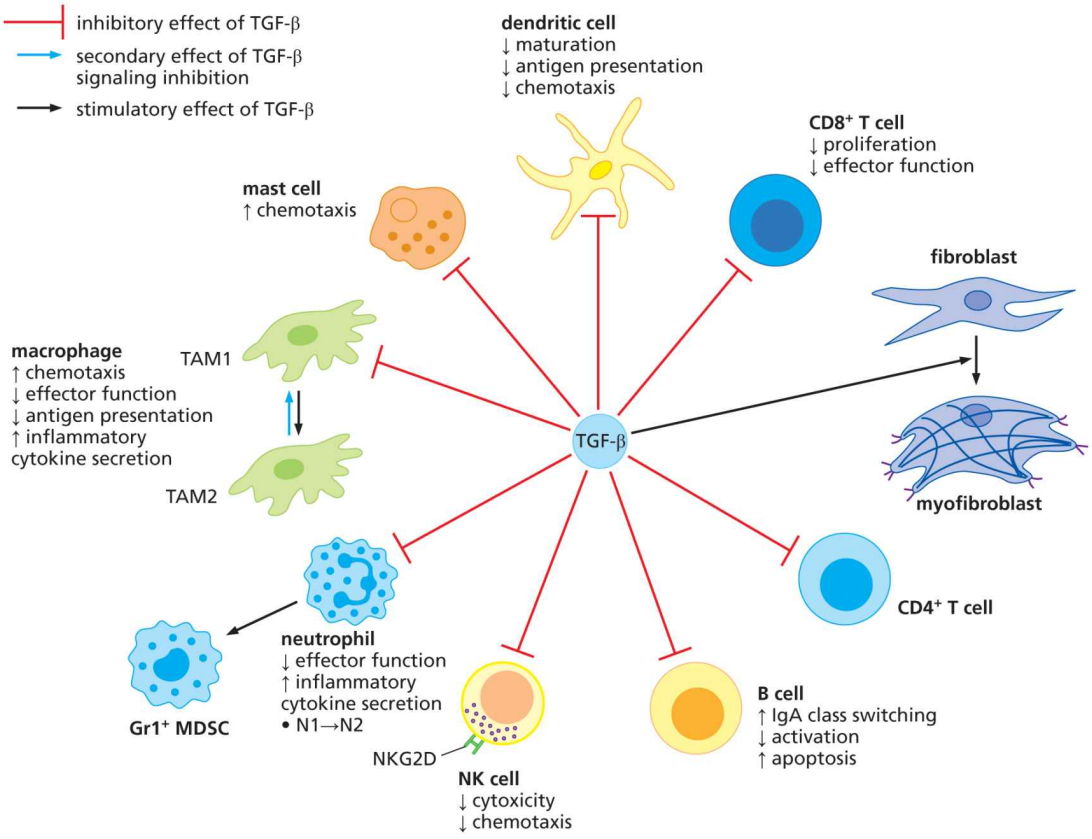
Two histology images of embryonic mouse mammary tissue. In the first image, labeled Notch 3 (receptor), blue luminal epithelial cells are littered with black dots. In the second image, labeled Jagged 1 (ligand), blue myoepithelial cells are littered with similar dots.

(D)

Figure 13.5 Heterotypic ligand–receptor signaling (A) In epithelial tissues, the synthesis of PDGF-A and its receptor (PDGF-Rα) is usually confined to distinct cell types. In the testis, expression of PDGF is confined to the cells of the tubular epithelium (*above*), while expression of its receptor is confined to the surrounding

mesenchymal cells (*below*). (B) The reciprocal expression of the Met receptor and its ligand, termed variously hepatocyte growth factor (HGF) or scatter factor (SF), is shown here in the embryonic mouse ileum (the lower section of the small intestine). In each fingerlike villus, seen in longitudinal section (see also Figure 11.5C), HGF/SF mRNA, detected by *in situ* hybridization, is made by the mesenchymal cells in the core of the villus (*above*), whereas Met is expressed by the epithelial cells coating the surface of the villus (*below*). (C) In the developing oral cavity of the mouse, the FGF10 ligand (*red*) is produced by the mesenchymal cells of the stroma of the developing palate (*left*), whereas its cognate receptor, FGF-R2b (*red*), is displayed by the overlying epithelial cells (*right*). Other work not shown here indicates that the epithelial cells respond to resulting ligand-mediated activation of their FGF-R2b by releasing Sonic Hedgehog (Shh), which signals back to Patched (Ptc) receptors displayed by mesenchymal cells in the stroma. (D) In the normal mouse mammary gland, use of antisense probes to detect mRNAs indicates that the Notch 3 receptor (*left)* is expressed (*black dots*) in the luminal epithelial cells, but its ligand, Jagged 1 (*right*), is expressed (*black dots*) in myoepithelial cells. (A, from L. Gnessi et al., *J. Cell Biol*. 149:1019–1026, 2000. With permission from Rockefeller University Press. B, courtesy of S. Britsch and C. Birchmeier. C, from R. Rice et al., *J. Clin. Invest.* 113:1692–1700, 2004. With permission from American Society for Clinical Investigation. D, from M. Reedijk et al., *Cancer Res*. 65:8530–8537, 2005. With permission from American Association for Cancer Research.)

Within individual tumors the complexity that we will confront exists in at least three dimensions: To begin, there are multiple distinct cell types that are recruited to the stroma (see Figures 13.2 and 13.3). Second, multiple signals are exchanged between these distinct cell types; our focus here will be on bidirectional interactions between cancer cells and individual stromal cell types. Finally, each signal that is exchanged between neoplastic and recruited stromal cells evokes multiple distinct responses in the various cell types recruited to the tumor-associated stroma. Shown in **Figure 13.6** is one example of this complexity—the effects of a single type of released signal, TGF-β , on the various mesoderm-derived cell types present in the stroma of a carcinoma. [Not addressed by this figure is yet another target of TGF-β action—the carcinoma cells themselves. These are often induced by TGF-β to activate their previously latent cell-biological program termed the EMT (epithelial–mesenchymal transition), which confers on them higher degrees of aggressiveness and will be described later in this chapter.] The realities of heterotypic signaling dictate that we will only scratch the surface of its complexity in the present chapter, attempting to understand mechanistic principles rather than to enumerate systematically all of the cell–cell signaling pathways that operate within the confines of a single tumor.

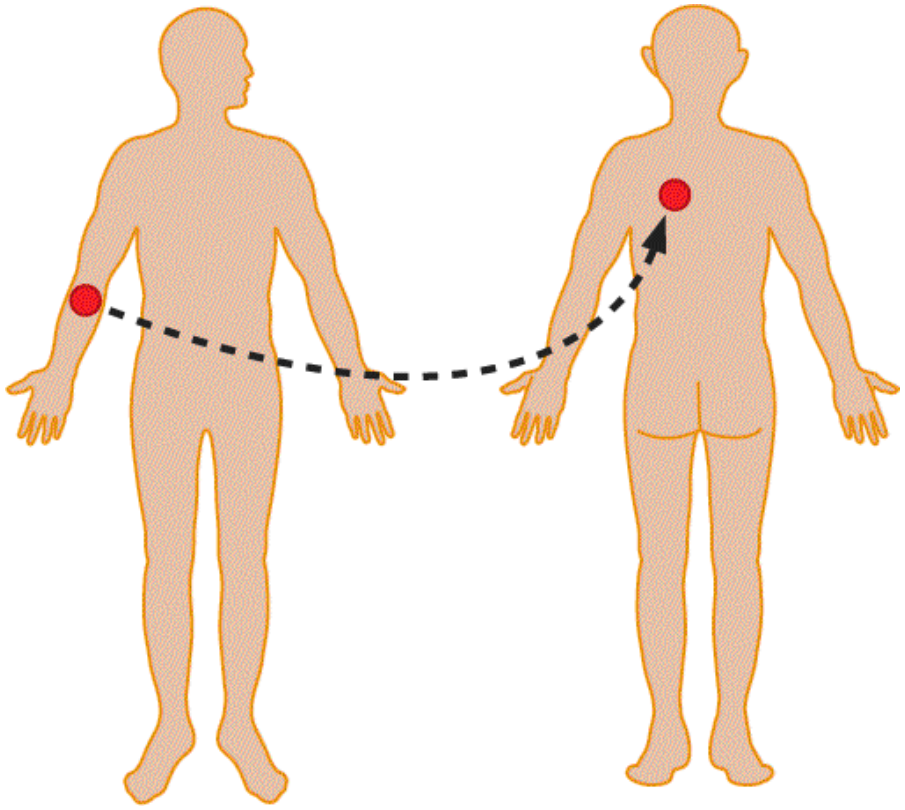


An illustration of the influences that T G F beta, shown in the center, has on various cell types, which are shown in a circle around T G F beta. In a dendritic cell, T G F beta decreases maturation, antigen presentation, and chemotaxis. In a C D8 plus T cell, T G F beta decreases proliferation and effector function. In a fibroblast, T G F beta increases conversion into a myofibroblast. T G F beta decreases the formation of C D 4 plus T cells. In a B cell, T G F beta decreases activation and increases I g A class switching and apoptosis. In an N K cell, shown with an attached N K G 2 D, T G F beta decreases cytoxicity and chemotaxis. In a neutrophil, T G F beta decreases effector function and increases inflammatory cytokine secretion of N1 to N2. The effects on neutrophils stimulate the production of G r 1 plus M D S C cells. In a macrophage, T G F beta decreases effector function and antigen presentation, and increases chemotaxis and inflammatory cytokine secretion. It stimulates conversion between tumor associated macrophages 1 and 2. Finally, in a mast cell, T G F beta increases chemotaxis.

Figure 13.6 Paracrine signaling: the case of TGF-β Various signaling molecules are exchanged between carcinoma cells and the nearby stroma. These molecules often operate similarly in corresponding normal epithelial tissues but their effects may be altered during the course of tumor progression. Among these paracrine signaling factors, the most widely acting is likely to be TGF-β, which perturbs the

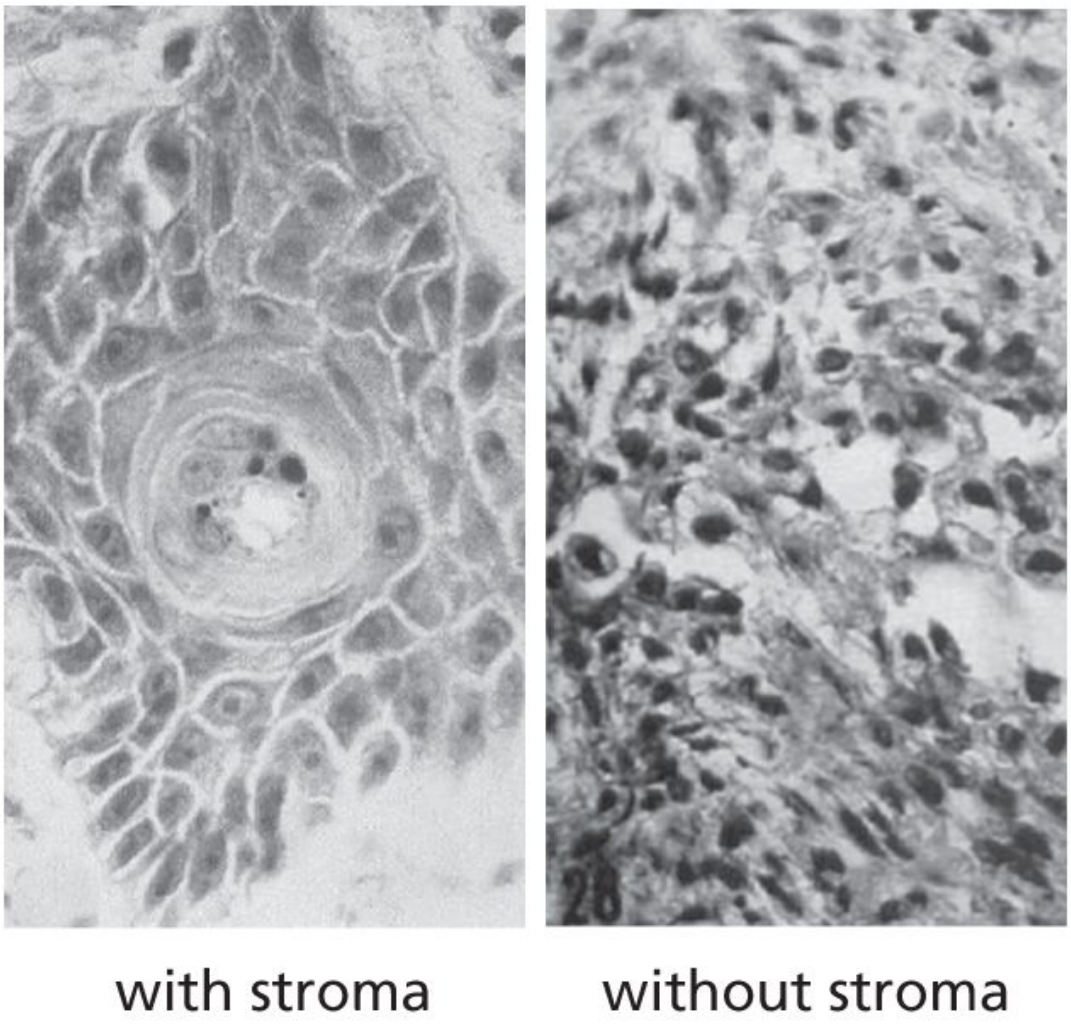
functions of a wide range of cell types that are recruited to the tumor-associated stroma, often termed the tumor microenvironment (TMEN). Most of the cell types that are illustrated here are components of the innate and adaptive immune systems that are described in detail in Chapter 15. In addition, TFG-β can induce stromal fibroblasts to become myofibroblasts that express α-smooth muscle actin (α-SMA; *right*), which play critical roles in inflammation and wound healing. (Adapted from R. Derynck, S. Turley and R. Akhurst *Nat. Rev. Clin. Oncol*. 18, 9–34, 2021. With permission from Nature.)

Given these complex interactions within tissues, what evidence can we muster to support the notion that such heterotypic interactions are *functionally important* for tumor growth rather than representing vestiges—functionally irrelevant relicts—of normal tissue physiology? Until the mid-twentieth century, the role of stromal cells in supporting the growth of epithelial tumors was not appreciated. Experiments reported in 1961 provided some of the first evidence for the importance of these interactions in tumor biology; these were experiments of a sort that could not be repeated these days, given existing regulations on clinical testing of human subjects. Basal cell carcinomas of the skin were excised from patients and then reimplanted in normal areas of the skin elsewhere in the same patients (**Figure 13.7A**). Because these were autotransplantations, with each patient receiving a graft of his or her own cells, no immune rejection occurred (see Section 3.5). When the implanted cells included only groups of carcinoma cells, the grafts failed to grow; however, if these carcinoma grafts included both epithelial cancer cells and the underlying tumor-associated stroma, they became well established at the sites of implantation (Figure 13.7B). This experiment provided strong indication that the mesenchymal cells of the stroma are indeed essential to supporting the growth of the tumor as a whole.



A diagram showing the transplantation of tissue from the anterior surface of a person’s right forearm to the same person’s left upper back.

(A)



Two histology images. The one on the left, labeled with stroma, shows a large round nodule growing in a rectangular field of normal looking cells. The image on the right, labeled without stroma, shows many small, irregularly shaped and spottily colored cells, and no prominent nodule.

(B)

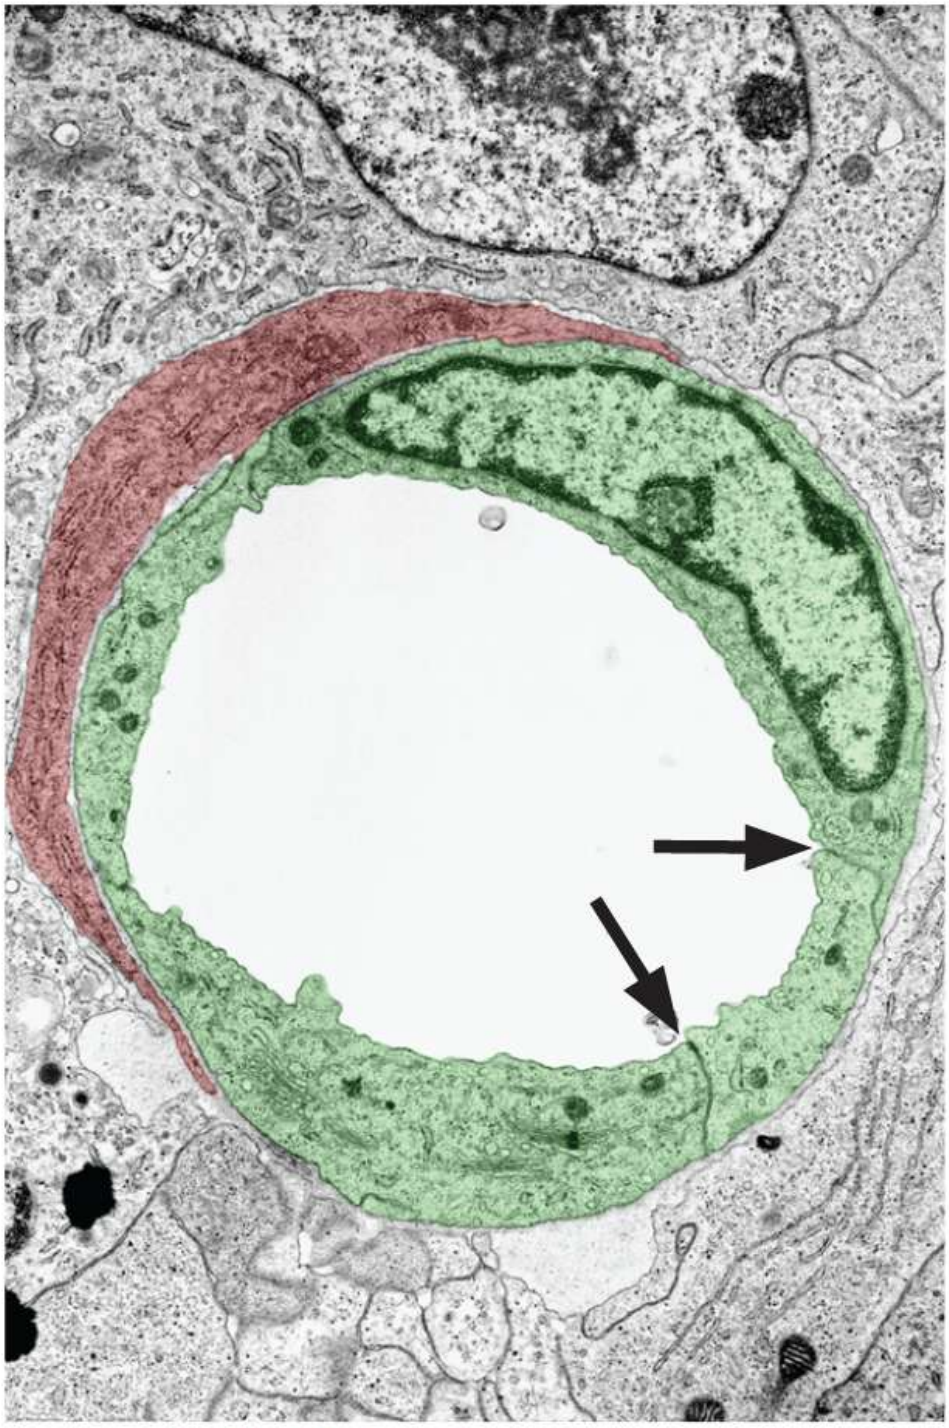
Figure 13.7 Autologous transplantation of skin tumors (A) Basal cell carcinomas of the skin were excised from patients and the carcinoma cells were reimplanted, either together with or without carcinoma-associated stromal cells, in distant anatomical sites on the skin of the back of the patients who had borne the original tumors. (B) The implanted tissues were excised 1 to 5 weeks later. Those that had been implanted together with stroma (*left*) yielded robustly growing carcinoma cells, whereas those that were implanted without concomitantly implanted stroma (*right*) failed to grow and yielded only vacuolated cells and cell

debris. (A, courtesy of S. McAllister. B, from E.J. Van Scott and R.P. Reinertson, *J. Invest. Dermatol.* 36, 109–131, 1961. With permission from Elsevier.)

Now, more than half a century later, the details of many stromal–epithelial heterotypic interactions and their roles in tumor progression have been elucidated in great detail. We now know that they play key roles in virtually all the stages of tumor progression (see Chapter 11), beginning with the initial formation of tumors. For example, carcinoma cells release growth factors, cytokines, and chemokines that recruit macrophages, neutrophils, and lymphocytes to the tumor-associated stroma; the recruited cells then orchestrate an inflammatory response that involves the release of TNF-α and prostaglandins, which proceed to stimulate the proliferation of nearby epithelial cells and the process of neoangiogenesis—the formation of blood vessels within the tumor stroma.

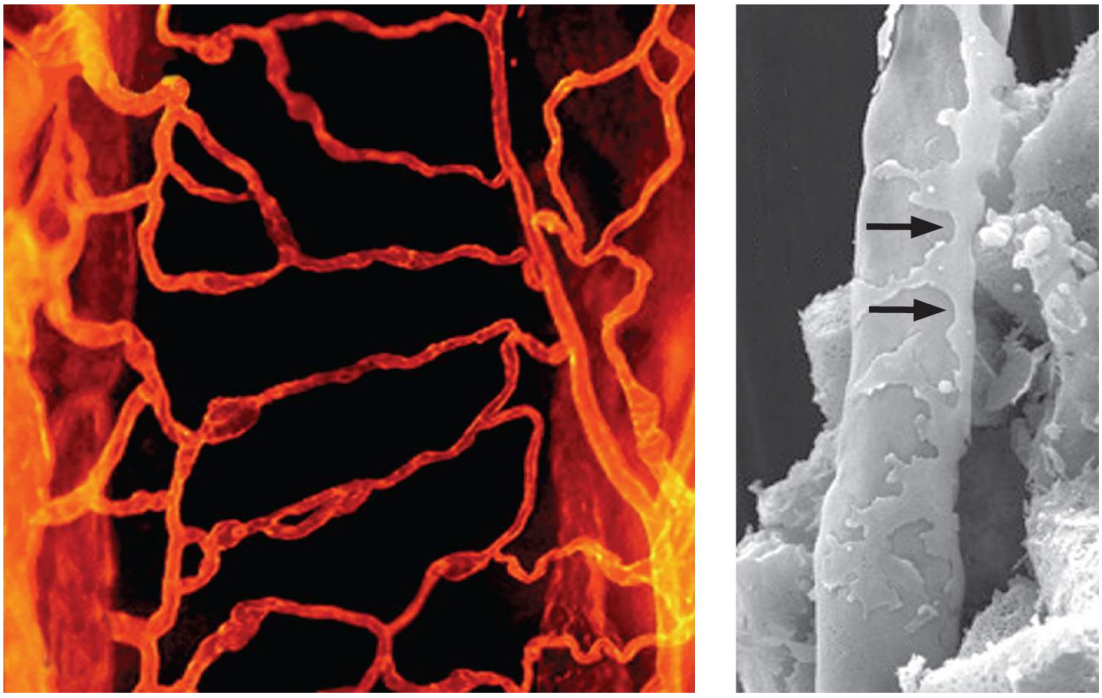
Many of these heterotypic interactions continue to operate after fully neoplastic tumors have been formed. To cite some examples, epithelial cells within a carcinoma often release PDGF, for which stromal cells—notably fibroblasts, myofibroblasts, and macrophages—possess receptors; the stromal cells reciprocate by releasing IGF-1 (insulin-like growth factor-1), which benefits the growth and survival of the nearby cancer cells. Similarly, the neoplastic cells within melanomas release PDGF, which elicits IGF-2 production from nearby stromal fibroblasts; this IGF-2 helps to maintain the viability of the melanoma cells. Stromal cells in breast cancers release the factor SDF-1/CXCL12 (a chemokine) and the HGF/SF growth factor, which stimulate the proliferation and survival of nearby epithelial cancer cells. More generally, by regulating each other's numbers and positions, epithelial and stromal cells ensure the optimal representation and localization of each cell type within both normal and neoplastic tissues. Additional examples are illustrated in **Supplementary Sidebar 13.2**.

The endothelial cells (**Figure 13.8A**), which assemble to form the linings of the walls of capillaries and larger blood vessels (Figure 13.8B) as well as lymphatic ducts (Figure 13.8C), represent vital components of the normal and neoplastic stroma. As discussed in greater detail later, proliferation of the endothelial cells forming capillaries is encouraged by other cells in both the epithelium and stroma in order to guarantee access by all of these cells to an adequate blood supply. Once capillaries are successfully assembled and become fully functional, they supply essential nutrients and oxygen to nearby tumor-associated cells; at the same time, they serve the equally important function of evacuating metabolic wastes and carbon dioxide from tissues including tumors.



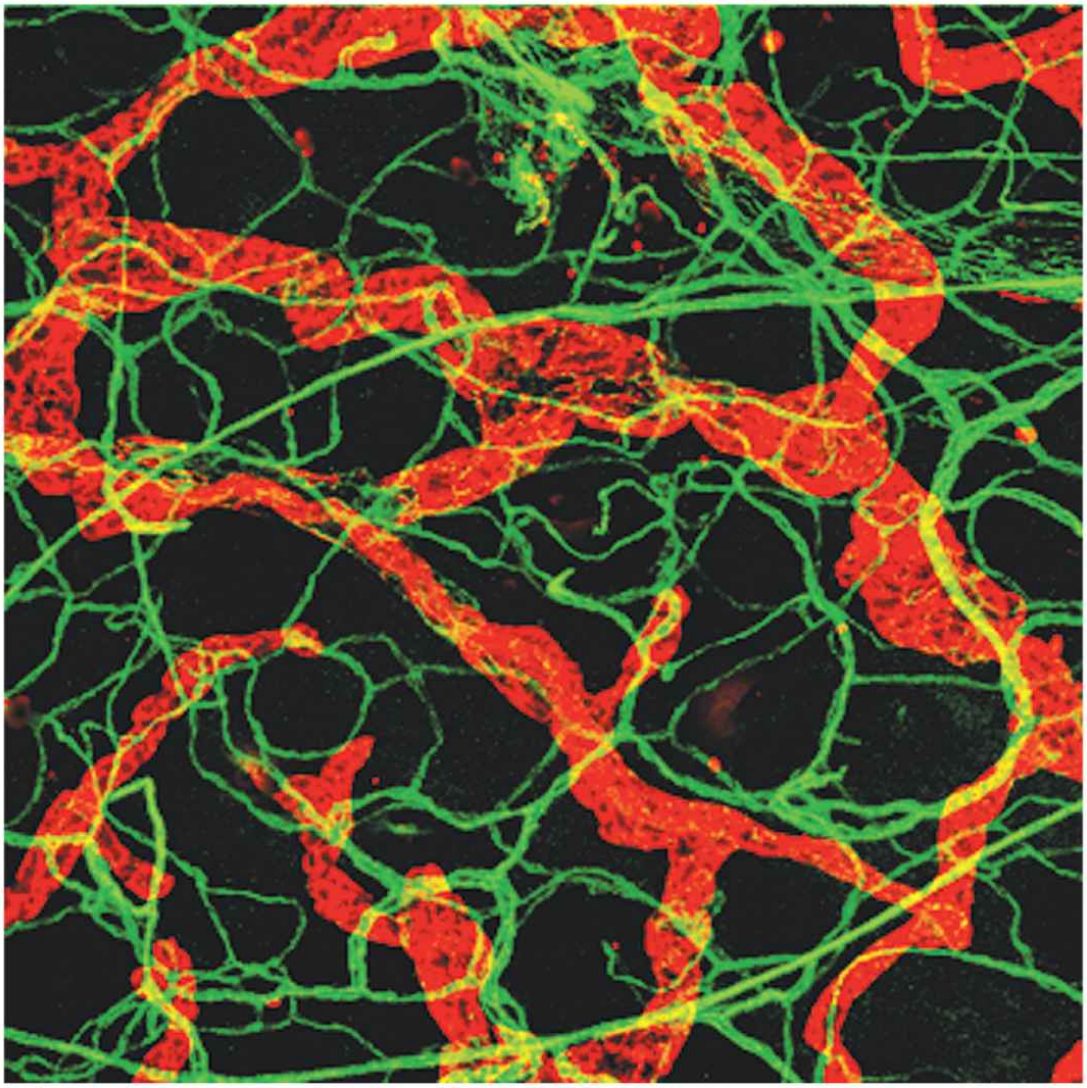
A transmission electron micrograph showing a cross section of a capillary. A cell shown in green forms nearly the entire capillary wall. A small section, also in green, represents another cell. A cell shown in red forms a kind of secondary semiperimeter around the green cell.

(A)



An Immunofluorescent microscopy image of capillaries, shown in red-orange, and a higher-magnification scanning electron microscopy image in which arrows point to an irregular layer of cells adhering to an otherwise smooth capillary.

(B)



A fluorescence microscopy image of blood capillaries, shown in green, and larger, less numerous lymph ducts, shown in red-orange.

(C)

Figure 13.8 Microvessels in normal tissues (A) This transmission electron micrograph presents a cross section of a capillary within the stroma of a tumor formed by mouse Lewis lung carcinoma cells. The endothelial cell and its nucleus have been colorized *green*, and the pericyte, which helps maintain capillary rigidity and intraluminal blood pressure, is colorized *red*. At least one additional endothelial cell has contributed to the formation of this section of the capillary, as indicated by the arrows at the joints between the cytoplasms of the two endothelial cells. (B) Immunofluorescent microscopy (*left*) of the capillaries in a normal

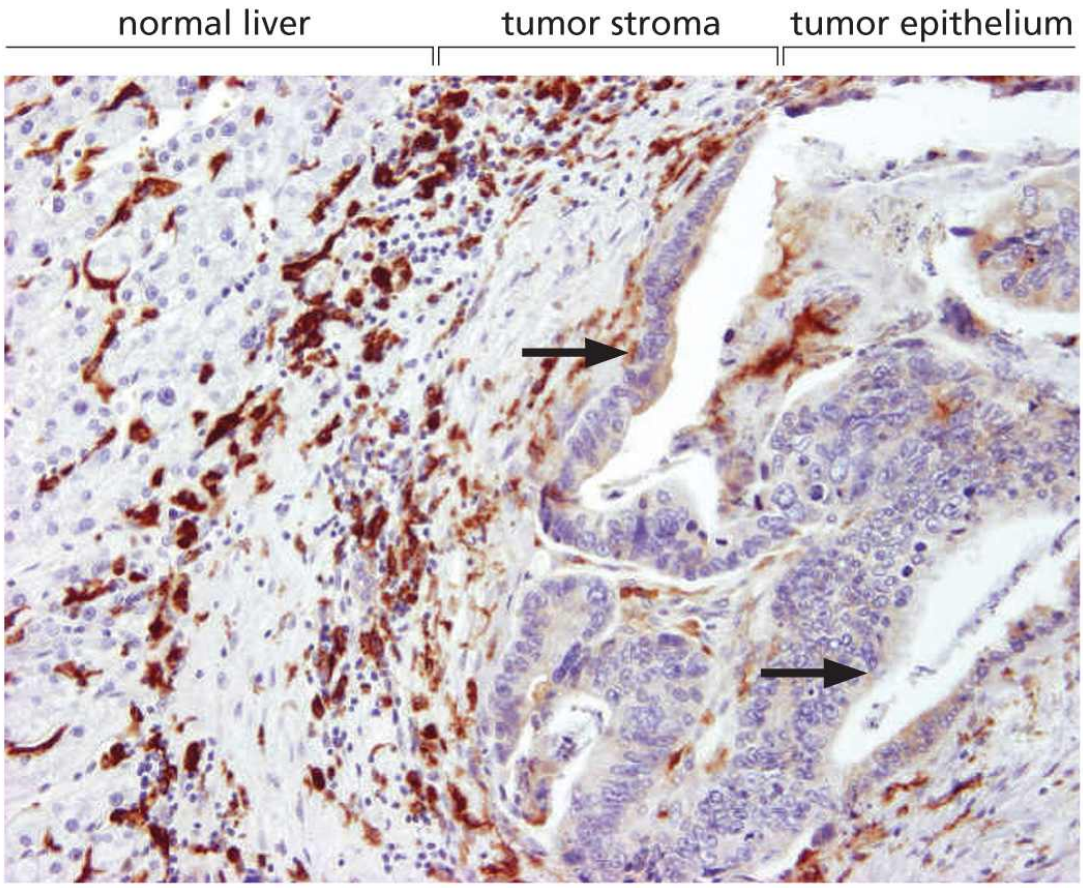
mouse trachea reveals (using an antibody that recognizes the endothelial cell–specific CD31 antigen) a well-organized network of microvessels. At the level of scanning electron microscopy (*right*), a capillary is seen to resemble a smooth-walled tube with pericytes (*arrows*) adhering to its outer surface. (C) Most normal tissues are interlaced with networks of capillaries (*green*) and lymphatic vessels (*red-orange*). As is apparent here, the diameters of lymphatic vessels are far larger than those of capillaries. Unlike capillaries, however, the endothelial cells of lymphatic vessels are not supported by underlying mural cells—pericytes and smooth muscle cells (*not shown*). (A, from B. Sennino et al., *Cancer Res.* 67:7358–7367, 2007. With permission from American Association for Cancer Research. B, from T. Inai et al., *Am. J. Pathol*. 165:35–52, 2004. With permission from Elsevier. C, courtesy of T. Tammela and K. Alitalo.)

While capillary formation is proceeding, the endothelial cells secrete growth factors that stimulate the proliferation of nearby nonendothelial cell types. Most important, endothelial cells release PDGF and HB-EGF (heparin-binding EGF), which enables them to attract (see **Supplementary Sidebar 13.1**) the peri-endothelial cells called pericytes and the vascular smooth muscle cells that together create the outer cell layers of capillaries, sometimes called the mural cells to distinguish them from the luminal endothelial cells (see Figure 13.8A and B). Once in place, the pericytes (which closely resemble smooth muscle cells) reciprocate by releasing vascular endothelial growth factor (VEGF) and angiopoietin-1 (Ang-1), which provide important survival signals to the endothelial cells that recruited them in the first place. In addition, these mural cells provide the endothelial tubes with structural stability and an ability to resist the forces exerted by the pressure of blood (see Figure 13.8B).

At present we are far from being able to enumerate all the key heterotypic interactions that operate within normal tissues and, by extension, in tumors. Because tumors rarely invent novel signaling mechanisms (rather than exploiting normal ones), a subset of the interactions operating in normal tissues must be operating in tumors, including those that underlie the support of carcinoma cells by nearby recruited stromal cells. Given the multiple distinct cell types present in normal tissues and tumors and the bidirectional intercommunications between different pairs of these cell types, the total number of these signaling channels, calculated combinatorially, is surely vast.

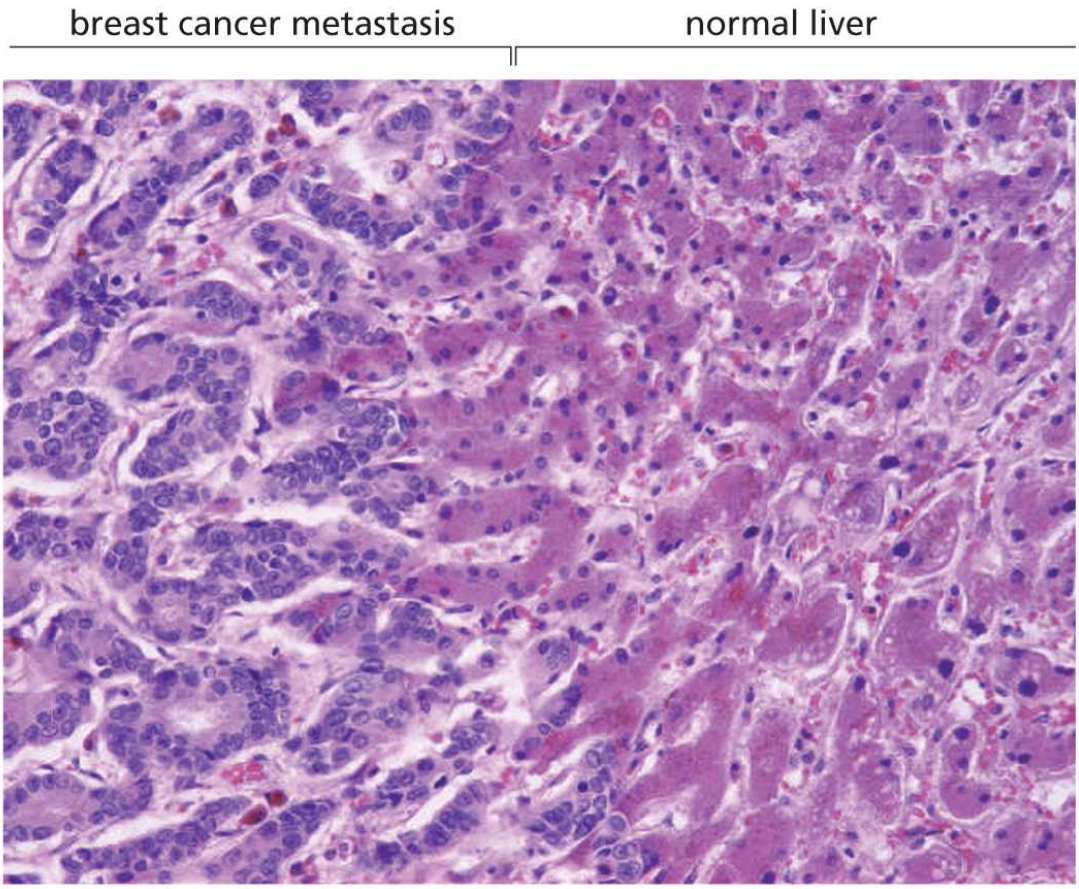
Stromal cells are often found to be layered between carcinoma cells in most metastases. This arrangement shows that even those cancer cells that are independent enough to disseminate from the primary tumor and to found new tumors at distant sites usually find it necessary to recruit stromal cells and encourage their proliferation (**Figure 13.9A**). On occasion, metastatic cells will insinuate themselves into the existing stroma of the tissue in which they have landed (Figure 13.9B), once again demonstrating their need to secure stromal support by one means or another. Finally,

we should note that an entire class of stromal cells—immunocytes—plays a critical role in the immunobiology of tumors, indeed a role so critical and far-reaching that we will devote two chapters to these cells and their implications for tumor growth and therapeutic elimination.



A histology image of liver tissue, on the left, being invaded from the right by tumor tissue. The leading edge of the advancing tumor is tumor stroma.

(A)



A histology image of normal liver tissue, on the right, being invaded from the left by breast cancer metastasis. There is no distinct region of stromal cancer tissue.

(B)

Figure 13.9 Metastasis and dependence on stroma (A) This micrograph of a metastasis originating from a primary colon carcinoma reveals that the metastasis found in the liver is as complex histologically as the primary tumors seen in Figure 13.1B. Here, we see that the carcinoma cells that have formed a metastasis (*light purple*, *right*) have constructed the same ductal structures (*arrows*) as are seen in primary adenocarcinomas of the colon. In addition, the carcinoma cells have recruited substantial stroma (*middle*), which includes macrophages (*dark brown*). (B) Most breast cancer metastases to the liver (*left*) behave quite differently from colon carcinoma metastases to this organ, in that the mammary carcinoma cells infiltrate into normal liver tissue (*right)* and displace resident hepatocytes, thereby taking advantage of the existing stroma, including its vasculature. These metastatic cells appear to be as dependent on stromal support as the colorectal carcinoma cells of (A) but acquire access to it in an entirely

different way. (From F. Stessels et al., *Br. J. Cancer* 90:1429–1436, 2004. With permission from Nature.)

Certain classes of metastases teach important overarching lessons about the roles of neoplastic cells in organizing their associated TME. For example, melanomas that have metastasized to the brain recruit abundant T lymphocytes to their stroma, whereas primary brain tumors growing in similar locations—gliomas and glioblastomas—although being rich in macrophages and microglia, attract hardly any of these immune cells. This these vignettes emphasize the role of the neoplastic cells in orchestrating the cellular composition of the TME.

In one extreme version of these scenarios, we might imagine that all heterotypic interactions needed to maintain normal tissue function continue to operate within carcinomas, being essential for the neoplastic cells to thrive and multiply within these tumors. However, such a depiction cannot be literally true, because many of the acquired traits that we associate with cancer cells (see Chapter 3), including a decreased dependence on mitogens, an increased resistance to apoptosis, and the acquisition of anchorage independence, are certain to affect the interactions between epithelial and stromal compartments and to lessen their interdependence. So, we conclude that these acquired traits generally *reduce* the dependence of epithelial cancer cells on stroma but do not seem to *eliminate* it. Finally, there are examples of outliers—cancer cells that appear to be almost totally independent of neighboring stromal cells and their signaling. Certain highly progressed carcinomas will generate free-floating cancer cells that accumulate in various body fluids—generating tumors known as ascitic tumors (**Supplementary Sidebar 13.3**). The ascites formed during ovarian carcinoma progression contain clumps of carcinoma cells—sometimes termed spheroids—that often seem to lack identifiable stromal cells.

Human cancer cell lines—there are several dozen in common use—are standard reagents used in many types of cancer research (**Sidebar 13.2**). Cells from virtually all of these can be implanted into immunocompromised host mice, where they proliferate, often vigorously, and form tumors termed xenografts (because they result from grafting the tissues of one species into a host animal of another). Mice of the Nude, NOD/SCID, and RAG1/2 strains, lacking fully functional immune systems (see Chapter 15), are used in these experiments because they tolerate the growth of introduced, genetically foreign cells. The resulting xenografts growing in these mice can then be tested for their responsiveness to anti-cancer drugs under development. The outcome of such experiments is not necessarily predictive of eventual clinical responses to these drugs (**Sidebar 13.3**).

Sidebar 13.2 Cancer cell lines and stromal support

The ongoing dependence of almost all types of carcinoma cells on stromal support explains the enormous difficulties that researchers have experienced when attempting to adapt tumor cells to *in vitro* culture conditions. Their goal has been to create cancer cell lines—populations of cancer cells that can be propagated in tissue culture indefinitely and can serve as experimental models of the cells encountered in the tumors of human cancer patients. To do so, cells are prepared directly from tumor biopsies and placed into culture, with the hope that colonies of vigorously growing cancer cells will eventually emerge. In most cases, however, such cell colonies do not appear, foiling attempts to generate carcinoma cell lines. More often than not, the cells that do thrive in culture are of stromal origin—specifically the fibroblasts whose growth is favored by the platelet-derived growth factor (PDGF; see Figure 5.8) that is present in abundance in the serum component of standard tissue culture medium.

It is clear that human carcinoma cells propagated under standard conditions of tissue culture are being forced to proliferate in environments that differ from those experienced by their precursors residing in the tumors of cancer patients. For example, the high concentration of serum present in most culture media is growth-inhibitory for many types of normal and neoplastic epithelial cells, which rarely experience large concentrations of the serum-associated factors *in vivo* except acutely after wounding. Even more important, carcinoma cells are being selected *in vitro* for their ability to proliferate without intimate contact with stroma, because the proper balance of epithelial and stromal cells present in tumors cannot be reproduced in the tissue culture dish.

On rare occasion, vigorously proliferating colonies of carcinoma cell populations have indeed emerged following extended culture of tumor fragments in the Petri dish. Because they have been selected *in vitro* for their ability to grow autonomously, and therefore independently of stromal support, such cancer cells have evolved beyond the stage of tumor progression that is reached *in vivo* by the neoplastic cells of most human tumors. In fact, many of the successes in establishing human tumor cell lines have depended on culturing cells from the few tumors that had already progressed *in vivo* to a stage where they no longer depended on stroma for their survival and proliferation (see **Supplementary Sidebar 13.3**). For whatever reason, the cancer cell lines that are established for long-term growth in culture have, almost invariably, evolved to a biological state that is significantly different from that of the cells in corresponding human tumors.

Sidebar 13.3 The development of anti-cancer therapies has been imperfectly served by the use of existing human cancer cell lines

Human cancer cell lines, when grown as tumor xenografts in immunocompromised mice, often respond to the anti-proliferative effects of cytotoxic drugs under

development. However, the ability of these xenograft models to predict the clinical responses of patients to these drugs is limited. A 2001 retrospective study of 39 different anti-cancer drugs showed a weak correlation between the responses of xenografted tumors and comparable tumors borne by cancer patients to these drugs. For example, candidate drugs that were effective in halting the growth of more than one-third of a disparate collection of mouse tumor xenografts had only a 50% likelihood of showing any therapeutic activity (including halting tumor growth) in some human tumor types treated in the clinic. And drugs that affected smaller proportions of the mouse xenograft models had essentially no meaningful activity in the clinic.

These disappointing outcomes are not surprising, because the human tumor cell lines commonly used in such drug testing experiments bear little resemblance to cells in the tumors frequently encountered in the oncology clinic. These cell lines have been propagated *in vitro* under conditions that differ dramatically from their sites of origin in patients (see Figure 13.11), including (1) the absence of a supporting stroma, (2) the lack of similarity between existing tissue culture media and the composition of the fluid bathing cells in actual living tissues, (3) the often used two-dimensional culture (on the bottom of Petri dishes) that does not recapitulate the three-dimensional conditions of cells growing *in vivo*, (4) the selection of cancer cell lines that proliferate relatively rapidly in culture and, in that respect, do not correspond to cells growing *in vivo*, which may have vastly slower doubling times, and (5) the absence of components of the adaptive immune system in the mouse hosts in which human tumor xenografts are grown (as described in Chapter 15) that influence stromal composition and behavior. This helps to explain why the tumors implanted that these cell lines form often look quite different histologically from those routinely encountered in a clinical pathology laboratory (see Figure 13.11).

Yet another difficulty arises because cells of various human tumor cell lines are usually implanted in mice subcutaneously, which represents an ectopic site within the host that has little resemblance to the tissue in which the tumor originated. For example, pancreatic carcinoma cells may behave differently when growing under the skin than when they are implanted into the host animal's pancreas, their natural, orthotopic site, presumably because the stromal microenvironments in these two locations are so different.

One experimental response to these difficulties involves attempts at introducing fragments of tumors directly into immunocompromised mice without intervening propagation in tissue culture. These implanted tumor grafts contain both epithelial and stromal cells, which may co-proliferate to form histologically complex tumors in host mice that resemble the original tumors from which they derive. Unfortunately, like the cancer cells in actual human tumors, the cells in these xenografts usually proliferate very slowly, and their propagation involves labor-intensive transplantation from one

host animal to another. These properties preclude their routine use in the testing of anti-cancer drugs.

The inadequacies of currently available human tumor models and the resulting inability to accurately predict the clinical effectiveness of anti-cancer drugs under development cost the pharmaceutical industry hundreds of millions of dollars annually and therefore represent one of the major impediments to the development of new anti-cancer drugs.

OceanofPDF.com

Glossary

stroma

(pl., **stromata**; adj., **stromal**) (1) The mesenchymal components of normal epithelial and hematopoietic tissues, which may include fibroblasts, adipocytes, endothelial cells, and various immunocytes as well as associated extracellular matrix. (2) A spectrum of similar cell types that constitute the stromal cells within a tumor and are recruited into the tumor from host tissues and lack the somatic mutations born by the tumor cells. *See also* **reactive stroma**.

tumor microenvironment

The areas within a tumor that are populated by recruited non-neoplastic cells, including various types of immunocytes and inflammatory cells, often synonymous with stroma. *See also* **stroma**.

immunocyte

A cell associated with one of the multiple types of cells that form the functional arms of the immune system.

heterotypic

Referring to interactions between two or more distinct cell types. *See also* **homotypic**.

neoangiogenesis

Process by which new blood vessels are formed by sprouting from existing vessels; *also called* **neoangiogenesis** in certain circumstances. *Compare* **vasculogenesis**.

chemokine

(1) A polypeptide that serves as an attractant for motile cells, notably leukocytes, via chemotaxis. (2) More narrowly, a member of a family of low–molecular-weight (8–10 kD) secreted proteins, most of which contain four cysteine residues in evolutionarily conserved sites. *See also* **chemotaxis**.

lymphatic

Referring to vessels and nodes that drain interstitial fluid from tissues and eventually deposit this fluid in the venous circulation.

pericytes

Cells closely related to smooth muscle cells that surround capillaries and provide the capillary walls formed by endothelial cells with tensile

strength and contractility; pericytes also provide trophic signals to nearby endothelial cells. *See also* **trophic**.

mural

Referring to the outer cell layers of blood vessels, which are composed of pericytes and smooth muscle cells and surround the luminal endothelial cells.

spheroid

Small, sphere-shaped cluster of cells typically observed when cells are propagated *in vitro* in three-dimensional matrices.

xenograft

A normal or neoplastic tissue derived from one species that has been implanted into a host animal from another species.

ectopic

(1) Referring to the expression of a gene or protein in a location or physiological situation where it normally would not be expressed. (2) Referring to the presence of cells or tissues in an anatomical site where they would not naturally be found in the body. *See also* **orthotopic**.

orthotopic

Referring to an anatomically proper or native site. *See also* **ectopic**.

endothelial cells

(1) Mesenchymal cells that form the walls of capillaries or lymph ducts by assuming shapes that allow the assembly of tubelike structures. (2) Mesenchymal cells lining the luminal walls of larger blood vessels or lymph ducts.

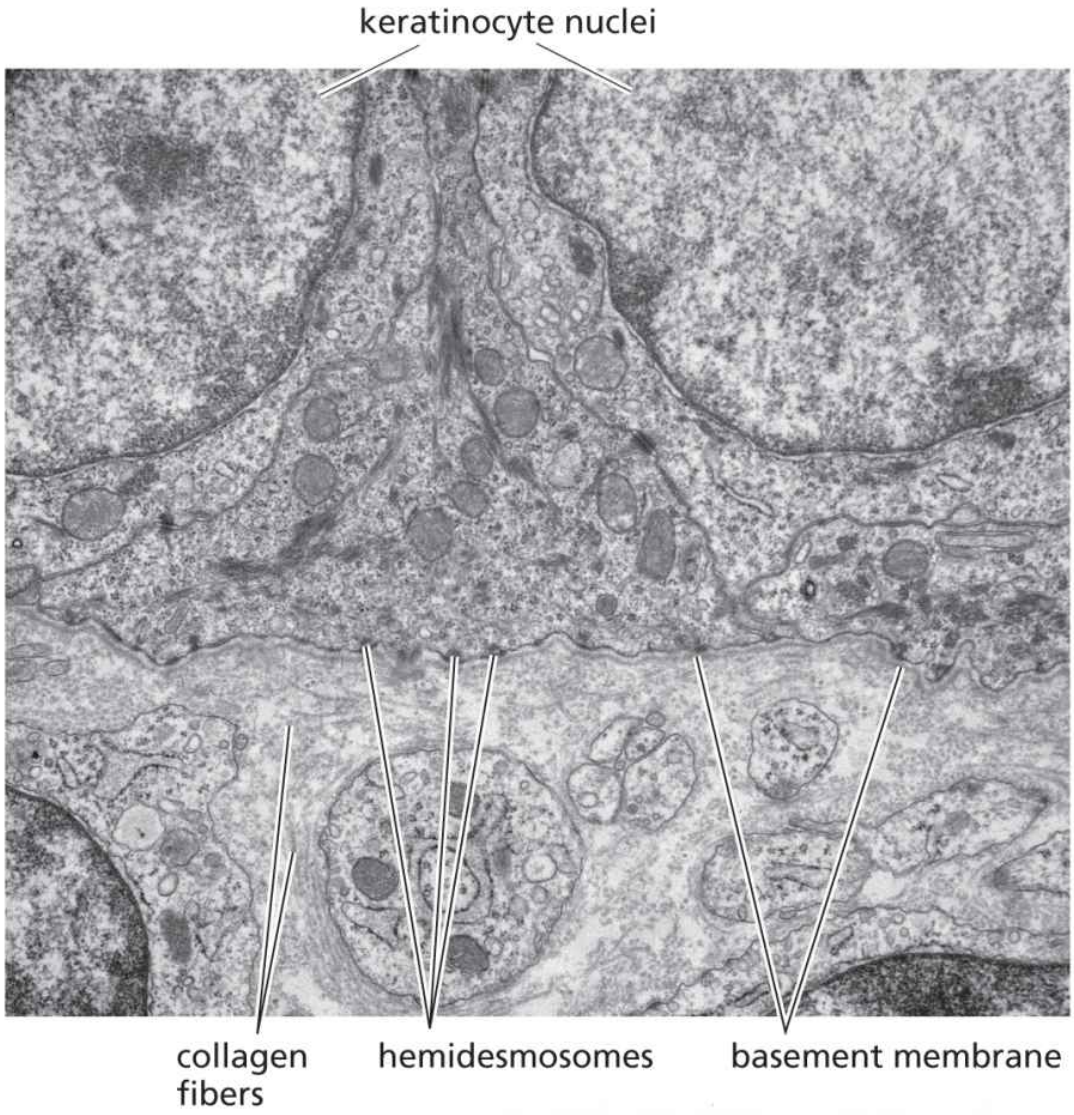
ascites

(adj., - **itic**) Fluid that accumulates in the peritoneal cavity of some cancer patients, often containing malignant cells.

OceanofPDF.com

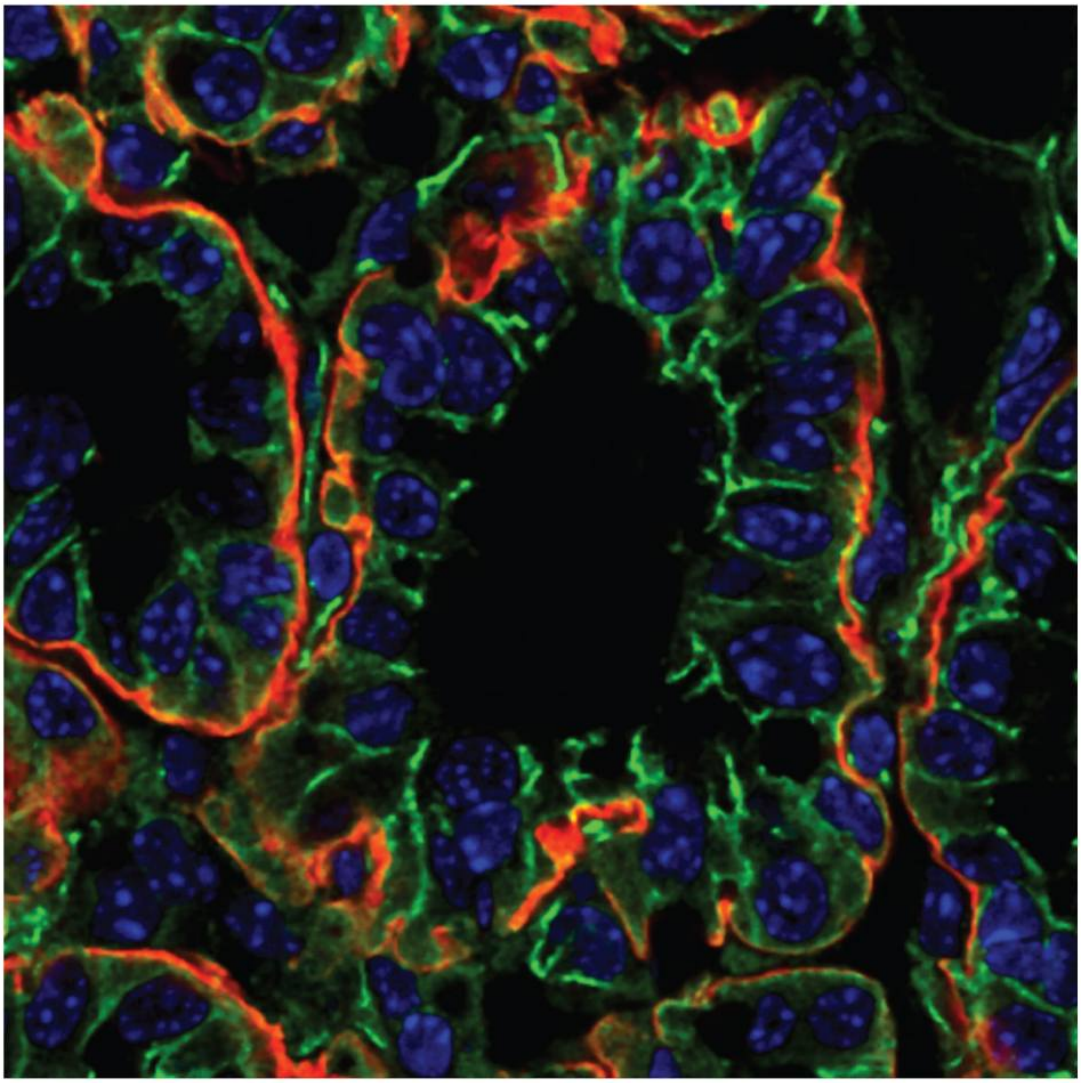
13.2 The extracellular matrix represents a critical component of the tumor microenvironment

Our overview of the tumor microenvironment (TME) must include, in addition to the stromal cell types described above, the complex extracellular matrix (ECM) that can be found between individual cells, sometimes termed the interstitial matrix (**Figure 13.10A**). We encountered its complexity earlier when we enumerated some of the cell-surface receptors, such as integrins, that epithelial cells deploy in order to physically tether themselves to the ECM and, equally important, to sense the presence of specific ECM components in their immediate surroundings (see Figures 5.21, 5.22, and **Supplementary Sidebar 5.9**).



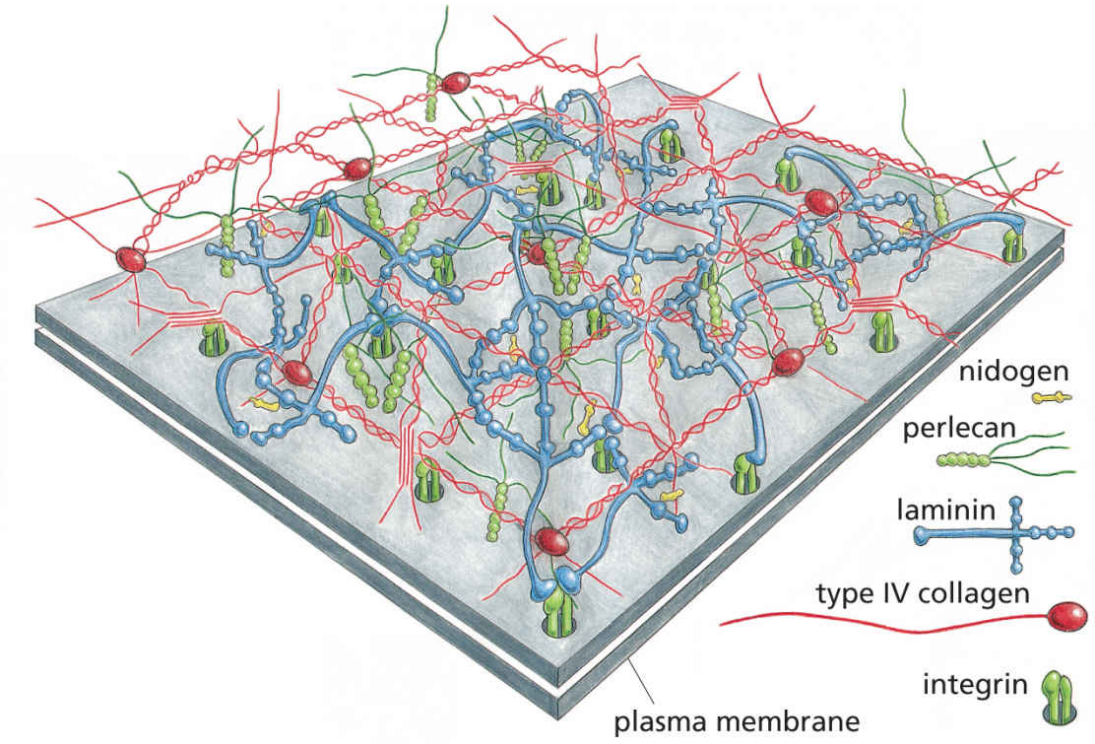
A transmission electron micrograph of the skin of a newborn mouse, seen in cross section. At the top of the image are two large keratinocyte nuclei. Running across the middle of the image is the basement membrane. Dark spots at intervals along the basement membrane are hemidesmosomes. Below the basement membrane is a space filled with collagen fibers.

(A)



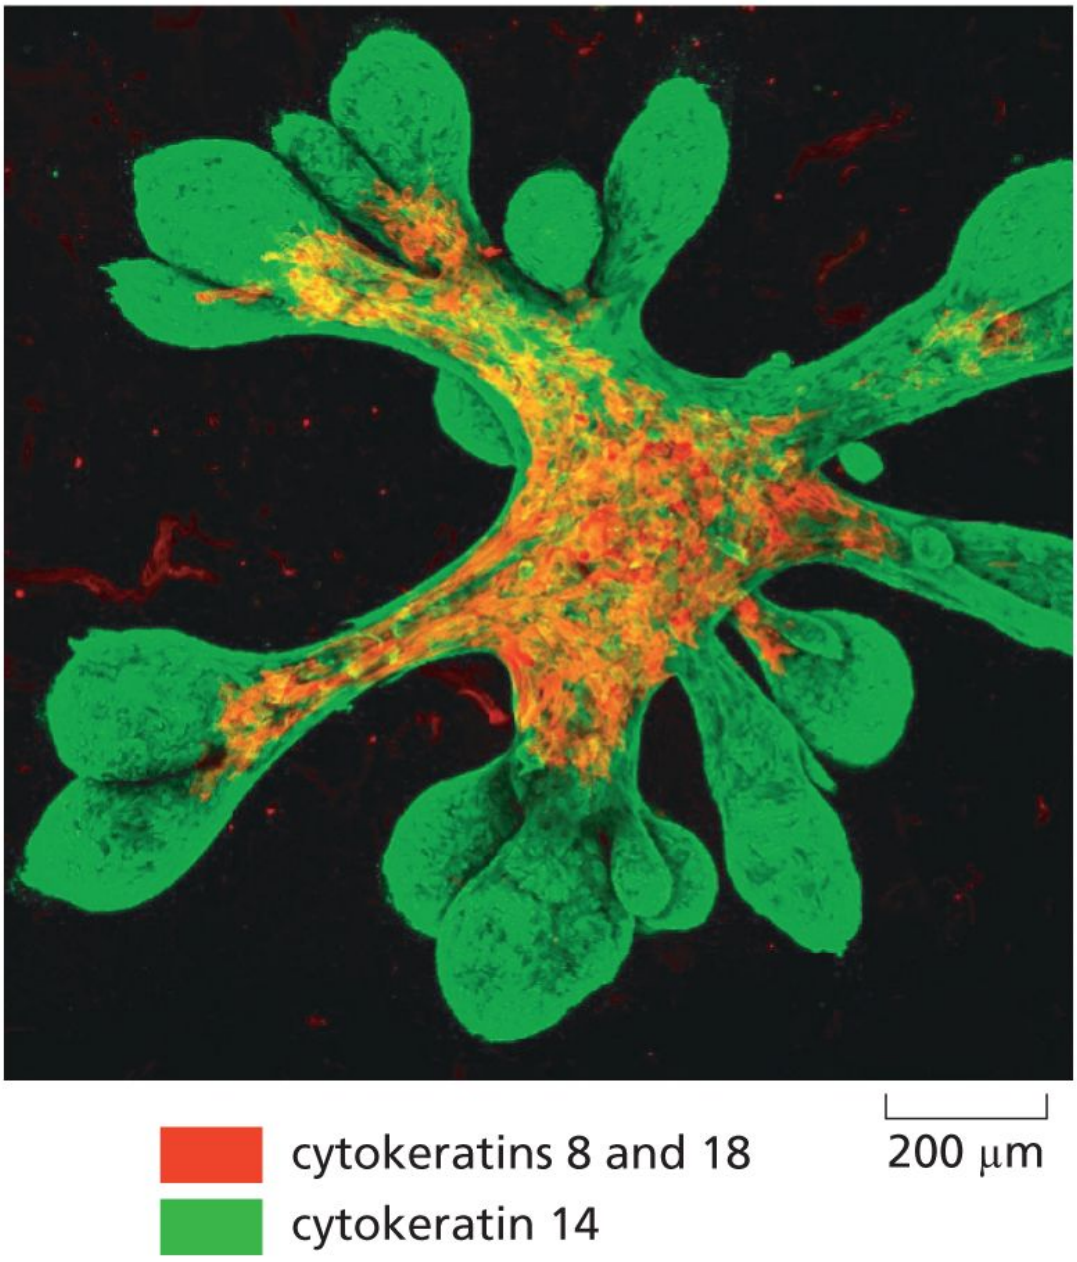
An immunofluorescence micrograph of a mouse mammary duct, showing basement membrane in orange, E-cadherin in green, and nuclei in blue, forming ring-like structures.

(B)



A schematic of the basement membrane. As shown, it lies over the top of a cellular plasma membrane and is a network of nidogen, perlecan, laminin, and type IV collagen fibers connected to integrins that rise up through the plasma membrane below.

(C)



An image of a multi-lobed or multi-petaled flower-like structure, roughly 1 millimeter across. It is mostly green, indicating the presence of cytokeratin 14 but in the central areas, it contains a heavy dusting of orange and red, indicating the presence of cytokeratins 8 and 18.

(D)

Figure 13.10 The extracellular matrix and its role in tissue development (A) In epithelial tissues, the specialized extracellular matrix (ECM) termed the basement membrane (BM) separates the epithelial cells (*above*) from the stroma

(*below*). As shown in this transmission electron micrograph of the skin of a newborn mouse, the epithelial cells of the skin (termed keratinocytes) are tethered to one side (*above*) of the BM, being anchored in part through structures termed hemidesmosomes, which are composed of clusters of integrins that bind BM proteins, notably laminin. Below the BM are collagen fibers, which represent important components of the interstitial matrix and the mesenchymal cells that constitute the stroma of the skin, i.e., the dermis. (B) This immunofluorescence micrograph of a mammary duct in a lactating mouse reveals the E-cadherin molecules (*green*) that form the lateral junctions tying together the mammary epithelial cells forming the lumen of the duct; the epithelial cells are underlain by a basement membrane, which is revealed here by the presence of laminin (*orange*). Outside of the BM are various types of stromal cells (*not shown*). (C) This schematic drawing indicates that the basement membrane is composed largely of four major ECM proteins, namely laminin, collagen type IV, perlecan, and nidogen. This highly permeable molecular meshwork allows a variety of molecules to pass through in both directions. A specialized BM, not shown here, underlies endothelial cells in capillaries. (D) Mammary epithelial cells were prepared from reduction mammoplasty-derived tissues and propagated in a 3-dimensional gel composed of ECM modeled after the interstitial matrix present in the normal mammary gland plus a series of defined growth factors in the absence of serum. No stromal cells were present in these cultured cells. Cytokeratin 14 is expressed by basal cells in the intact mammary gland, whereas cytokeratins 8 and 18 are expressed by luminal cells. (A, courtesy of H.A. Pasolli and E. Fuchs. B, courtesy of E. Lowe and C. Streuli; from J. Muschler and C. Streuli, *Cold Spring Harb. Perspect. Biol.* 2:a003202, 2010. With permission from Cold Spring Harbor Laboratory Press. C, from B. Alberts et al., Molecular Biology of the Cell, 5th ed. New York: Garland Science, 2008, based on H. Colognato and P.D. Yurchenko, *Dev. Dyn*. 218:213–234, 2000. D, from E. Sokol, D.H. Miller, A. Breggia et al. *Breast Cancer. Res.* 18:19–32, 2016.)

In the case of the interface between normal epithelial and stromal cells, recall that it is created by the physical barrier established by the specialized ECM termed the basement membrane (BM) or basal lamina (see Figure 13.10A; see also Figure 2.3). In the case of the epithelial cells of the skin, as an example, the keratinocytes express genes specifying many of the major protein components of the basement membrane, including type IV collagen and laminins; the stromal cells also contribute to its construction, doing so in ways that have yet to be documented in detail. Certain proteoglycans in the basement membrane, such as perlecan, provide it with increased hydration and with sites to which growth factors can be attached for long-term storage (see Figure 13.10C). Continuous tethering to the basement membrane, mediated largely by integrins and the hemidesmosomes that they construct (see Section 5.9,

Figure 13.10A), is essential for the survival of many kinds of epithelial cells, and loss of this tethering often provokes anoikis, the form of apoptosis resulting from loss of anchorage to a solid substrate (see Section 9.13). In many carcinomas, the ECM constitutes as much as 25% of the total tumor-associated mass. In the extreme seen in pancreatic ductal adenocarcinomas, as much as 90% of the mass is formed by the ECM.

In its most simple depiction, we can imagine that the epithelial and stromal cells of normal and carcinomatous tissues collaborate to lay down the ECM. Once assembled, the ECM provides most of the instructive cues that the epithelial cells employ in order to organize themselves.

These cues are conveyed by the structural scaffolding of the ECM, by the various physical forces that influence epithelial cell biology (such as rigidity and tensile strength), and by the myriad mitogenic and survival factors that are attached to the ECM during its formation, creating a reservoir of signaling molecules that can be mobilized and, in solubilized form, stimulate the various receptors whose signals influence epithelial cell biology, as was described in Chapter 5.

Some have likened the role of the ECM (when acting as a reservoir of signaling proteins) to a “message board” that is consulted with frequency by epithelial cells, guiding various aspects of their behavior. The initial attachment of growth factors (GFs) to the ECM soon after their synthesis and release into the extracellular space obviously complicates our understanding of how these signaling molecules actually operate. Depictions of them floating in soluble form from GF-producing cells to cognate GF receptors displayed by recipient cells overly simplify the multiple steps that make them *available* to their partner receptors.

Careful curation of the genes in the human genomes has led to an enumeration of the proteins forming the “core matrisome,” that is, the proteins that form the essential structural scaffolding of ECMs. There are about 300 in mammals, and they are distinguished from the numerous proteins that are tethered reversibly to the ECM, such as the GFs cited above, as well as others, such as proteases, that are responsible for continuously modifying the core scaffolding.

The key biological role of the ECM in instructing morphogenesis can be illustrated most dramatically by its essentiality in tissue models constructed *in vitro*. As seen in Figure 13.10D, a hydrogel was assembled experimentally that incorporated many of the ECM proteins present in normal human breast tissue, together with a glycosoaminoglycan polysaccharide and three growth factors—insulin, EGF, hydrocortisone. This hydrogel was constructed to have a degree of elasticity comparable to that present in normal mammary ECM. Normal mammary epithelial cells (MECs) were introduced into this gel and their behavior monitored

microscopically. This arrangement provided a three-dimensional environment, which contrasted starkly with the highly unnatural two-dimensional environment created by the bottom surfaces of Petri dishes that were used almost universally since the mid-twentieth century to propagate cells in culture.

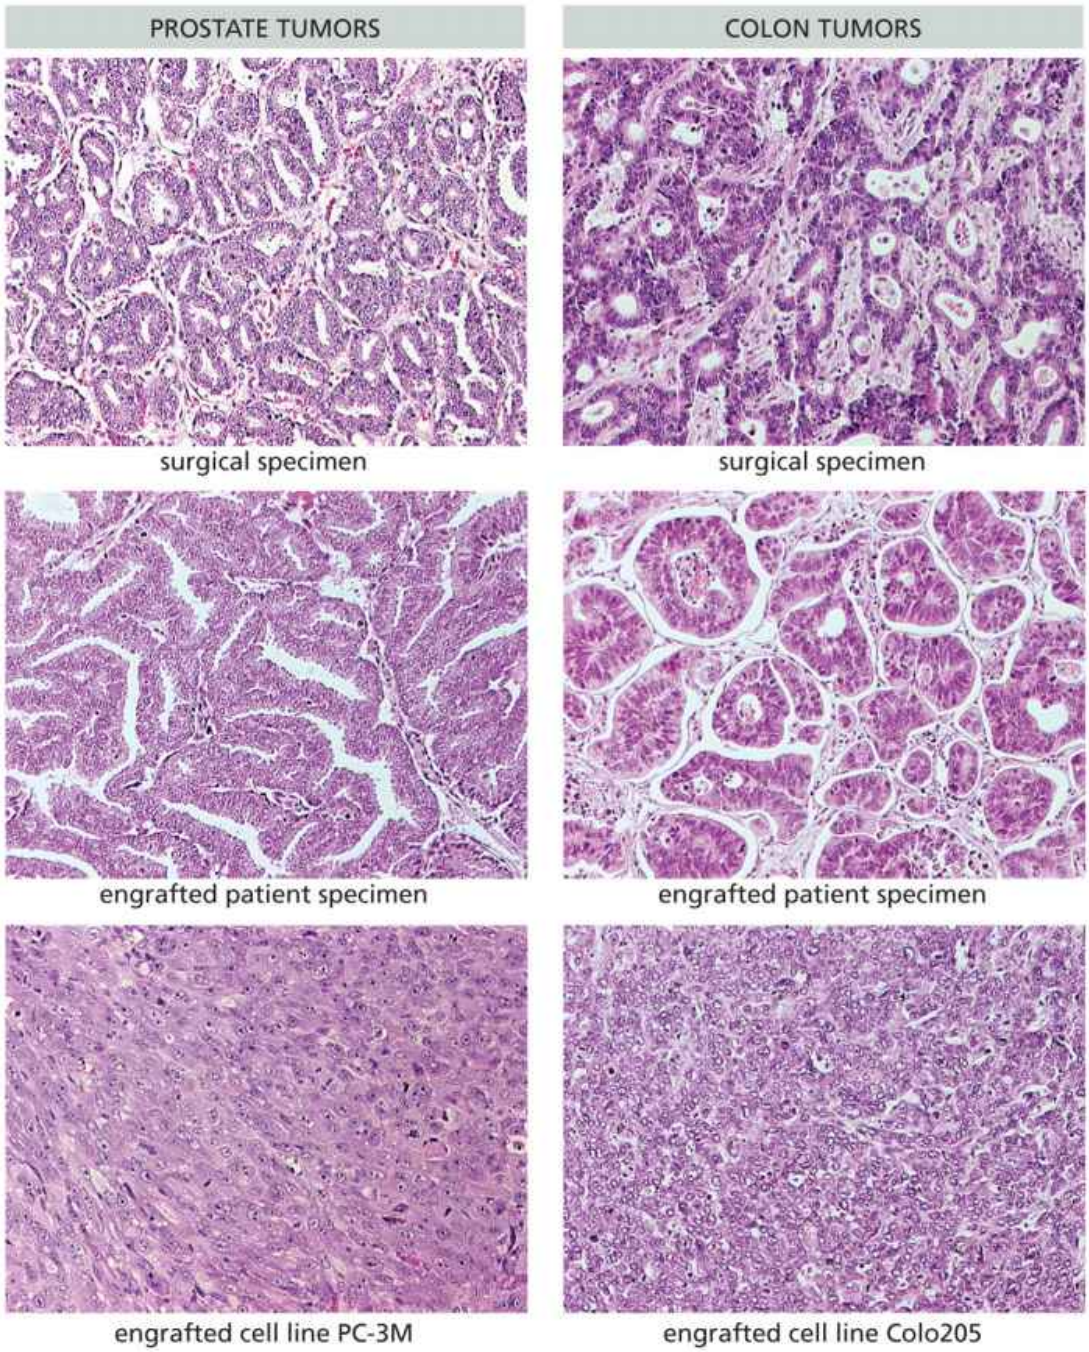
In this particular tissue culture model, the introduced normal human MECs formed lobules and ducts that closely resembled the ductal and lobular morphologies seen in developing human breast tissues. Gels formed instead exclusively from collagen did not work nor did ECM composed only of basement membrane proteins. Importantly, the alveoli that formed developed cytokeratin 8/18-positive luminal cells and cytokeratin 14-positive myoepithelial/basal cells, which reflected the composition of the two cell layers (that is, luminal and basal) forming normal mammary epithelium. About 5% of the mammary epithelial cells developed steroid hormone receptors—ER and PR—and these organoids responded to the steroid hormones by undergoing hollowing of the ducts and lobules. Application of the prolactin hormone caused the formation of lipid droplets in the lumina of the alveoli; such droplets are suggestive of the formation of milk components. Moreover, the myoepithelial/basal cells expressed the Slug and Sox9 transcription factors (see Chapter 14) that are known to be responsible for inducing the mammary stem cell state. Strikingly, this essentially normal morphogenesis proceeded in the presence of only ECM and thus in the absence of any admixed stromal cells, indicating that the contextual signals required for this particular morphogenetic program were provided entirely by ECM constituents and thus proceeded without dependence on stromal cells.

The continued dependence of most cancer cell populations on stromal support, including both the cells and the ECM that together form the stroma, has represented a major obstacle to understanding the biology of human tumors, given the inability of existing cancer cell lines to generate tumors that are encountered in the oncology clinic (see Sidebar 13.2). Nevertheless, an ability to grow human cancer cells that are prepared from patient tumor fragments and implanted directly into host mice represents a major step toward generating populations of human cancer cells that more closely resemble the cells living within actual human tumors. Thus, such patient-derived xenografts (PDXs), never experience the artificial environment of tissue culture. Presumably, the heterotypic interactions with recruited mouse stromal cells more closely mimic the stroma that was assembled in the original tumors within cancer patients (**Figure 13.11**). However, even the PDXs are associated with certain problems. Some of the heterotypic interactions that operate in human tumors may fail to do so in PDXs because of signaling incompatibilities between mouse growth factors and cytokines and the corresponding human receptors. Moreover, the use of immunocompromised mouse hosts dictates that certain cells responsible for creating an inflammatory stroma (see below) may be missing. Finally, PDX tumors usually grow very slowly, making them impractical for use in many types of experiments.

CONDITION	HUMAN TISSUE	HUMANIZED 3D CULTURE	2D CULTURE
oxygen:	0–5%	< 5%	21%
stiffness of ECM:	200–4000 Pa	<4000 Pa	$3x10^9$ Pa
pH:	acidic (<7)	acidic (<7)	buffered (7.2)
dimensionality:	3D	3D	2D
glucose availability:	limiting	limiting	not limiting
stroma:	present	absent	absent
growth factors:	human	rodent and human	bovine

A chart comparing various properties of HUMANIZED 3D CULTURE tumor cells to tumor cells in normal human tissue on the left and to 2D CULTURE cells on the right. With respect to the first six properties listed, HUMANIZED 3D CULTURE cells are like normal human cells: oxygen less than 5 percent, compared to 2D culture's 21 percent; stiffness of ECM less than 4000 Pascals, compared to 2D culture's 3 times 10 to the 9th Pascals; pH less than 7, compared to 2D culture's 7.2; dimensionality 3D instead of 2D; and glucose availability limiting, compared to 2D culture's not limiting. However, stroma is absent in HUMANIZED 3D CULTURE just as in the 2D culture. Finally, HUMANIZED 3D CULTURE has human and rodent growth factors, compared to only human in normal human and to bovine in 2D culture.

(A)



Six histology images that compare prostate tumors and colon tumors, showing in each case a surgical specimen, an engrafted patient specimen, and a grafted cell line–PC-3M in the case of prostate cancer and Colo 2 O 5 in the case of colon cancer. The engrafted patient specimens look generally similar to the surgical specimens, with a lumpy appearance, whereas the grafted cell line specimens look smoother in texture.

(B)

Figure 13.11 Tumors and derived xenografted tumor cell lines (A) The conditions under which human tumor cell lines are usually propagated (*red font*) differ drastically from those operating in an actual autochthonously arising human tumor, i.e., one that arose spontaneously in a living human tissue (*second column*). Attempts to remedy this by developing culture models that more closely resemble conditions in actual tumors (*third column*) address some but not all the shortcomings of existing means of propagating human tumor cells. (This figure does not indicate the differences in the chemical compositions of the fluids surrounding individual cells or the molecular compositions of the ECMs, which are likely to differ dramatically between the three conditions.) Pa, pascals, unit of pressure here denoting pressure, mechanical stress. (B) The histologies of a primary prostate carcinoma (*left*) and of a colon carcinoma (r*ight*) that were removed surgically from patients are shown in the top row. Below these (*middle row*) are the histologies arising from implantation of chunks of tumor derived from cancer surgery at subcutaneous sites in immunocompromised SCID mice; these implanted chunks, growing as patient-derived xenografts, contained both epithelial and stromal tumor components. Three to six months after implantation, these engrafted tumor samples, which have grown from a 2-mm to a 1-cm diameter, still retain the architecture of the primary tumors from which they derive. However, the tumors formed by a prostate and a colon cancer cell line (*bottom row*), which have been propagated extensively in tissue culture as pure cancer cell populations, bear little histological resemblance to the tumors typically encountered in the oncology clinic and shown above. OceanofPDF.com

Glossary

interstitial matrix
: Portion of the extracellular matrix that resides between cells and is not a component of the basement membrane.

proteoglycan
: Molecule with one or more glycosaminoglycan chains attached to a protein core. *See also* **glycosaminoglycan**.

matrisome
: The collection of molecular species that together form the extracellular matrix of a tissue or of cultured cells.

hydrogel
: A three-dimensional network of highly hydrophilic polymer molecules that can absorb 10- or even 100-fold its mass of water and can serve as an experimental model of natural matrices, such as the extracellular matrix.

prolactin
: A polypeptide hormone made largely by the pituitary gland that stimulates mammary gland growth and milk production among other functions.

patient-derived xenograft
: A population of cancer cells that is derived by implanting fragments of patients' tumors directly into immunocompromised mouse hosts, thereby avoiding initial *ex vivo* propagation of tumor cells in tissue culture.

alveolus (pl., **alveoli)**
: A small sac within a tissue that is connected to a duct, such as the sacs seen in the lung and in the mammary gland during pregnancy.

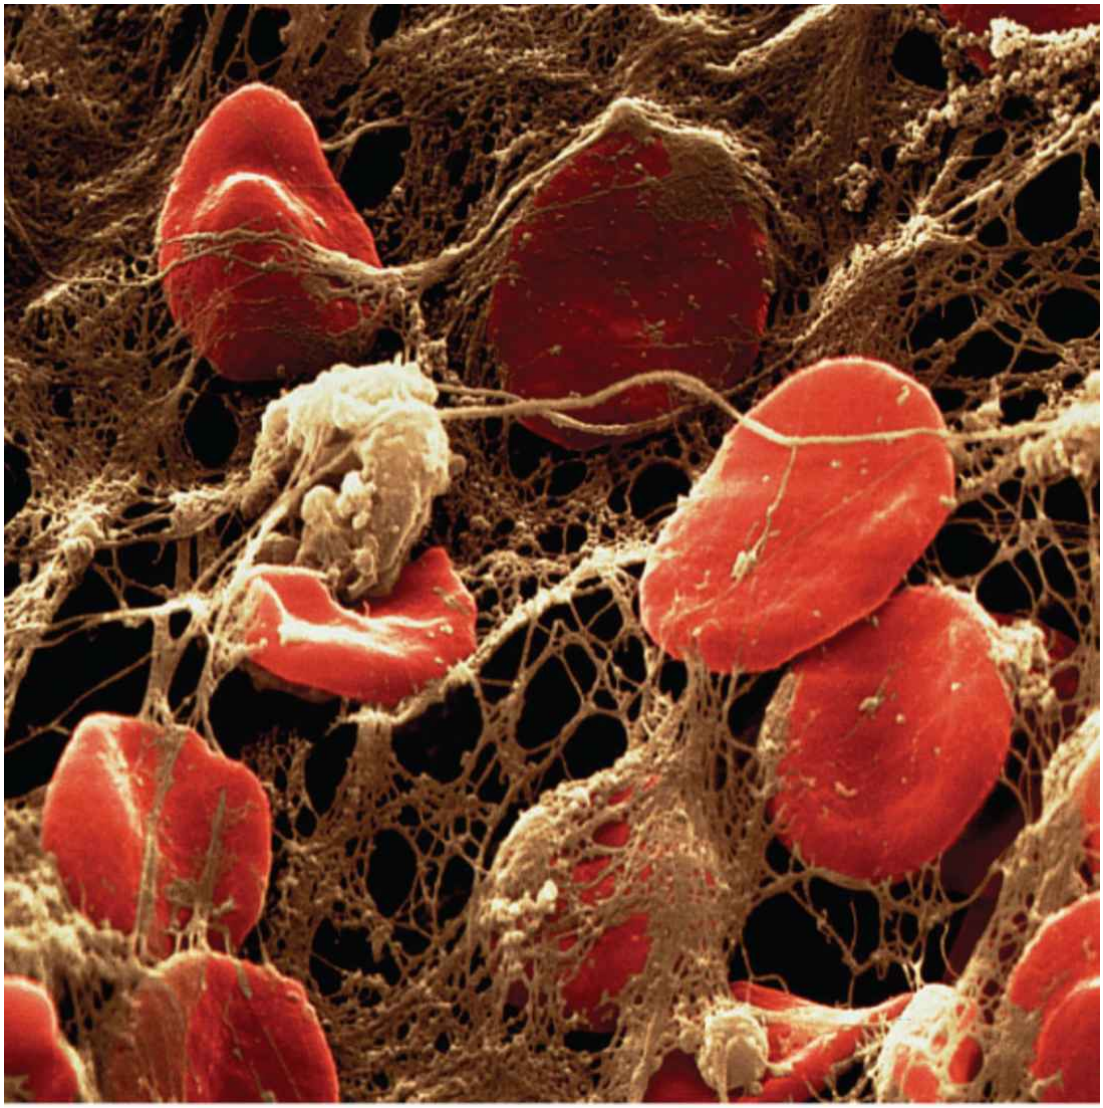
13.3 Tumors resemble wounded tissues that do not heal

As argued above, heterotypic signaling governs much of the biology of carcinomas, and experimental models of cancer that ignore this important process generate tumors that differ biologically from those found in cancer patients (see Figure 13.11). As mentioned above, the heterotypic interactions operating within tumors are highly complex and involve the exchange of dozens of distinct molecular species that mediate cell-to-cell signaling between the various cell types that together form these growths.

This complexity raises some fundamental questions: How do cancer cells develop the capacity to release and respond to an array of diverse heterotypic signals? Are the complex signaling programs and resulting biological responses invented anew, being cobbled together piece by piece, each time normal cells evolve progressively into cancer cells? Or do cancer cells exploit preexisting, multifaceted cell-biological programs that are normally used by tissues for other purposes?

One attractive solution to these questions has come from an insight gained in 1986. A researcher studying the histological appearance of both tumors and wound-healing sites noted the striking resemblance between many of the signaling processes involved in tumor progression and those that occur during wound healing. Indeed, these similarities have been extensively documented in the years since this notion was first proposed, yielding a clarifying explanation for the complex behavior of neoplastic tissues: they acquire aggressive behavior simply by activating a complex, normally latent cell-physiological program—wound healing—that is encoded in the normal genome. By accessing and exploiting this preexisting biological program, cancer cells are spared the task of re-inventing it anew each time a tumor arises.

Wound healing has been studied most extensively in the context of the skin. Following the formation of a superficial wound to the skin and underlying tissues, blood platelets aggregate and release granules containing, among other factors, platelet-derived growth factor (PDGF) and transforming growth factor-β (TGF-β). Wounding also causes release of vasoactive factors, which increase the permeability of blood vessels near the wound. This helps the wound site to acquire fibrinogen molecules from the blood plasma, which, when converted to fibrin, create the scaffolding of the blood clot (**Figure 13.12**). The resulting fibrin bundles, which become entwined around clumps of platelets, help to stanch further bleeding.

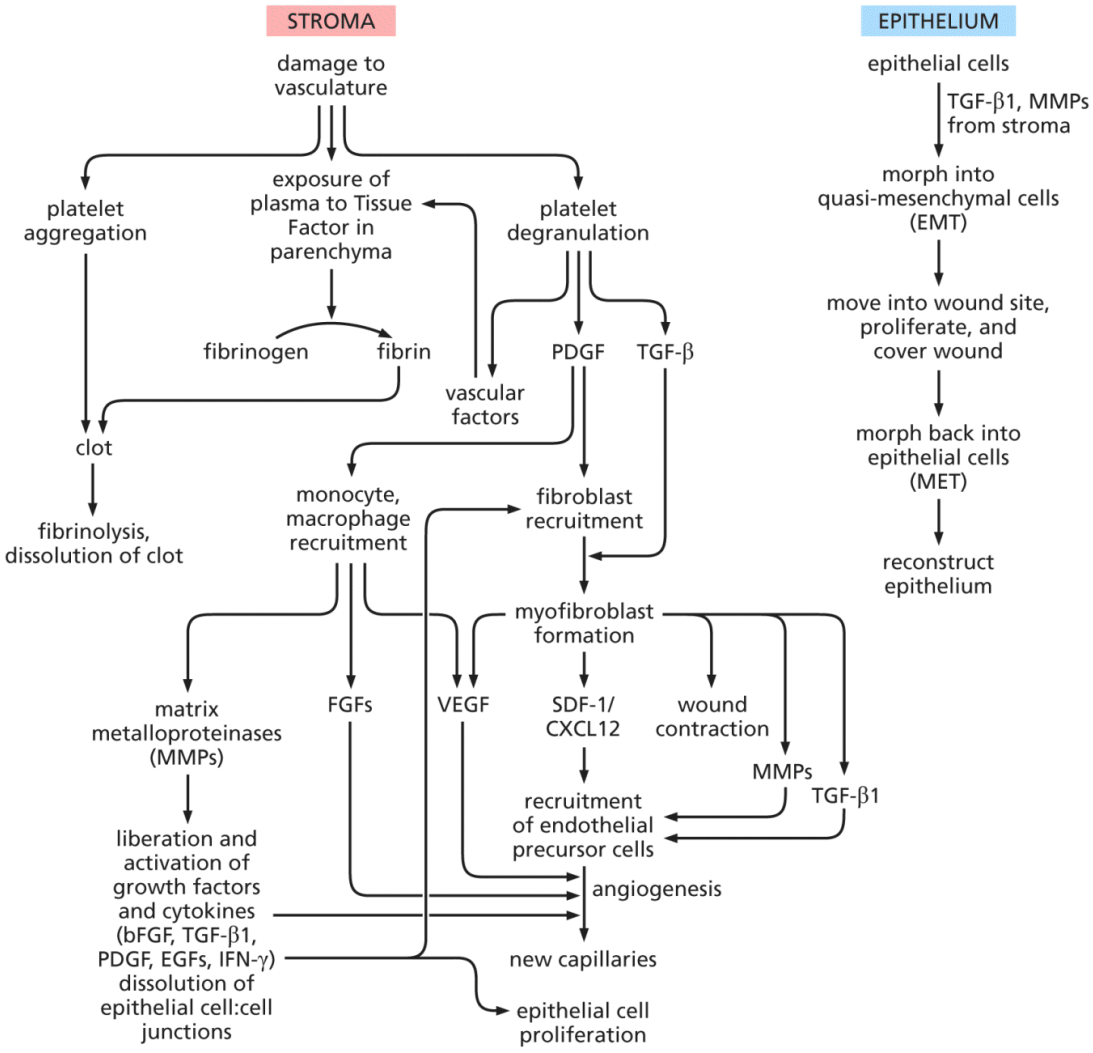


A scanning electron micrograph of a blood clot. Red blood cells are immobilized by thick mats of pale brown fibers.

Figure 13.12 Scanning EM of a blood clot This scanning electron micrograph, which has been colorized, shows that clots are composed of dense networks of fibrin fibers *(light brown*) that have trapped erythrocytes/red blood cells (*orange-red*). Prior to clotting, platelets undergo activation, which leads to the release of the granules seen in Figure S5.1. (Eye of Science/Science Source.)

The PDGF released by the platelets attracts fibroblasts and stimulates their proliferation (**Figure 13.13**). Thereafter, the platelet-derived TGF-β activates these fibroblasts, converting them into myofibroblasts, and induces the latter to release a class of secreted proteases termed matrix metalloproteinases (MMPs; **Table 13.1**),

which are also produced by macrophages that have been recruited in large numbers into the wound site. Unlike most secreted proteases, which have a serine in their catalytic clefts, MMPs carry zinc ions to aid in catalysis; indeed, these ions inspired their name. Activated fibroblasts also secrete mitogens, such as various fibroblast growth factors (FGFs), that can stimulate the proliferation of certain subtypes of epithelial cells.



Two flowcharts of wound healing. The first flowchart begins with damage to vasculature in the stroma. This leads to platelet aggregation, exposure of plasma to Tissue Factor in parenchyma, and platelet degranulation. The first two events lead to clot formation and eventually clot dissolution through fibrinolysis. Platelet degranulation leads to the recruitment of monocytes, macrophages, and fibroblasts, which eventually leads to epithelial cell proliferation and the formation of new capillaries. The second flowchart begins with epithelial cells, which under the influence of T G F-beta1 and M M Pees from the stroma

undertake epithelial-mesenchymal transition to morph into quasi-mesenchymal cells. These move into the wound site, proliferate, and cover the wound. They then undergo mesenchymal-to-epithelial transition to morph back into epithelial cells and reconstruct the epithelium.

Figure 13.13 Flowcharts of wound healing These flowcharts indicate many of the major events occurring after an epithelial tissue is wounded. Many of the changes occur in the stroma of the wounded tissue (*left*) and thereby provide a foundation for reconstructing the overlying epithelial cell layer (*right*). A short-term effect of wounding is the process of hemostasis—the stanching of further hemorrhage. It involves both the plugging of damaged vessels and the degranulation of platelets, which release several distinct growth factors (GFs), including importantly PDGF and TGF-β; in addition, the exposure of plasma and platelets to Tissue Factor (expressed on the surfaces of a wide variety of nonendothelial cell types) triggers the formation of fibrin and thus clot formation (see Figure 13.12). PDGF and TGF-β recruit and activate both macrophages and fibroblasts. Macrophages, in turn, produce a number of products that are critical to initiating wound healing, including MMPs (to remodel the extracellular matrix and liberate various GFs); this allows recruitment of more macrophages and stimulates the proliferation of epithelial cells. The fibroblasts are activated by the actions of TGF-β and CXCL12/SDF-1 and, functioning thereafter as myofibroblasts, produce more of these factors that function, together with macrophage products, to stimulate angiogenesis. The epithelial cells respond to these signals by activating EMT (epithelial–mesenchymal transition) programs (see Figure 13.15) that provide them with the ability to move into the wound site, proliferate, and eventually revert via an MET (mesenchymal–epithelia transition) program to the epithelial phenotypic state of the undamaged nearby epithelium.

Table 13.1 Some matrix metalloproteinases and their extracellular matrix substrates

Name of MMP[a]	**Alternative name of MMP**	**Major ECM substrates**[b]
MMP-1	collagenase-1	fibrillar collagens (collagen I, II, III)
MMP-2	gelatinase A	collagen IV, denatured collagens/gelatins

Name of MMP[a]	Alternative name of MMP	Major ECM substrates[b]
MMP-3	stromelysin-1	proteoglycans, glycoproteins (laminin, fibronectin, vitronectin)
MMP-7	matrilysin	similar to MMP-3
MMP-9	gelatinase B	similar to MMP-2
MMP-12	metalloelastase	elastin
MMP-14	MT1-MMP	fibrillar collagens, gelatins

Courtesy of L. Matrisian and B. Fingleton, adapted in part from information from K. Kessenbrock, V. Plaks and Z. Werb, *Cell* 141: 52–67, 2010.

Once released, the MMPs begin to degrade specific components of the extracellular matrix (ECM; see Table 13.1). This degradation has two major consequences. On the one hand, it allows for structural remodeling of the ECM, thereby carving out space for newly formed cells. On the other, it results, as cited above, in the release of a variety of growth factors that have been tethered in an inactive form to the proteoglycans of the ECM and now become solubilized and activated. Included among these are basic fibroblast growth factor (bFGF), TGF-β1, PDGF, several EGF-related factors, and interferon-γ (IFN-γ). (In addition, virtually every MMP has been found to act on a variety of non-ECM proteins in the extracellular space; among these substrates are the latent pro-enzyme forms of other proteases, which are converted into active enzymes following cleavage by MMPs.) These wound-healing associated factors appear to provide a compelling explanation for a phenomenon frequently observed in the oncology clinic (**Sidebar 13.4**).

Sidebar 13.4 Breast cancer surgery may lead to the stimulation of tumor growth

Epidemiological studies of breast cancer patients undergoing surgery (that is, partial or total mastectomy) for removal of their primary tumors have revealed a peak of

recurrence of breast cancers at the primary site as well as in distant anatomical sites about three years after surgery. The timing of these relapses suggests that the surgery is responsible for stimulating their formation. Examination of the fluids draining from the wound sites created by the surgery revealed the presence of potent mitogenic factors that are associated with the wound-healing process. Among these are mitogens for breast cancer cells, especially those cancer cells that overexpress the HER2/Neu receptor protein (see Figure 4.3). In addition, a burst of vascular endothelial growth factor (VEGF) synthesis occurs following surgery; as discussed later in this chapter, VEGF is a potent stimulant of tumor angiogenesis. It is therefore plausible that surgery stimulates the proliferation of residual micrometastases (small deposits of metastatic cells) that are not detected and removed when the primary tumors are excised. Indeed, some have argued that the clinical relapses stimulated by surgery nullify much of the therapeutic benefit that should, by all rights, be achieved by the removal of primary tumors and nearby lymph nodes. The clinical importance of such surgery-stimulated tumor progression remains a matter of great contention.

Another clinical observation may eventually be found to bear on this issue: when Herceptin (a therapeutic monoclonal antibody to be described in Chapter 16 that blocks the action of the HER2/Neu receptor) is applied postoperatively in women who have borne relatively small, low-grade tumors, the rate of clinical relapse is reduced by as much as 50%. This stunning therapeutic success may, quite possibly, be associated with the ability of Herceptin to block stimulation of residual cancer cells by the growth factors elaborated during healing of the surgical wound site.

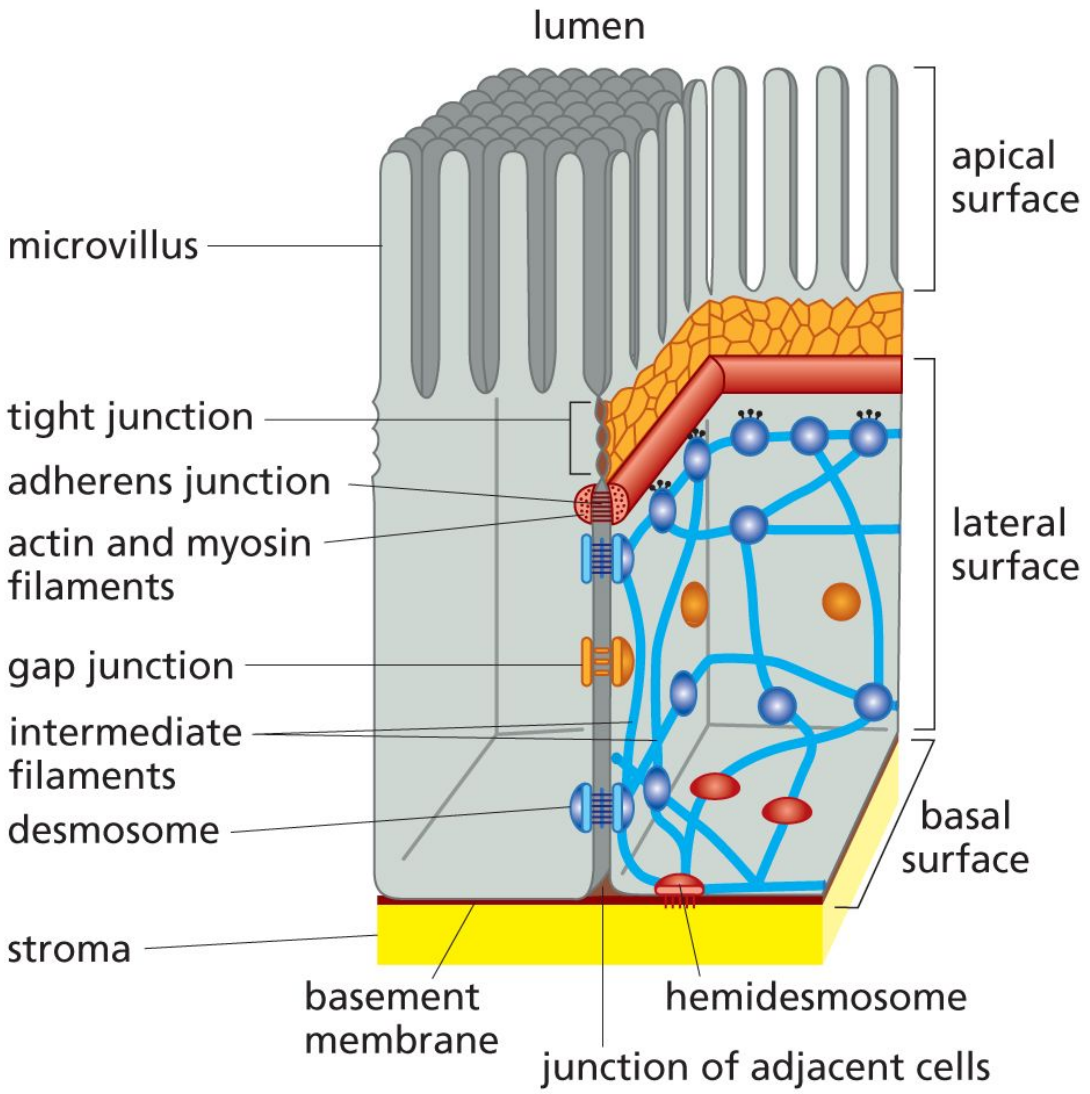
The growth factors released by platelets and those mobilized from the ECM then attract monocytes (which soon differentiate into several subtypes of macrophages) and another class of phagocytes, termed neutrophils, which infiltrate the wound site. (Yet other types of immune cells, including eosinophils, mast cells, and lymphocytes, are also recruited to this site.) These recruited cells scavenge and remove foreign matter, bacteria, and tissue debris from the wound site; at the same time, they release and activate mitogenic factors, such as fibroblast growth factors (FGFs) and vascular endothelial growth factor (VEGF). Such factors proceed to stimulate endothelial cells in the vicinity to multiply and to construct new capillaries—the process of angiogenesis (sometimes termed neoangiogenesis). As we will see shortly, VEGF and its cognate receptors play multiple roles in angiogenesis and related hematopoietic processes (**Table 13.2**).

Table 13.2 Properties of VEGFs

capillary and lymph duct formation

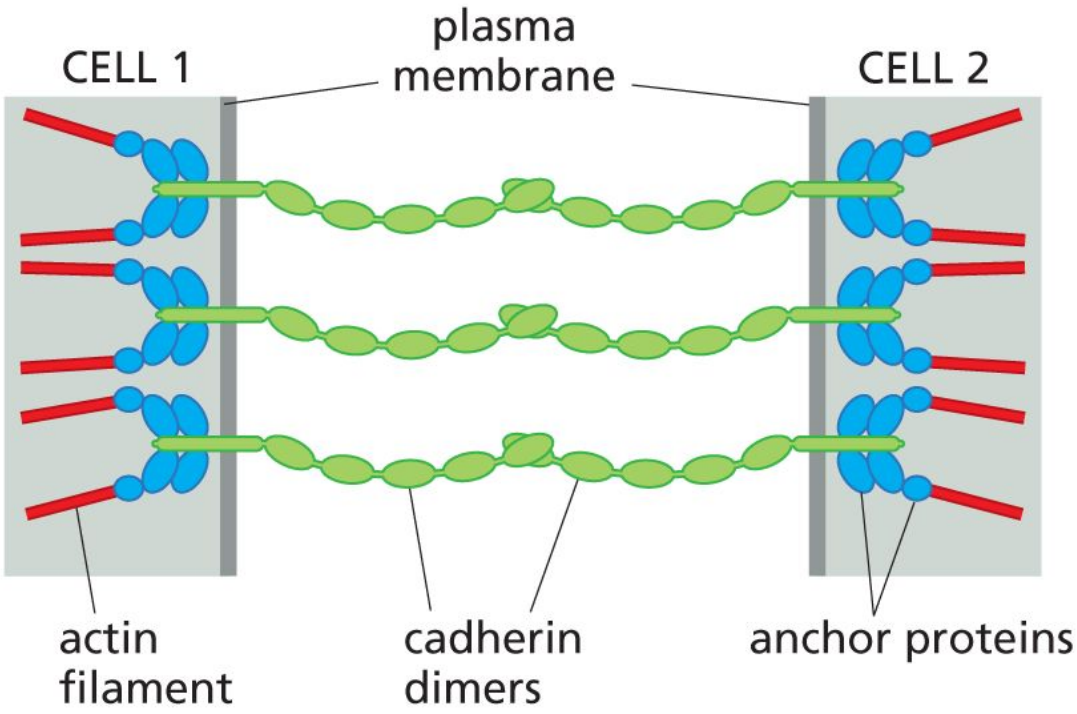
monocyte migration
hematopoiesis
recruitment of hematopoietic progenitor cells from the bone marrow
regulation of the endothelial cell pool during development
capillary permeability

While all this is occurring, largely in the stromal region of a wound site, the epithelial cells around the edges of the wound are undergoing their own alterations. Their goal is to reconstruct the epithelial sheet that existed prior to wounding. To do so, epithelial cells reduce their adhesion to the ECM, specifically to the basement membrane (see Section 2.2 and Figure 2.3) that separates them from the stromal compartment (**Figure 13.14A**). By severing these connections, the epithelial cells gain increased mobility.



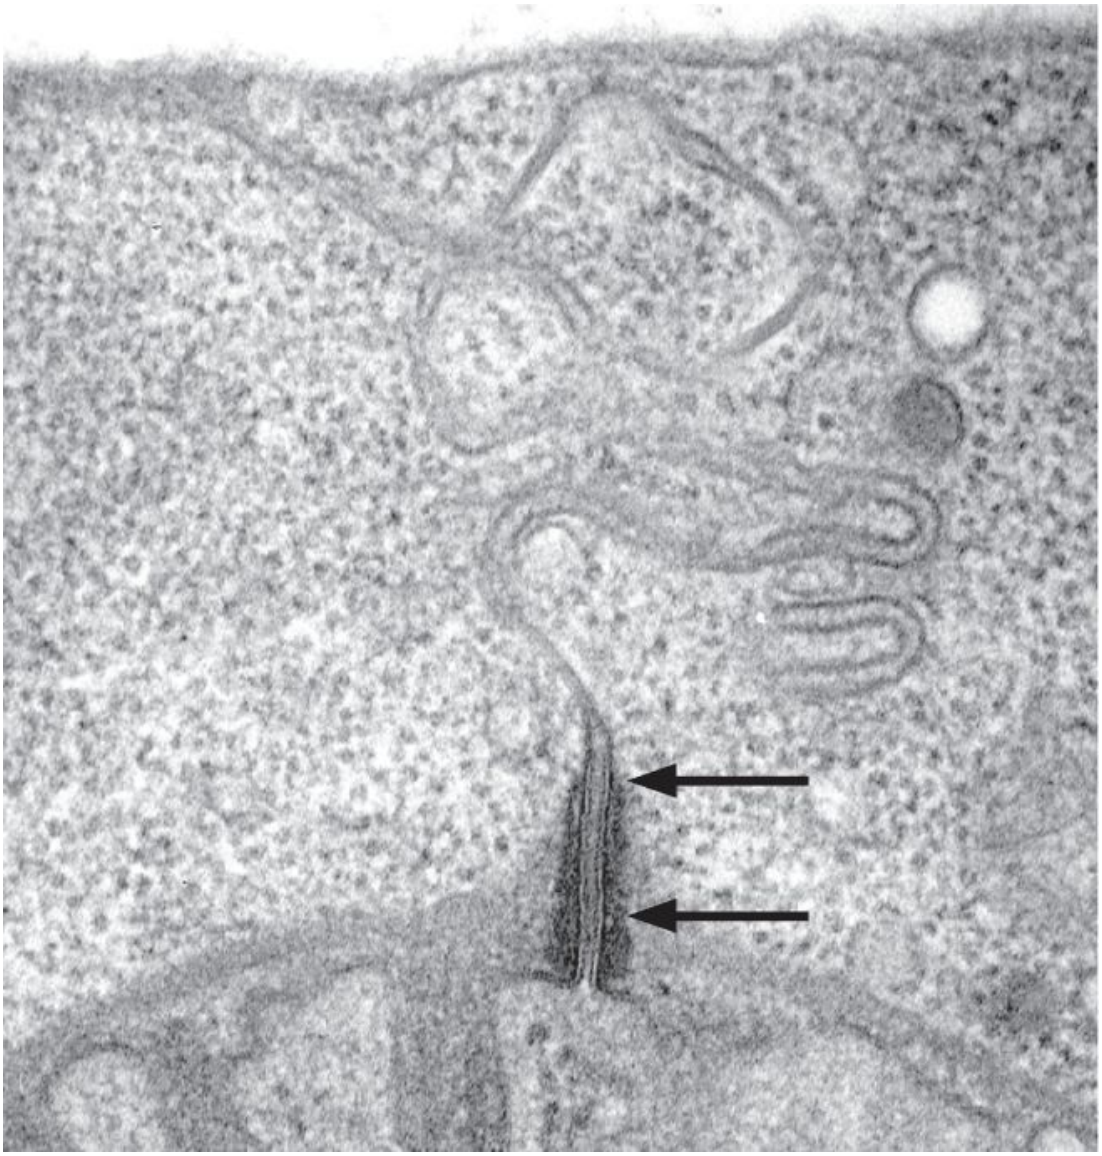
A diagrammatic cross section of intestinal epithelium. On top, covered with microvilli and facing the lumen, is the apical surface. At the bottom is the stroma, separated from the cells above it by the basement membrane. Parts of two cells are shown atop the basement membrane. Within the basal surface of one of those cells, a hemidesmosome penetrates down to the stroma. The rest of the cell contains intermediate filaments. The two cells have a vertical junction between them, where their two lateral surfaces meet. This junction contains, from top to bottom, a tight junction, an adherens junction, containing actin and myosin filaments, a gap junction, and a desmosome.

(A)



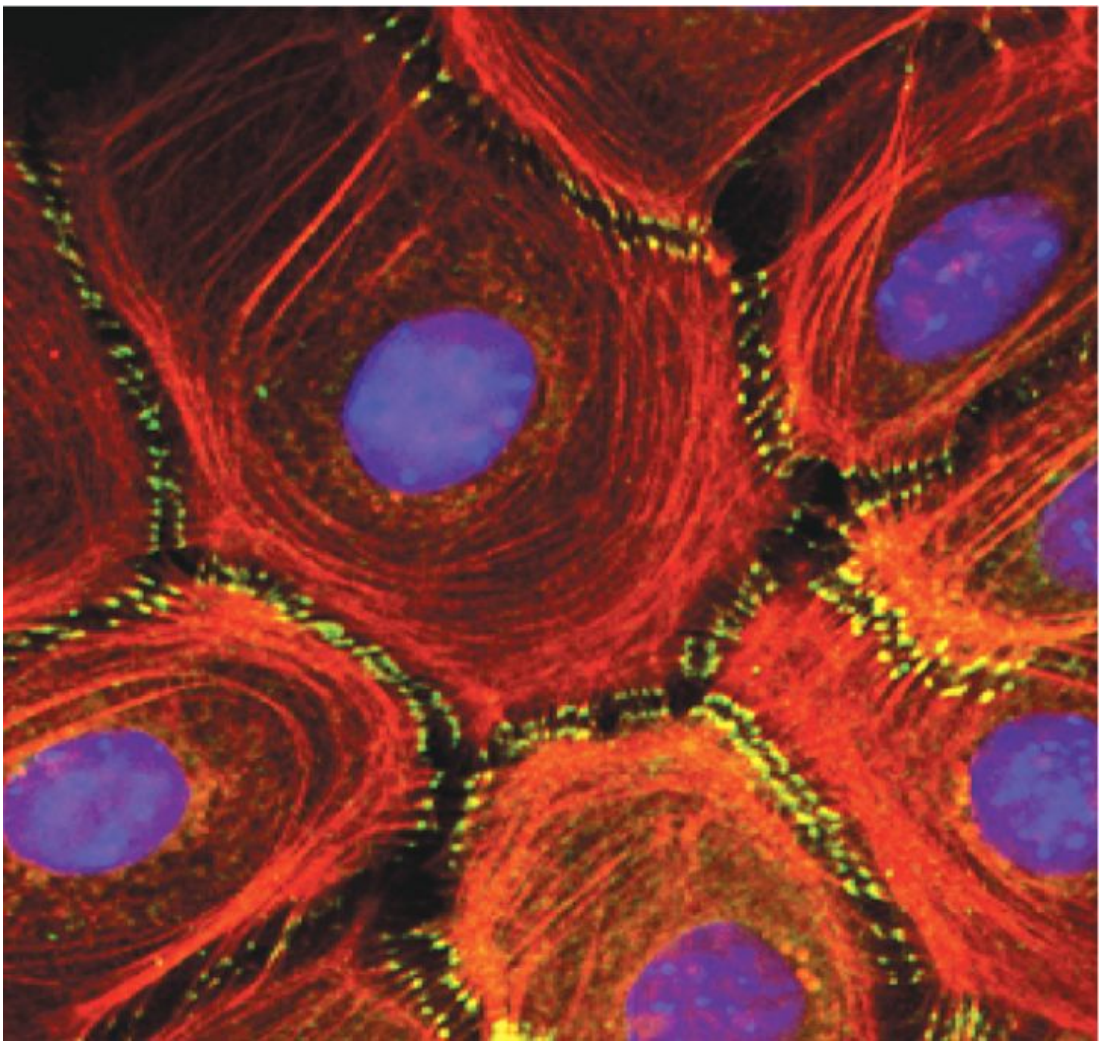
A diagram showing a gap between two cells bridged by a ladder of cadherin dimers linking up from either side. Each cadherin dimer is attached to its home cell by anchor proteins just inside the plasma membrane. These proteins, in turn, are tethered in place by actin filaments.

(B)



A transmission electron micrograph of epithelial tissue in cross section. Two arrows indicate a dark, tapered vertical streak near the bottom of the image.

(C)



An immunofluorescence micrograph of several cells, each with a blue-purple nucleus surrounded by many red fibrous rings. The cells crowd against each other, but running between the cells is a dark border filled with pairs of bright yellow dots.

(D)

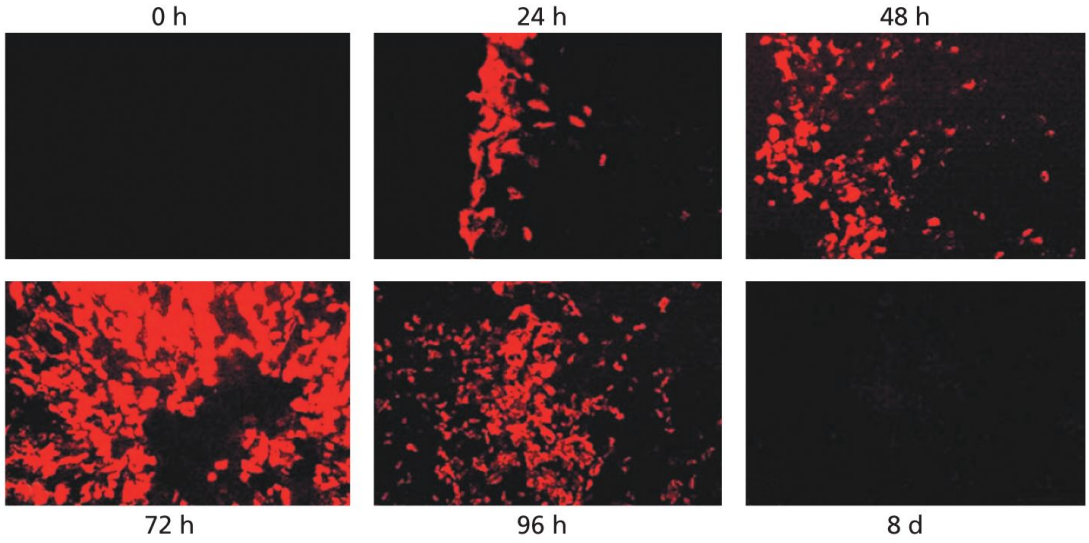
Figure 13.14 Attachments of epithelial cells to their neighbors and the basement membrane (A) Epithelial cells are anchored via hemidesmosomes on their basal surfaces to the underlying basement membrane (*yellow*) and via their lateral surfaces to adjacent epithelial cells (see also Figure 13.10A). These lateral connections include tight junctions (which create a fluid seal between the luminal and basolateral spaces, *light orange*), adherens junctions and desmosomes (which link the cytoskeletons of adjacent epithelial cells, *red*, *blue*), and gap junctions (which permit low–molecular-weight solutes to pass between adjacent cells, *light orange*). (B) The adherens junctions, which play a central role in regulating

epithelial cell behavior, depend on oligomerization between E-cadherin molecules (*light green*) displayed by two adjacent cells. The “anchor proteins” (*blue*), which include prominently α- and β-catenin and p120, form physical bridges between the cytoplasmic tails of E-cadherin proteins and the actin cytoskeleton (*red*; see also Figure 6.19A). As discussed in Section 7.10 and illustrated in Figure 6.19B, β-catenin has a second, quite independent function: when it is not sequestered in adherens junctions, it may move into the nucleus and serve as a subunit of a transcription factor complex that drives the expression of key genes. (C) This transmission electron micrograph shows the adherens junctions (*arrows*) between two closely apposed plasma membranes of adjacent epithelial cells, in this instance those creating the intestinal lining of the worm *Caenorhabditis elegans*. Virtually identical structures are seen in mammalian cells. (D) This immunofluorescence micrograph illustrates the interactions between the lateral surfaces of neighboring keratinocytes in 2-dimensional monolayer culture. E-cadherin “zippers” (y*ellow*) form adherens junctions between neighboring cells and are attached via their cytoplasmic domains and other intermediary proteins (*not shown*) to the actin cytoskeletons of these cells (*red*). Nuclei are stained *blue-purple.* Some of these interactions in actual epithelial tissues can be visualized via immunostaining of E-cadherin and laminin (a basement membrane protein). (A, from H. Lodish et al., Molecular Cell Biology, 6th ed. New York: W.H. Freeman, 2008. With permission from Macmillan. B, from B. Alberts et al., Molecular Biology of the Cell, 4th ed. New York: Garland Science, 2002. C, courtesy of D. Hall. D, from M. Perez-Moreno, C. Jamora and E. Fuchs, *Cell* 112:535–548, 2003. With permission from Elsevier.)

The epithelial cells also sever their attachments to one another. These side-by-side associations are stabilized in part by adherens junctions (Figure 13.14B–D), which are assembled as associations of E-cadherin molecules that are displayed by adjacent epithelial cells and tether the cells’ closely apposed plasma membranes to one another. Accordingly, E-cadherin expression is suppressed in the epithelial cells that are situated around the edges of a wound site and is often replaced by N-cadherin, another cell–cell adhesion molecule that is normally displayed by mesenchymal cells, notably fibroblasts. (These N-cadherin molecules, though related structurally to E-cadherin, do not reestablish adherens junctions between the epithelial cells, because they bind more weakly to one another.)

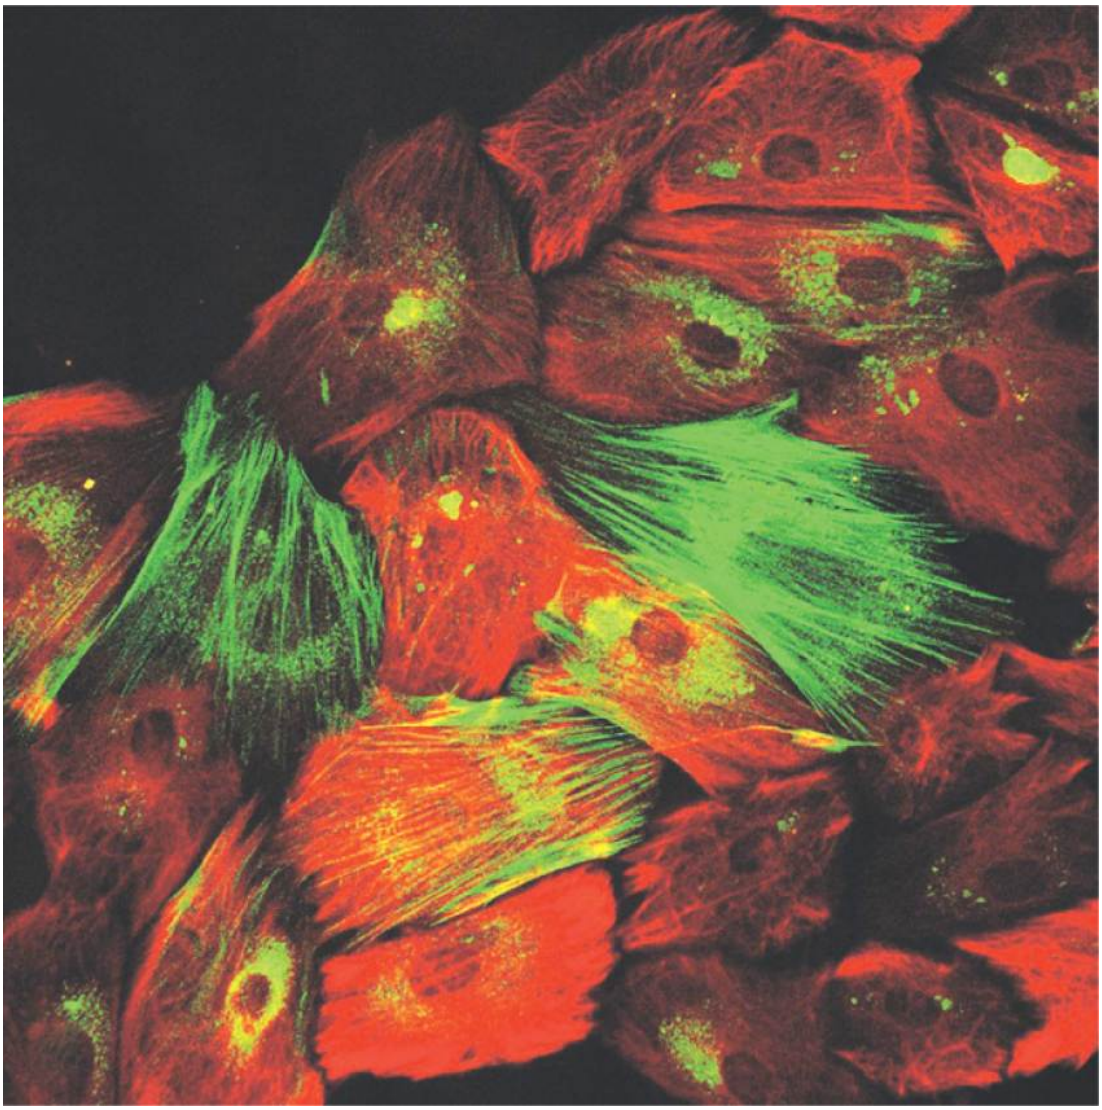
While shifting their display of cell-surface cadherins, the epithelial cells at the edge of a wound undergo a major change in phenotype, which causes them to assume, at least superficially, a fibroblastic appearance (**Figure 13.15**). This profound shift is termed an epithelial–mesenchymal transition (EMT) and enables the epithelial cells to become motile and invasive. The EMT program that becomes activated in these cells involves profound changes in their biology beyond those apparent under the microscope. Thus,

induction of several hundred genes creates a cell-biological *program* that imparts a variety of mesenchymal traits, causing these cells to transit from a fully epithelial state into a mixed epithelial/mesenchymal (quasi-mesenchymal) phenotypic state. Having dissolved the adherens junctions that bound them on their lateral surfaces to one another (see Figure 2.4), the resulting quasi-mesenchymal cells are now freed to move into the wound site and fill in the gap in the epithelium previously created by wounding.



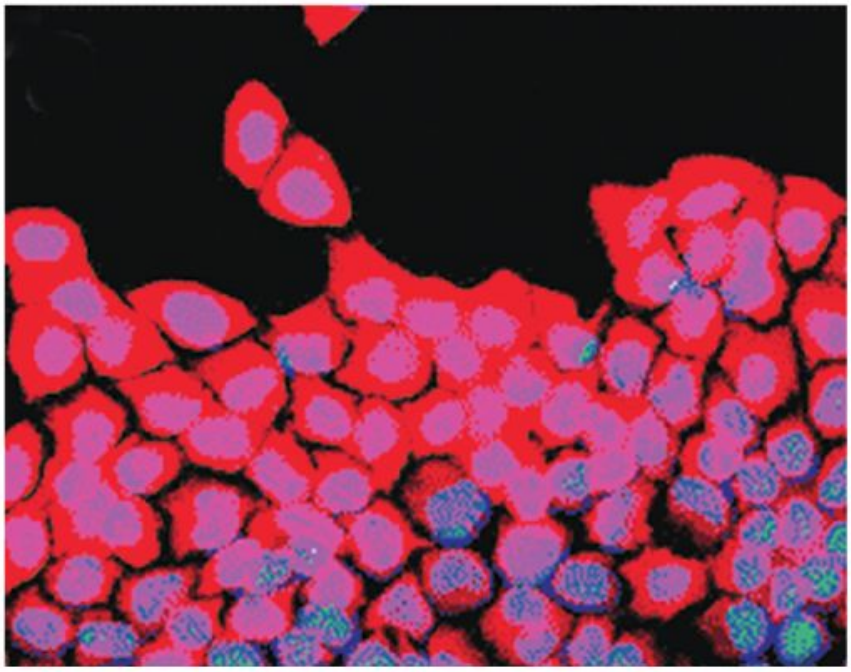
A series of six fluorescence microscopy images, each with a time stamp. The 0 hour image is black. The 24 hour image has an irregular streak of red splotches down the middle. Over the course of the 48, 72, and 96 hour images this streak explodes, so to speak, leftward and rightward, and then recedes. The 8 day image is black.

(A)

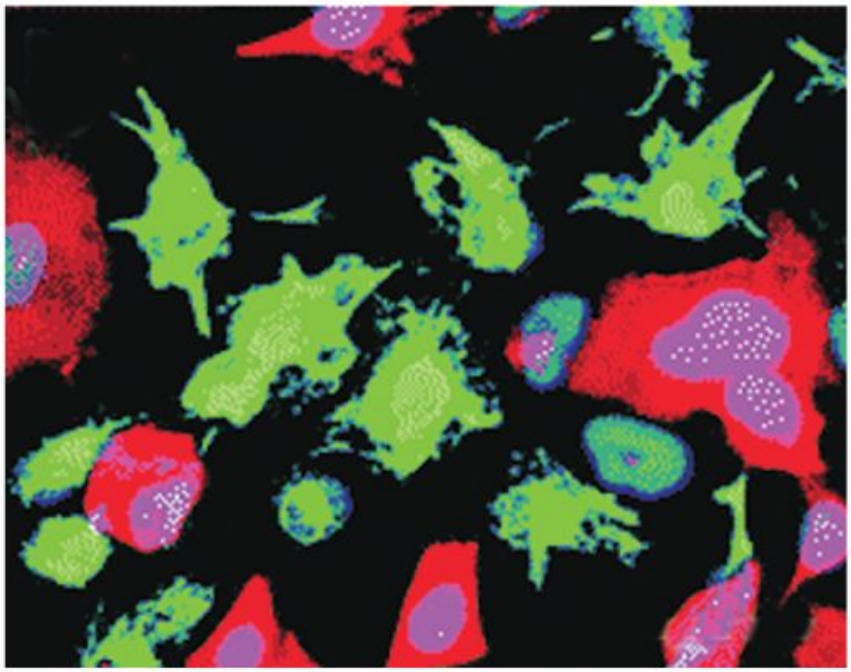


A fluorescence microscopy image of what looks like a heap of cells tightly bound together by fiber capsules or bundles. Most of the bundles are red with bits of green, but two are bright green.

(B)



control culture



+ MMP-3 for 3 days

Two fluorescence microscopy images. The upper one, labeled control culture, contains tightly packed cells with red borders that are mostly pink in the center, but in a few cases contain many small blue or blue-green dots. The lower image, labeled plus M M P-3 for 3 days, contains a loosely packed mix

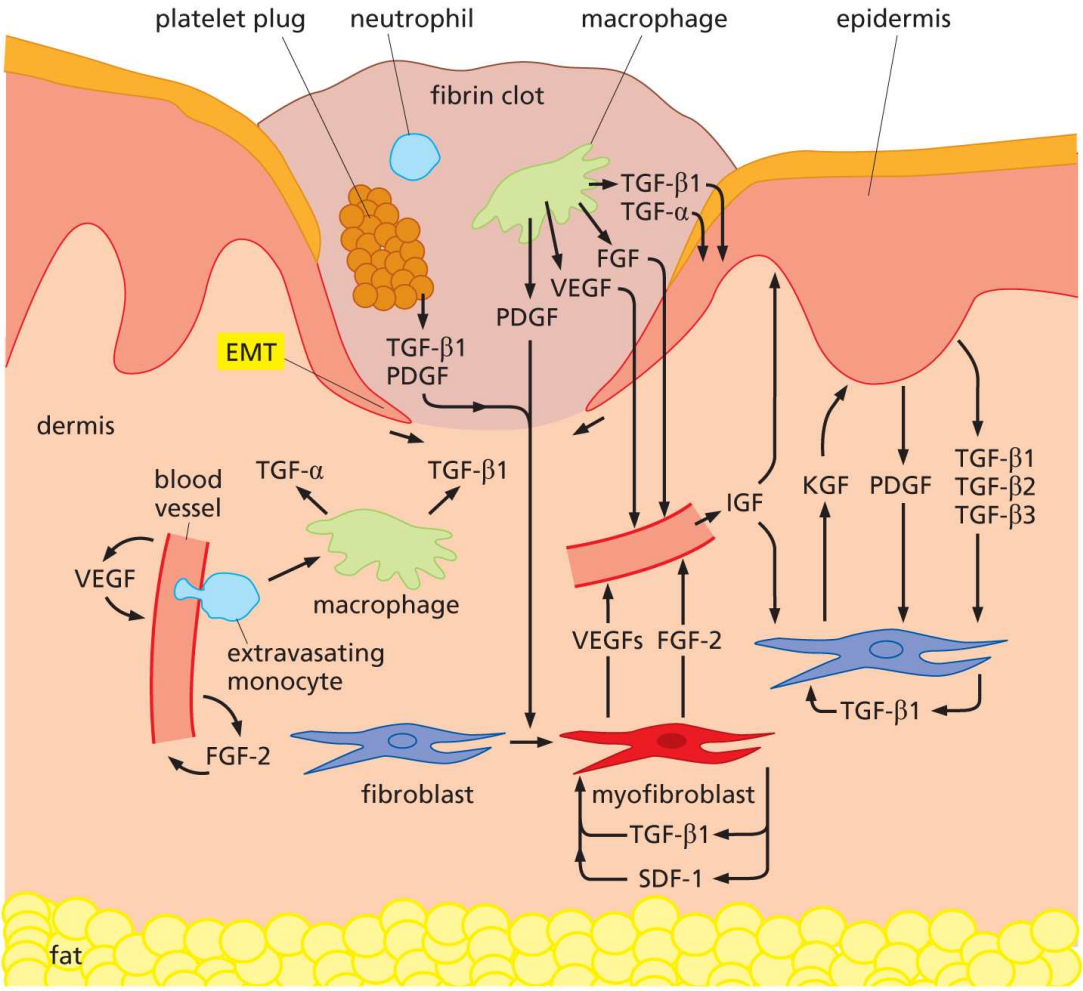
of irregularly shaped cells, some bright red with pink centers and others bright green.
(C)

Figure 13.15 The epithelial–mesenchymal transition Multiple signals and conditions trigger activation of EMT programs, including prominently the wounding of epithelial cell sheets studied here. (A) A confluent monolayer of MCF10A cells [a line of nontransformed, immortalized human mammary epithelial cells (MECs)], has been disturbed by removal of a patch of cells (*at left of each image*). Before wounding, no vimentin is expressed by these cells. However, soon after wounding, the epithelial cells at the edge of the wound undergo a partial epithelial–mesenchymal transition (EMT), enter into a quasi-mesenchymal phenotypic state, express vimentin (characteristic of more mesenchymal cells; *red*), migrate into the wound site, proliferate, and fill the wound site. After 8 days, the cell monolayer has become confluent, and these cells revert to a fully epithelial phenotype and shut down vimentin expression [indicating a mesenchymal–epithelial transition (MET)], thereby reconstructing an intact epithelium. (B) In some cell types in culture, individual cells may spontaneously shift from an epithelial phenotype, indicated by cytokeratin expression (*red*), to a more mesenchymal phenotype, indicated by α-smooth muscle actin expression (*green*). This mirrors a phenotypic plasticity that is apparent in certain cells during early embryogenesis and tumorigenesis. (C) An EMT was provoked here by a 3-day-long exposure to matrix metalloproteinase-3 (MMP-3), which may trigger an EMT through its ability to degrade E-cadherin. Thus, some of the epithelial cells have shut down expression of many typical epithelial cell markers, such as cytokeratins (*dark pink*) and E-cadherin (*not shown*), and express instead mesenchymal proteins, such as vimentin (*green*), fibronectin, and N-cadherin (*not shown*). In addition, they change their typically polygonal shape (*top*) to a fibroblastic shape (*bottom*) and concomitantly acquire motility and invasiveness. (A, from C. Gilles et al., *J. Cell Sci.* 112:4615–4625, 1999. With permission from Company of Biologists. B, from O.W. Petersen et al., *Am. J. Pathol.* 162:391–402, 2003. C, from M.D. Sternlicht et al., *Cell* 98:137–146, 1999. Both with permission from Elsevier.)

Although the EMT, as described above, can be observed in monolayers of cultured epithelial cells, within a living tissue, the triggering of this program is aided by stromal cells that underlie epithelia. The matrix metalloproteinases (MMPs) secreted by stromal cells liberate and activate latent growth factors, such as TGF-β1, that have been stored in the extracellular matrix. In ways that are only partially understood, these released factors stimulate and reinforce expression of the EMT program in the epithelial cells. Importantly, the EMT is only a temporary shift in cell phenotype. After the migrating cells have moved into position, proliferated, and covered the wound site,

they reconstruct the epithelium by reverting to an epithelial state via the program termed the mesenchymal–epithelial transition (MET; see Figure 13.15A). As a consequence, once wound healing is complete, the cells in the reconstituted epithelium show no trace of having passed transiently through a quasi-mesenchymal state. We will discuss the EMT program in much greater detail in the next chapter because it plays a key role in enabling carcinoma cells to acquire malignant traits. In fact, a complex array of heterotypic signals impinge on epithelial cells to encourage them to activate their previously silent EMT programs, as described in **Supplementary Sidebar 13.4**.

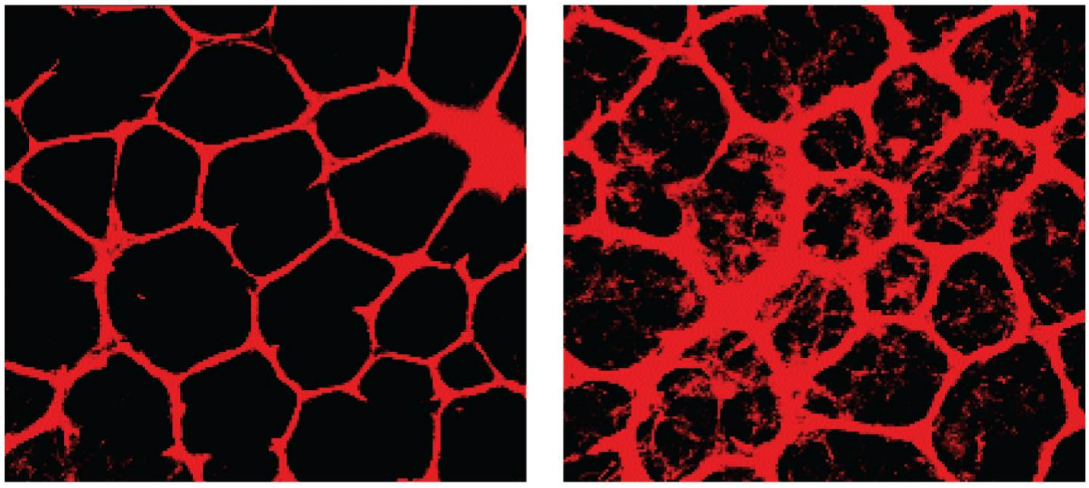
If we compare these processes (**Figure 13.16**) with the interactions of epithelial cancer cells and their stromal neighbors, we find striking parallels between wound healing and tumorigenesis. Among the similarities between the two is the presence of clumps of fibrin in the tumor-associated stroma. In the case of tumors, this does not derive from traumatic damage to blood vessels. Instead, the capillaries within tumors are constitutively leaky, unlike those in normal tissues (**Figure 13.17A**). Later, we will discuss the causes of this leakiness. For the moment, suffice it to say that the permeability of the capillary walls and venules (small veins) allows fibrinogen molecules from the plasma to come in direct contact with cancer cells; this provokes, through a series of intermediate reactions, the conversion of fibrinogen to fibrin and the formation of large bundles of fibrin strands (Figure 13.17B and C).



An illustration of the pathways involved in wound healing. An epidermal puncture is plugged by a large, round fibrin clot. Shown within the clot are a platelet plug, a neutrophil, and a macrophage. The hole in the epidermis is growing shut beneath the clot, with the growing edge labeled E M T. The dermis lies beneath the epidermis and above a layer of fat. Within the epidermis, multiple proteins and cell types participate in the healing process, including the formation of new blood vessels.

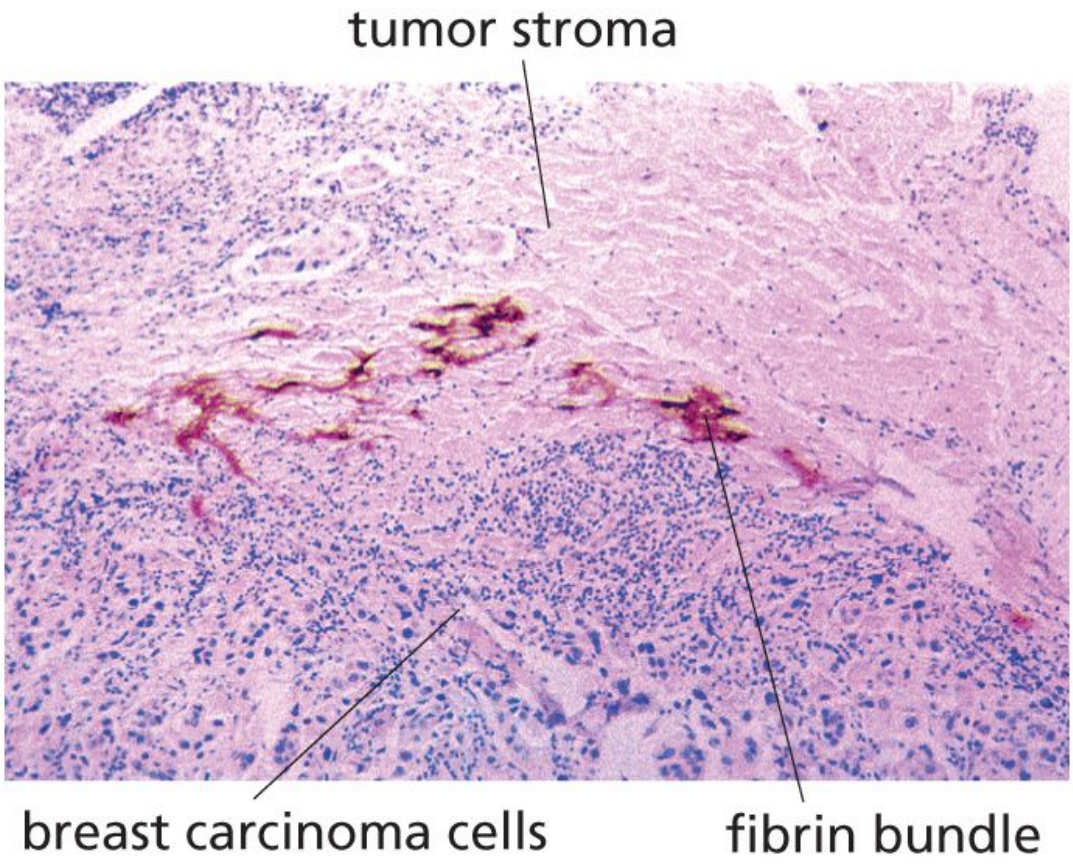
Figure 13.16 A program of epithelial wound healing This illustration depicts the heterotypic signaling occurring after the skin, a typical epithelial tissue, is wounded. A fibrin clot that carries platelets and red blood cells/erythrocytes (see Figure 13.12) initially fills the wound site. Day 3 of the wound-healing process is sometimes termed its inflammatory phase, because of the involvement of cell types that are associated with inflammation, notably neutrophils and monocytes; they are involved in removing cell debris, the clot, and invading bacteria. In addition, macrophages, which derive from differentiation of extravasated monocytes, release TGF-β1 and TGF-α; these factors stimulate the proliferation of

nearby epithelial cells from the epidermis and induce them to undergo an epithelial–mesenchymal transition (EMT). Tongues of the resulting cells, now exhibiting mesenchymal behavior, invade under the clot from both sides in order to cover the wound site (see Figure 13.15A). At the same time, TGF-β1 and PDGF-A and -B, which were released by the platelets during initial clot formation, stimulate the proliferation of fibroblasts (*blue-purple*) in the underlying dermal stroma and induce them to convert into the activated fibroblasts termed myofibroblasts (*red*); because of their contractility, myofibroblasts will pull the sides of the wound together. Myofibroblasts also release angiogenic factors, notably VEGFs and FGF-2 (fibroblast growth factor-2), which stimulate the formation of new blood vessels in the stroma underlying the wound site. Keratinocyte growth factor (KGF), another isoform of FGF, is released by mesenchymal cells and stimulates epithelial cell proliferation. In addition, insulin-like growth factors (IGFs) provide survival signals to various cells in the wound-healing site. Finally, after the wounded stroma is covered, the quasi-mesenchymal cells that had undergone an EMT revert, via a mesenchymal–epithelial transition (MET), to an epithelial state, thereby reconstituting the epithelium (*not shown*). (Redrawn from A.J. Singer and R.A.F. Clark, *N. Engl. J. Med.* 341:738–746, 1999. With permission from Massachusetts Medical Society.)



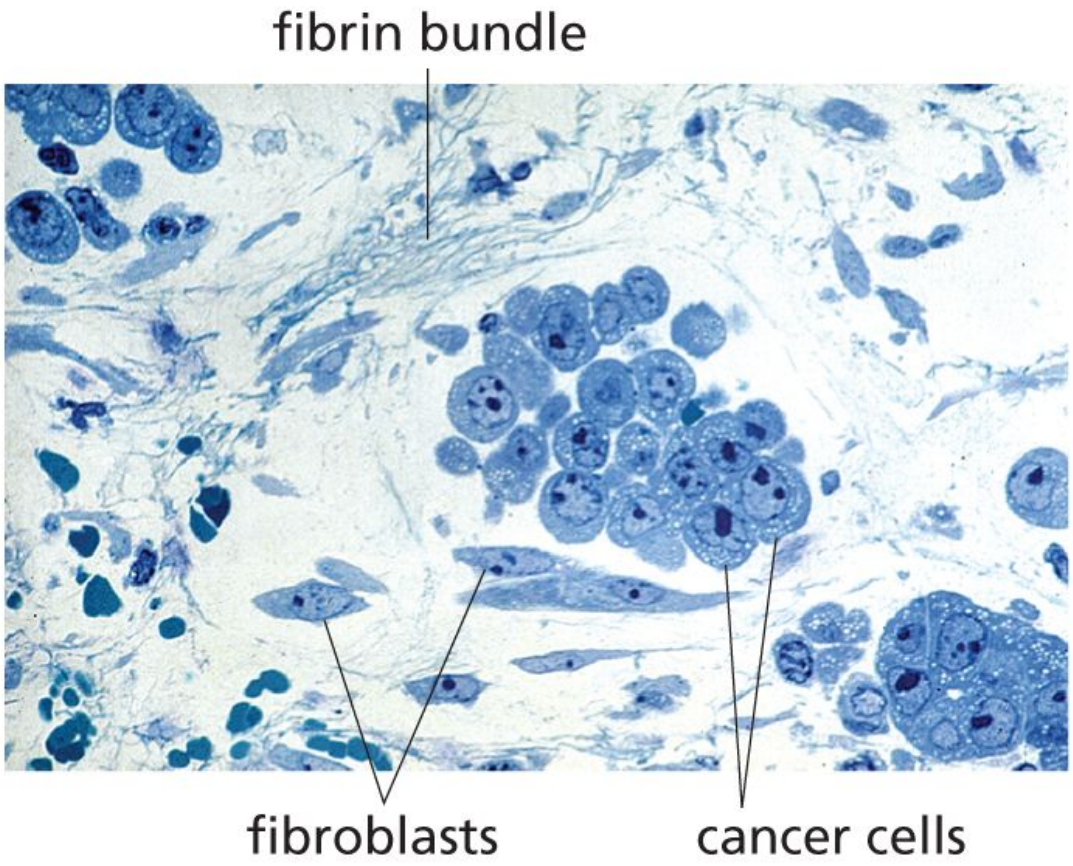
A comparison of the results of injecting red dye into normal microvasculature and into tumor-associated microvasculature. In normal tissue, the dye remains confined within the capillaries, whereas in tumor-associated tissue, it leaks into the surrounding parenchyma.

(A)



A histology image with breast cancer tissue, characterized by many blue nuclei at the bottom and more pinkish tumor stroma at top. The border between the two regions contains patches of brown fibrin bundles.

(B)



An image with a cluster of round cancer cells in the middle, a few horizontally elongated fibroblasts below, and a fibrin bundle above.

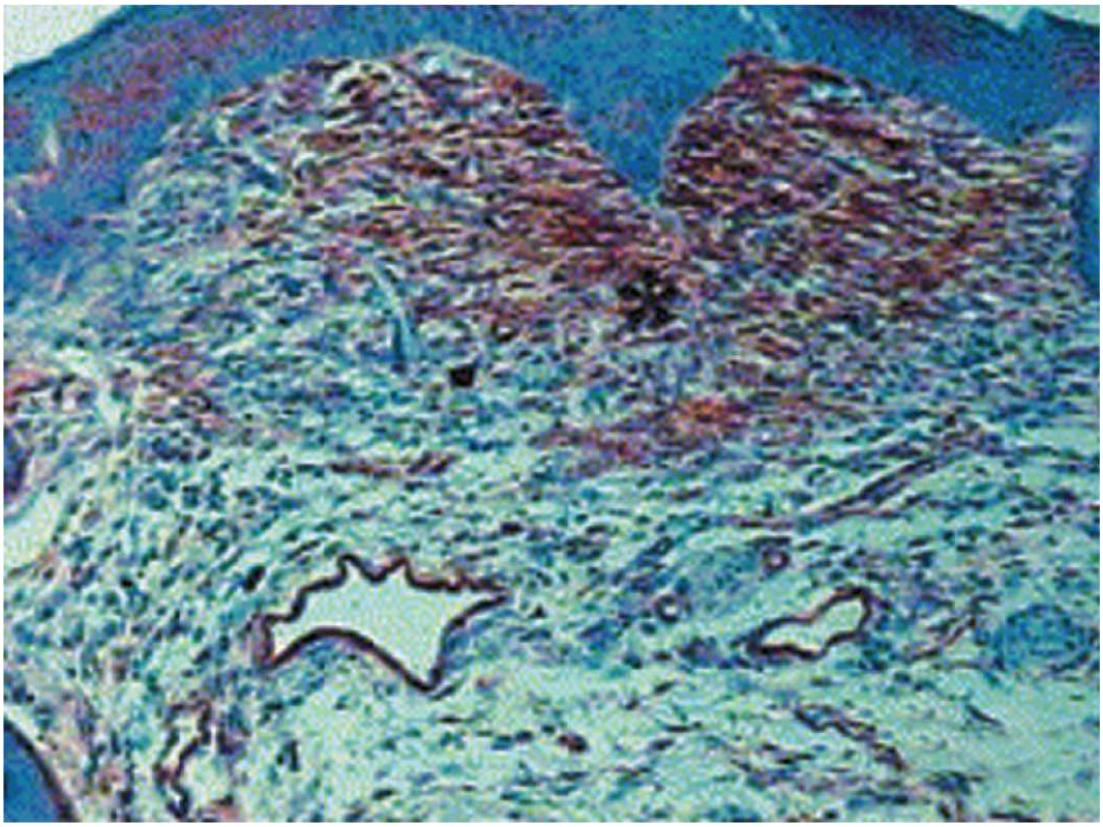
(C)

Figure 13.17 Capillary leakiness and deposition of fibrin bundles in the tumor-associated stroma(A) Injection of red dextran dye into normal microvasculature reveals that the walls of associated capillaries have relatively low permeability, as indicated by the sharply delineated profiles of these vessels (*left*). However, when injected into tumor-associated microvasculature, the dye leaks out of the capillaries and diffuses into the nearby parenchyma, yielding diffusely staining outlines of vessels (*right*). (B) The leakiness of tumor-associated microvasculature results in the continuous leaking of thrombin and fibrinogen molecules from the plasma into the parenchyma surrounding blood vessels. Tissue Factor, a protein displayed on the surface of cancer cells and many other nonendothelial cell types, activates plasma-derived thrombin upon contact, whereupon thrombin, functioning as a protease, converts fibrinogen into fibrin (see Figure 13.12). This results in the extensive network of fibrin bundles (*dark red*) seen here at the border between actively growing breast cancer cells (*below*) and the tumor stroma (*above*). (C) The fibrin bundles form an extracellular matrix

to which migrating cells, such as fibroblasts (*below cluster of cancer cells*) as well as endothelial cells (*not seen*), can attach, using it as a substrate on which they can move forward. In many tumors, such as this guinea pig liver carcinoma of bile duct origin, the fibrin matrix may eventually be dissolved by the process of *fibrinolysis* and replaced by a collagenous matrix. (A, courtesy of R. Muschel. B, from C.G. Colpaert et al., *Histopathology* 42:530–540, 2003. With permission from John Wiley & Sons. C, from H.F. Dvorak, *Am. J. Pathol.* 162:1747–1757, 2003. With permission from Elsevier.)

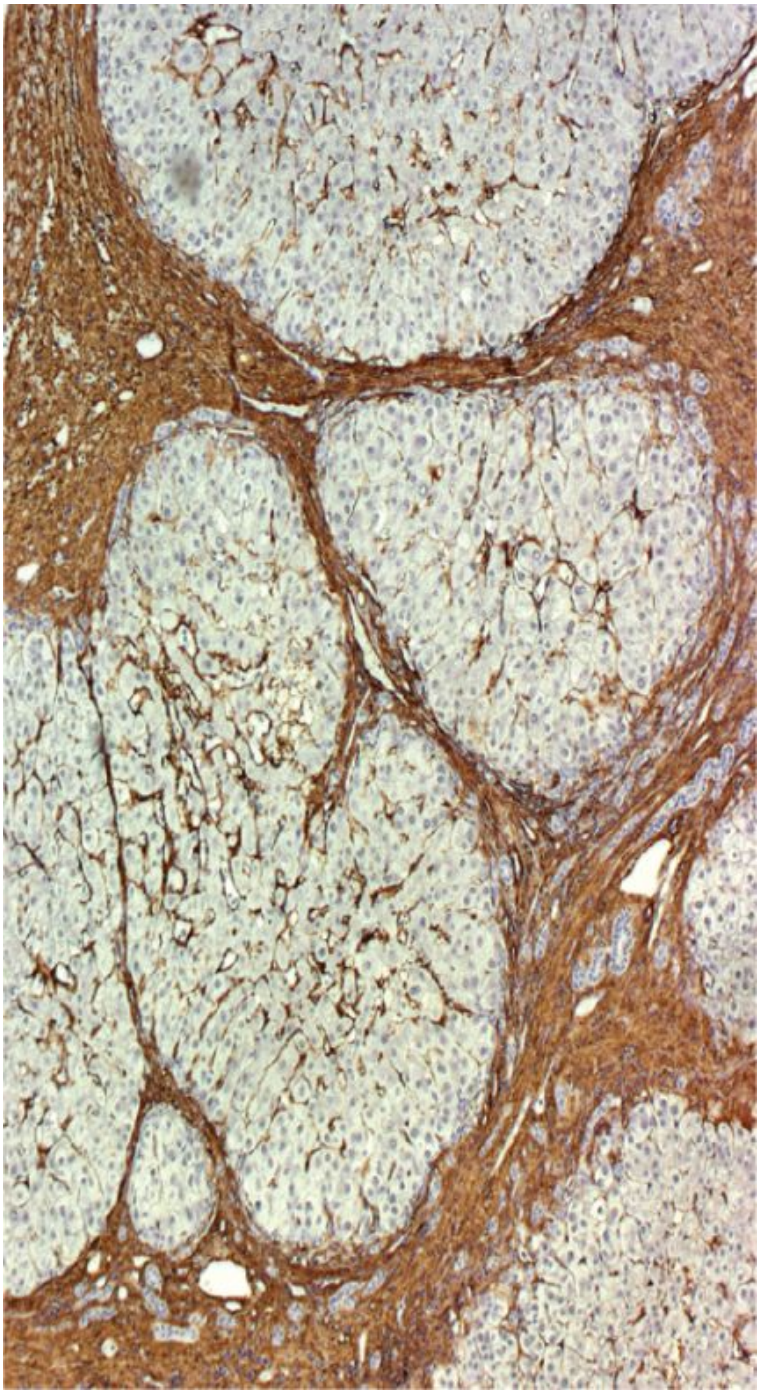
Many kinds of cancer cells, including those forming carcinomas of the breast, prostate, colon, and lung, continuously release significant levels of PDGF. This contrasts with the situation in wounds, in which PDGF is released in a brief burst by platelets as they form the initial blood clot (see Figure S5.1). As is the case in wound healing, the targets of the PDGF produced by cancer cells are mesenchymal cells in the stroma that display PDGF receptors, including smooth muscle cells, fibroblasts, and macrophages. PDGF functions here both as an attractant and as a mitogen for these stromal cells and appears to be the most important signaling molecule used by carcinoma cells to recruit and stimulate the proliferation of stromal cells. In breast cancers, for example, the level of PDGF expression generally increases with increased degree of tumor progression, which may explain the high proportions of stroma present in many advanced carcinomas; an extensive stroma, including high levels of collagens, is especially evident in adenocarcinomas of the pancreas. Indeed, in a variety of carcinomas, a high ratio of stromal to epithelial cells represents an unfavorable prognosis for the cancer patient.

The PDGF released by carcinoma cells initially succeeds in recruiting fibroblasts into the fibrin matrix. At the same time, the fibrin matrix (see Figure 13.17B and C) provides an important scaffolding that helps these recruited mesenchymal cells to attach, via integrins, and migrate. The invading stromal cells remodel this “provisional matrix” by degrading many of the initially formed fibrin molecules and replacing them with a more permanent matrix that is assembled from the collagen secreted by the myofibroblasts (**Figure 13.18**). This sequence of steps loosely parallels those occurring during wound healing.



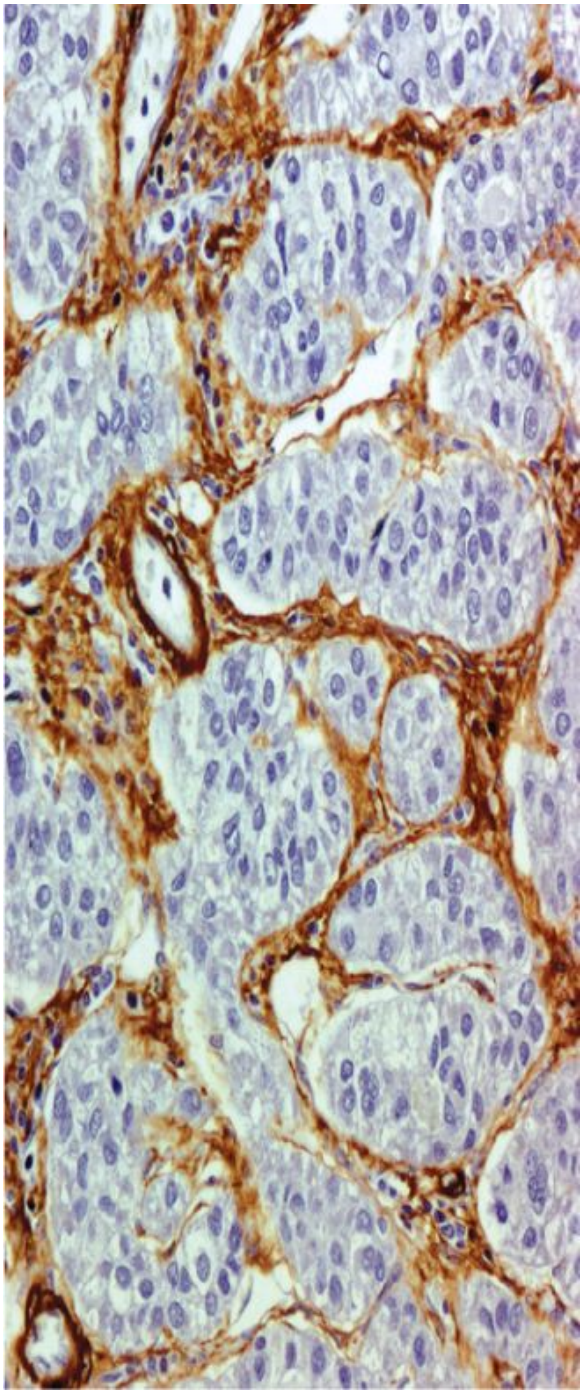
A mostly blue histology imagebut an area near what looks like an avulsed surface is brown.

(A)



A histology image of pale blobs and the spaces between them filled by a dense tangle of brown fibers.

(B)



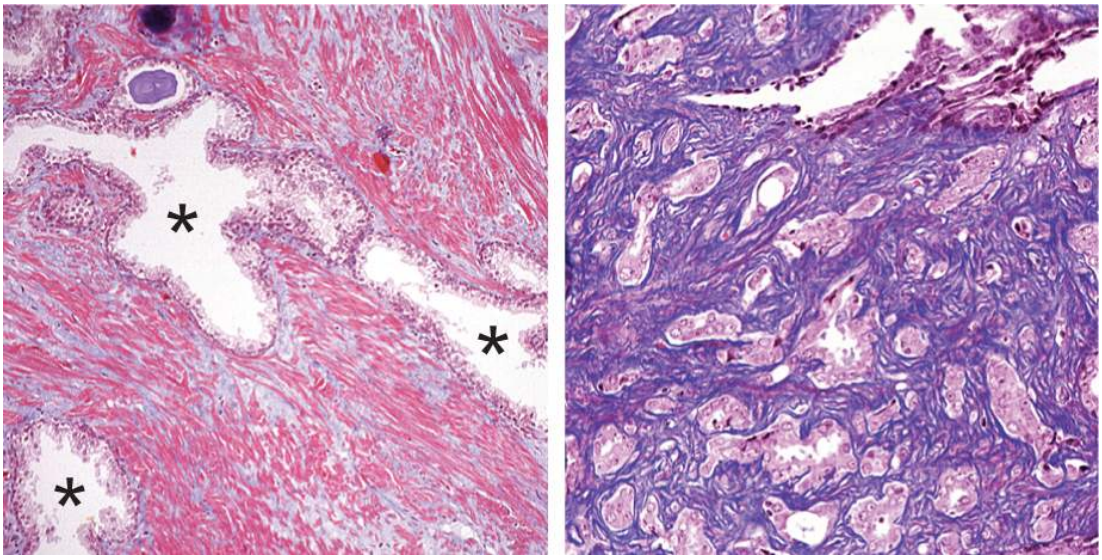
A histology image very similar to Part B, except that within the pale blobs blue nuclei are visible.

(C)

Figure 13.18 Myofibroblasts Myofibroblasts arise in sites of wound healing, during inflammation, and in tumor-associated stroma, in part through

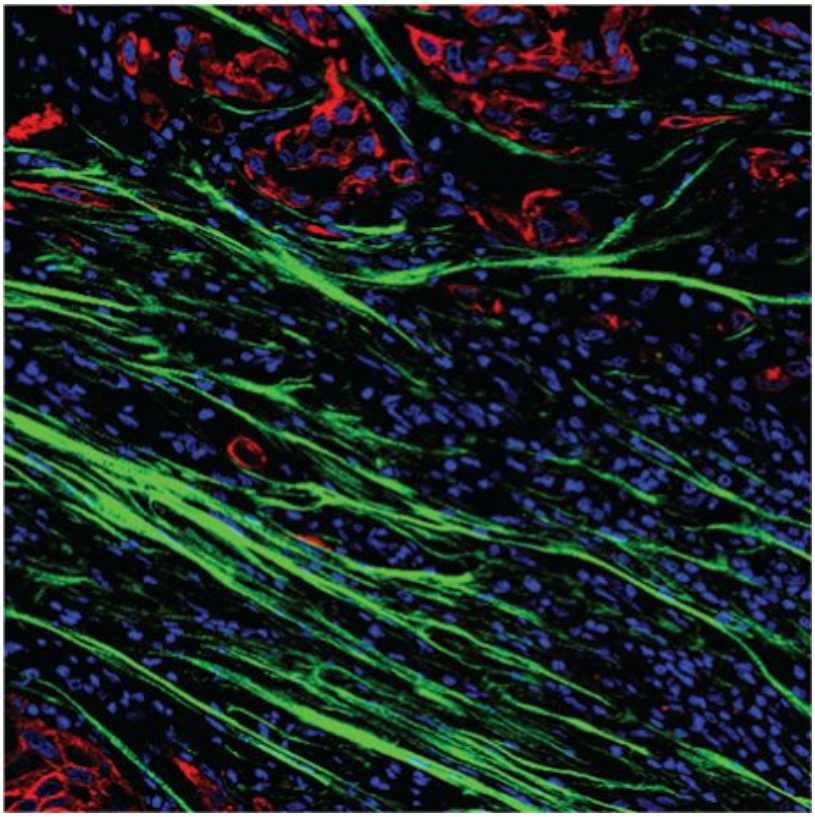
differentiation of stromal fibroblasts (see Figure 13.16) and recruitment of myofibroblast precursors, possibly fibrocytes and mesenchymal stem cells (MSCs), from the circulation. Their presence is revealed typically by their expression of α-smooth muscle actin (α-SMA). (A) Staining for α-SMA–positive myofibroblasts (*reddish brown*) shows them present in abundance 3 days after the skin of a mouse has suffered a wound. (B) Chronically inflamed tissues acquire a fibrotic stroma, such as the cirrhotic liver seen here stained with anti-α-SMA antibody, which reveals the presence of masses of myofibroblasts (*brown*). (C) A hepatocellular carcinoma stained with anti-α-SMA antibody (*brown*) reveals the striking resemblance of the stroma of a chronically inflamed tissue (panel B) to the stroma of a carcinoma arising in that tissue. (A, from P. Martin et al., *Curr. Biol.* 13:1122–1128, 2003. With permission from Elsevier. B and C, from A. Desmouliere, A. Guyot and G. Gabbiani, *Int. J. Dev. Biol.* 48:509–517, 2004. With permission from UPV/EHU Press.)

Recent work has revealed the complexity of carcinoma-associated fibroblasts (CAFs) (**Figure 13.19**). At least in the context of pancreatic adenocarcinoma, those that were near the carcinoma cells expressed α-smooth muscle acting (α-SMA), which is known to be induced by TGF-β released by carcinoma cells. These CAFs produced prodigious amounts of type I collagen, which eventually creates the desmoplastic (that is, fibrous, hard) stroma that is typical of this very aggressive tumor. (Quantitative physical measurements of the solid stresses, that is, the hardness of pancreatic carcinomas indicates that these tumors are 100 times harder than, for example, glioblastomas.) Yet other CAFs, situated further away from islands of carcinoma cells lack elevated α-SMA expression and instead released pro-inflammatory molecules, prominently interleukin-6 (IL6).



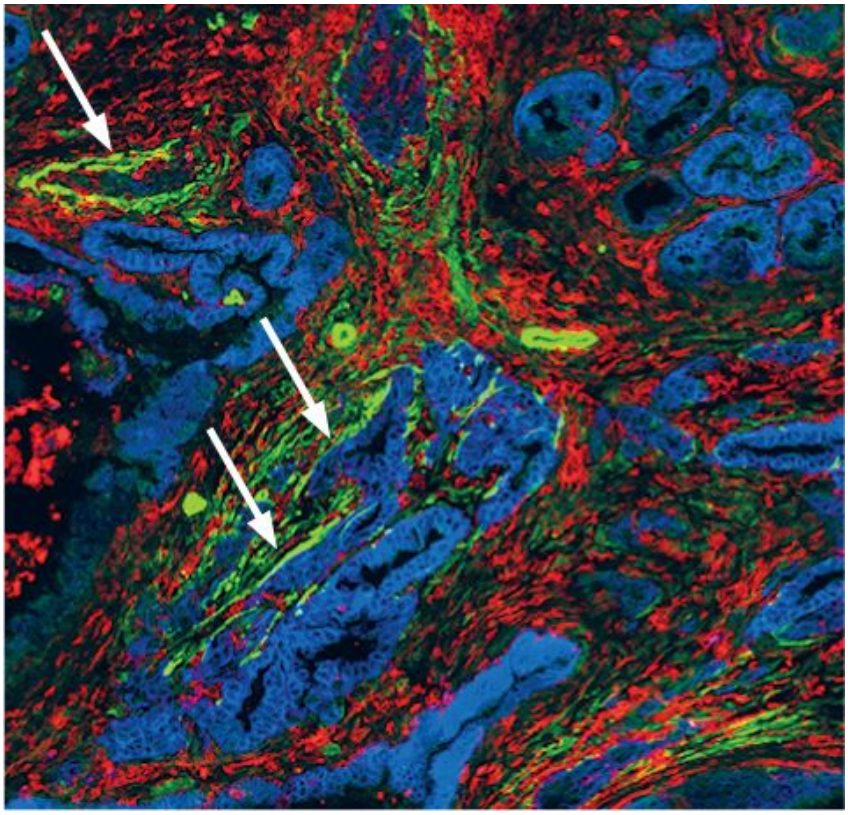
Two histology images. In the first one, smooth pink tissue is interrupted by white ducts marked by asterisks. In the second image, purplish tissue is more granular.

(A)



A fluorescence microscopy image in which many parallel green streaks run diagonally across a field of blue nuclei.

(B)



A fluorescence microscopy image dominated with swirls of red and blue, but there are a few streaks of green visible. Three of the longest green streaks have arrows pointing to them.

(C)

Figure 13.19 Micrograph of normal stroma and desmoplastic stroma The histologically complex stroma of normal tissue may eventually be replaced by the desmoplastic stroma of an advanced carcinoma. Here we see normal human prostate tissue (*left panel*) stained with Masson's trichrome stain, which reveals the extensive smooth muscle cells in the stroma as *pink*; normal ducts (*asterisks*) are scattered throughout this stroma. In contrast, an advanced prostate carcinoma (*right panel*), stained identically and viewed at the same magnification, reveals the extensive desmoplastic stroma, which is rich in extracellular matrix, notably collagen I (*blue-purple*). Islands of prostate carcinoma cells forming small ducts (*pink*) are scattered throughout this desmoplastic stroma, which lacks significant numbers of viable cells such as myofibroblasts and fibroblasts. (B) In this invasive ductal carcinoma of the breast, the deposition of parallel collagen fibers by fibroblasts and myofibroblasts (*green*; visualized here by 2-photon microscopy) creates a stiff extracellular matrix in the desmoplastic stroma that encourages epithelial–mesenchymal transitions (EMTs; described in Chapter 14) in nearby carcinoma cells (*red*). (C) A more complex stroma is seen in a mouse model of

pancreatic ductal adenocarcinoma (PDA). At this stage of tumor progression, the glandular carcinoma cells (stained for EpCam, *blue*), are greatly outnumbered by the immune cells that constitute the inflammatory and immunosuppressive components of the stroma (stained for CD45, *red*). The α-SMA-positive cells (*green*) are largely stromal myofibroblasts and, to a small extent, microvessel-associated pericytes (*arrows*). (A, from G. Ayala et al., *Clin. Cancer Res.* 9:4792–4801, 2003. With permission from American Association for Cancer Research. B, courtesy of S. Wei and J. Yang. C, from C. Feig, A. Gopinathan, A. Neesse et al. *Clin. Cancer Res.* 18, 4266-4276, 2012. Reprinted by permission from the American Association for Cancer Research.)

One of the tasks of the stromal cells in wound healing involves the physical contraction of the wound site in order to close wounds. This contraction is mediated by the specialized fibroblasts cited above to generate the mechanical tension needed for wound closure (see Figure 13.18A). These specialized fibroblasts are termed myofibroblasts (see Figure 13.16); these cells express α-smooth muscle actin (α-SMA) and are capable of using the actin–myosin contractile system (related to the one operating in muscle cells). In addition to their major contribution to the populations of cancer-associated fibroblasts (CAFs), myofibroblasts are also present in sites of chronic wounding, that is, continuously inflamed tissues (see Figure 13.18B). Provocatively, essentially identical α-SMA-positive fibroblasts are prominent components of the stroma present in most advanced carcinomas (for example, see Figure 13.18C). Of note, normal tissues, such as the prostate gland, may contain α-SMA-positive cells that, because they lack vimentin, can be identified as smooth muscle cells rather than the myofibroblasts present in sites of wound-healing, inflammation, and tumorigenesis (see Figure 13.19A). Myofibroblasts have been found to release a broad spectrum of growth factors, including HGF, CTGF, EGF, IGF, NGF, bFGF, Wnts, and cytokines (see Table 5.1); this list overlaps partially with key factors released by platelets upon clot formation.

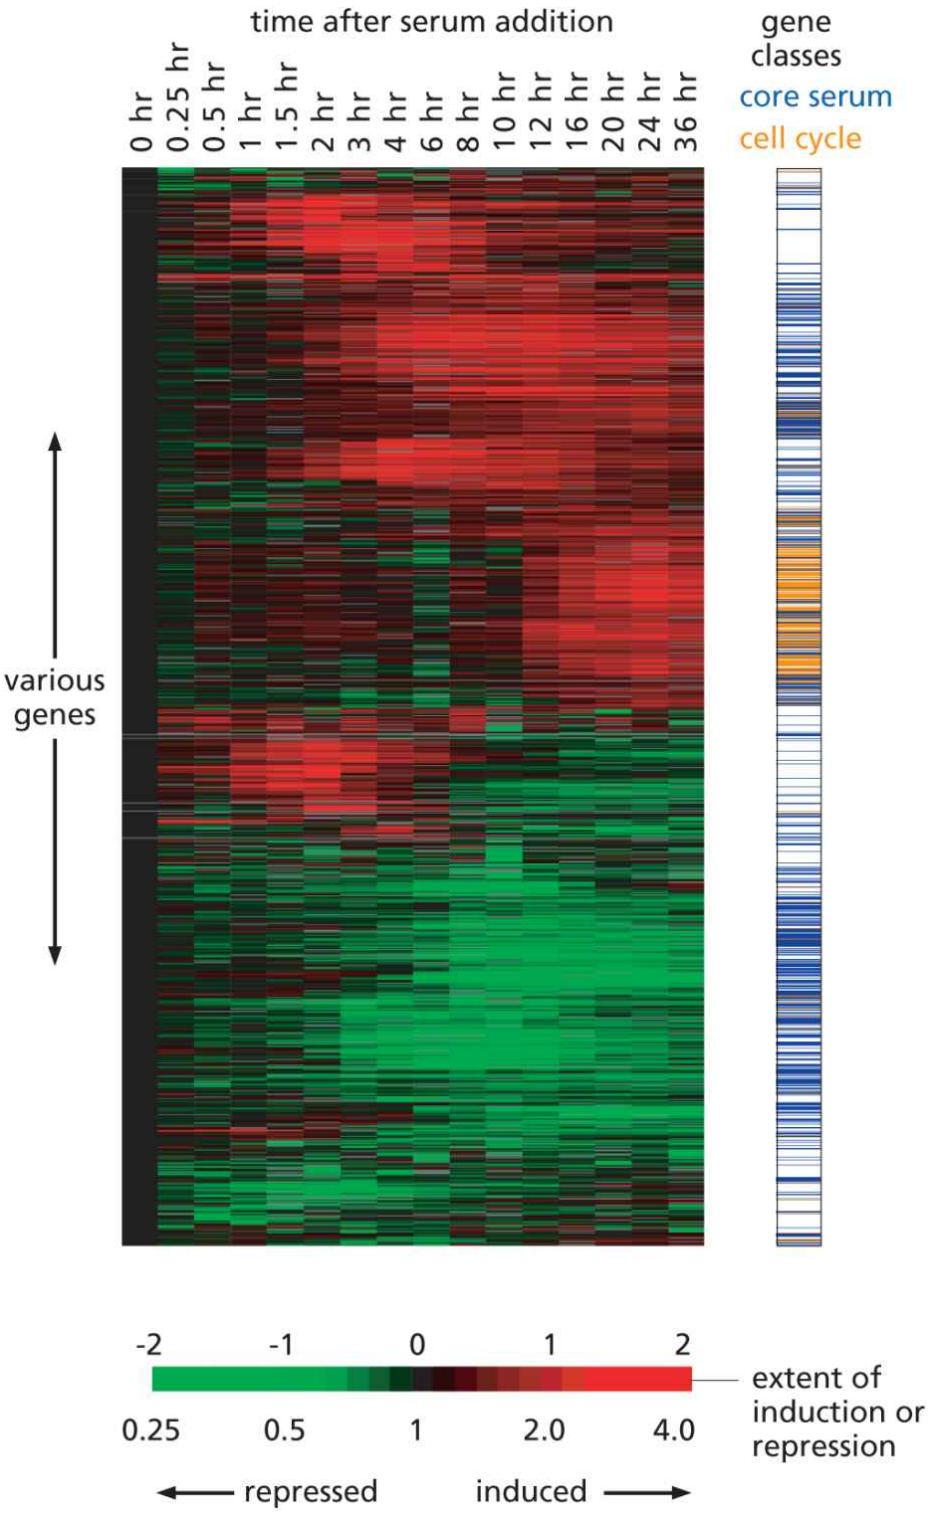
It remains unresolved precisely where most stromal fibroblasts and myofibroblasts originate. During wound healing, fibroblasts may initially be recruited from the stroma of adjacent unaffected tissues by the PDGF released by platelets participating in clot formation; myofibroblasts may then be produced through the TGF-β1–induced transdifferentiation of some of these recruited fibroblasts (see Figure 13.16). In fact, myofibroblasts can be produced *in vitro* simply by exposing normal fibroblasts to TGF-β1. This finding suggests that the TGF-β1 released by many types of carcinoma cells, especially those that have activated EMT programs, is a major factor responsible for the formation of myofibroblasts in the tumor-associated stroma.

Alternative sources of tumor-associated fibroblasts and fibroblasts have also been documented: they may arise from fibrocytes and mesenchymal stem cells (MSCs) of

bone marrow origin. Both types of cells can be found in the circulation and are known to home to areas of tissue damage, where they can differentiate into myofibroblasts and, quite possibly, fibroblasts, thereby facilitating the rapid reconstruction of stroma. Such mechanisms ensure that large numbers of cells can be mobilized rapidly from sources outside a wound site in order to expedite reconstruction of damaged stroma.

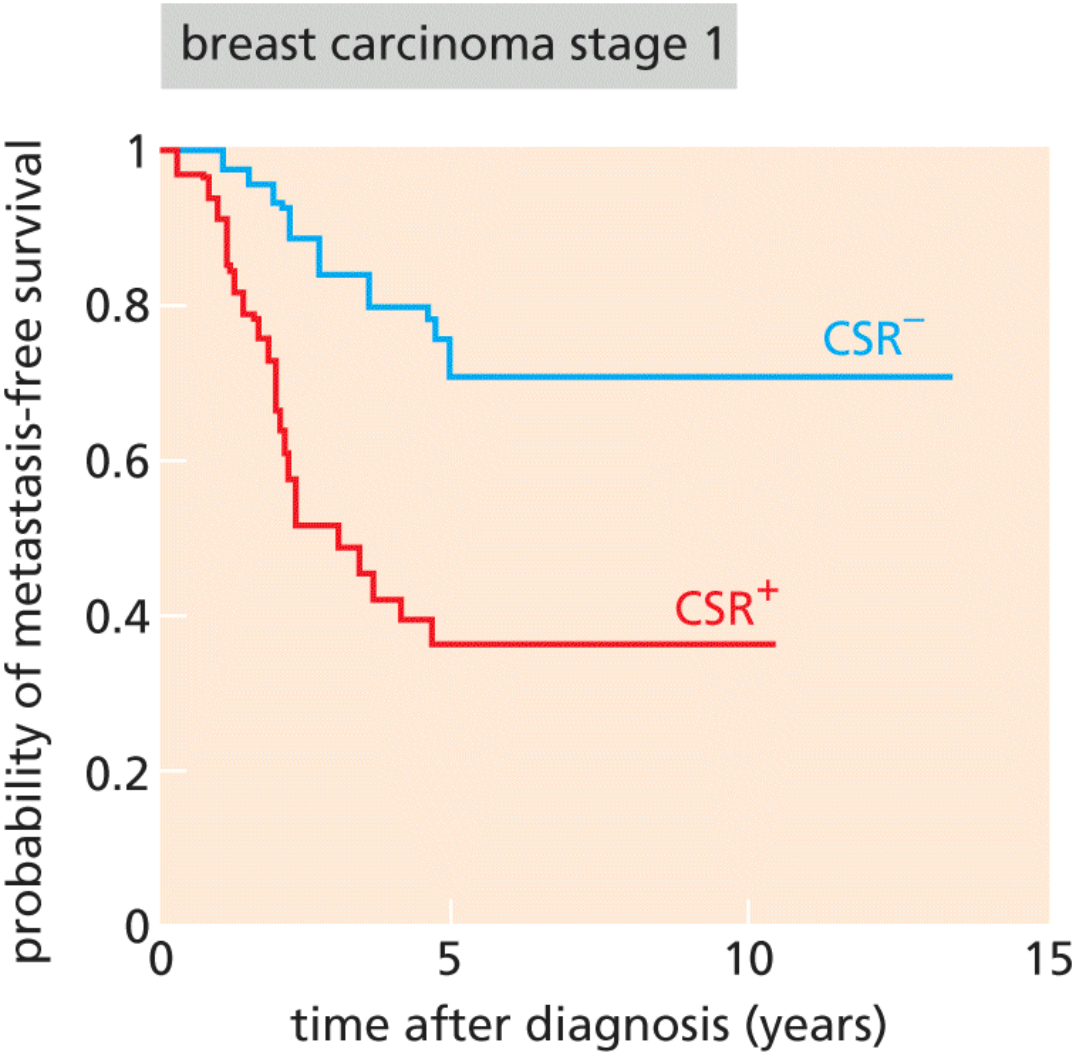
Yet another hint of parallels between wound healing and tumorigenesis comes from several studies indicating that agents known to inhibit tumor-associated angiogenesis also antagonize wound healing. Included among these agents are certain soluble inhibitors of the growth factor receptors that play key roles in angiogenesis, as well as an ECM component, termed thrombospondin-1 (Tsp-1), which is a potent anti-angiogenic molecule. The many common mechanisms shared by wound healing and by the epithelial–stromal interactions in tumors also have implications for clinical practice (see Sidebar 13.4).

The importance of various classes of fibroblasts in clinical progression has been illuminated by studies of serum-stimulated fibroblasts propagated *in vitro*, that is, fibroblasts that had been starved of serum and then exposed to high concentrations of fresh serum. This exposure re-creates the environment of fibroblasts during the initial stages of wound healing (a time when the various serum factors released by activated platelets act on stromal fibroblasts at the wound site, converting them, at least transiently, into myofibroblasts). A relatively small cohort of serum-induced and -repressed genes was extracted from these data and used to represent the characteristic “signature” of serum-stimulated fibroblasts (**Figure 13.20A**).



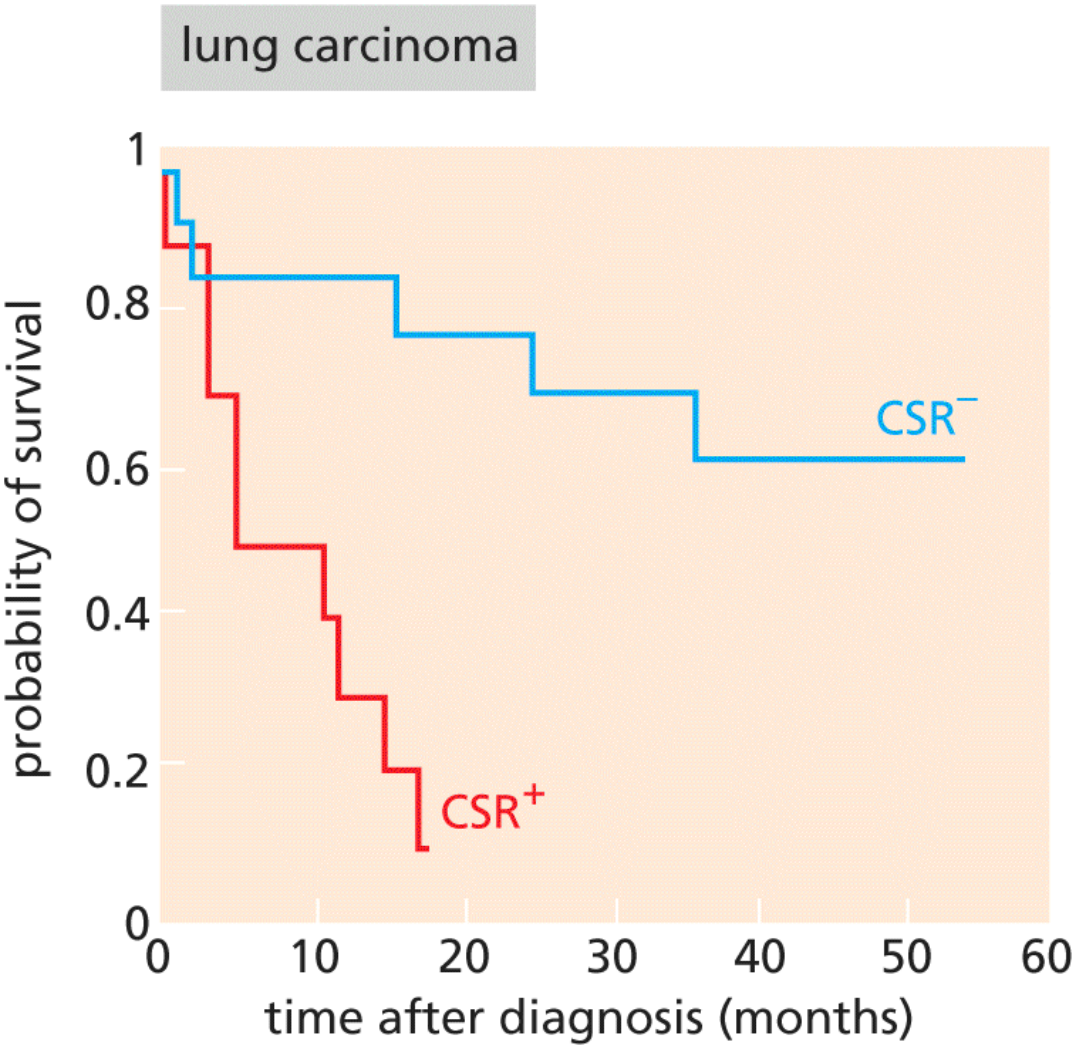
The results of a gene expression analysis with unnamed genes on the vertical axis and time after serum addition on the horizontal axis. Color coding indicates that the genes in the bottom half of the graphic are repressed over the full 36 hour period of observation. Genes in the top half of the graphic are

generally induced. A secondary graphic that identifies gene type shows that genes in the cell cycle class are induced starting at about 12 hours, while genes in the core serum class, or in neither class, are induced earlier, starting anywhere from 1 to 6 hours after serum addition.
(A)



A line graph titled breast carcinoma stage 1, with time on the horizontal axis and probability of metastasis-free survival on the vertical axis. The line for C S R negative declines from 100 percent at time 0 to 70 percent at 5 years, and is flat thereafter. The line for C S R positive declines from 100 percent at time 0 to about 35 percent at 5 years and is flat thereafter.

(B)



A line graph titled lung carcinoma, with time on the horizontal axis and probability of survival on the vertical axis. The line for C S R negative declines gradually from 100 percent at time 0 and is at 60 percent after 50 months. The line for C S R positive declines steeply from 100 percent at time 0 and is at 10 percent after less than 20 months.

(C)

Figure 13.20 Gene expression arrays of tumor-associated fibroblasts and serum-activated fibroblasts (A) In this gene expression analysis, the expression of cellular mRNAs was analyzed following the addition of fresh serum to previously quiescent, serum-starved human fibroblasts; this resulted in these cells' entering into the active cell cycle and the induction or repression of the expression of a large cohort of genes (see also Figure 8.9). Gene expression was measured at various times (*above*) after addition of serum. The cohort of genes analyzed (*not*

named) is arrayed vertically from *top to bottom*. Genes that were induced or repressed late after the addition of serum were classified as “cell cycle genes” (*orange lines*, *right vertical bar*), whereas genes that were induced or repressed early and did not fluctuate with the cell cycle phase were classified as “core serum response” (CSR) genes (*blue lines*, *right vertical bar*). The horizontal bar (*below*) is a key indicating the degree of induction (*red*) or repression (*green*) following serum addition, this being indicated logarithmically above the bar and in absolute numbers (limited to a 4-fold difference) below the bar. (B) The expression pattern of the CSR genes was analyzed in a series of tumors in women presenting with stage 1 (i.e., early-stage) breast cancer. As indicated here, those whose tumors expressed the CSR gene pattern (*red line*), which presumably reflected the states of stromal fibroblasts and related cell types within these tumors, showed a much greater probability for developing metastases in the years following initial treatment compared with those whose tumors did not show this gene expression pattern (*blue*). (C) Similarly, those patients whose lung adenocarcinomas (including all stages of tumor progression at the time of diagnosis) showed the CSR gene expression signature (*red line*) suffered dramatically higher mortality rates compared with those whose tumors did not show this gene expression signature (*blue line*). (From H.Y. Chang et al., *PLoS Biol.* 2:E7, 2004. © 2004 Chang et al. This is an open-access article distributed under the terms of the Creative Commons Attribution License.)

The RNA expression patterns of a large group of human carcinomas were then analyzed to determine whether the tumors expressed the signature of serum-stimulated fibroblasts. (Because all the genes being analyzed are associated specifically with fibroblasts, these analyses, by necessity, reflected the RNA expression patterns of the CAFs present in each tumor.) Many carcinomas were indeed found to express the signature of serum-stimulated fibroblasts. Significantly, the carcinomas that expressed this signature more intensely were associated with a grimmer clinical prognosis (see Figure 13.18B and C). Similarly, tumors that contain higher proportions of myofibroblasts indicate shorter survival rates of the patients bearing these tumors (**Supplementary Sidebar 13.5**). This correlation suggests that the activated, myofibroblast-rich stroma represents a potent force driving aggressive tumor progression, that is, invasion and metastasis as discussed in the next chapter.

OceanofPDF.com

Glossary

vasoactive
: Referring to a regulator of vascular function, such as a regulator of vascular permeability or constriction.

myofibroblast
: A type of fibroblast that is normally involved in wound healing and inflammation and is often defined by its expression of α-smooth muscle actin which, together with myosin, imparts to it contractile powers.

matrix metalloproteinases
: Secreted proteases that employ zinc ions in their catalytic sites and degrade extracellular proteins, largely components of the extracellular matrix.

pro-enzyme
: Catalytically inactive precursor form of an enzyme that requires some type of alteration (often proteolytic cleavage) in order to become catalytically active.

monocyte
: Phagocytic leukocyte of bone marrow origin that circulates briefly in the blood before migrating into tissues, where it can differentiate into macrophages, osteoclasts, dendritic cells, Langerhans cells, and possibly other phagocytic cell types.

neutrophil
: An abundant granulocyte in the circulation that expresses Fc receptors and is responsible for multiple functions, including recognizing and engulfing various types of infectious agents and participating in various types of inflammation.

mast cell
: Granulocyte of bone marrow origin that displays Fc receptors for binding IgE antibody molecules and undergoes IgE-mediated degranulation following encounter with antigens bound by the associated IgE molecules.

lymphocytes
: Class of leukocytes that mediate humoral or cellular immunity, encompassing B cells, T cells, and NK cells and derivatives thereof.

adherens junction
: Lateral cell–cell junction between adjacent cells, notably epithelial cells, that is formed by cadherins displayed on the opposing surfaces of participating pairs of cells; these junctions include the cytoplasmic proteins that are physically associated with the cytoplasmic domains of both participating cadherins and serve to link these junctions, in turn, to the actin cytoskeletons of the two cells.

apposed
: Physical entity located directly adjacent to a second one.

epithelial–mesenchymal transition
: Cell-biological program enabling acquisition by epithelial cells of some of the phenotypes of mesenchymal cells such as fibroblasts. *Compare* **mesenchymal–epithelial transition**.

quasi-mesenchymal
: Referring to a phenotypic state between the fully epithelial and the fully mesenchymal states and involving the expression of a mixture of genes characteristic of both states.

mesenchymal–epithelial transition
: The reversal of the epithelial–mesenchymal transition program that converts phenotypically more-mesenchymal cells into more-epithelial derivatives. *Compare* **epithelial–mesenchymal transition**.

venule
: A small vein that conducts blood from capillaries to larger veins.

desmoplastic
: Referring to a hard extracellular matrix that is rich in collagen and myofibroblasts.

fibrocyte
: A relatively undifferentiated circulating cell derived from monocytes in the bone marrow that expresses collagen, adheres tightly to substrates when cultured *in vitro*, exhibits certain features usually associated with macrophages, and serves as the precursor of fibroblasts and/or myofibroblasts in tissues to which it has been recruited.

mesenchymal stem cell
: An oligopotent mesenchymal cell, often of bone marrow origin, that can be recruited to various tissues in which it can differentiate into chondrocytes, osteoblasts, adipocytes, and possibly other mesenchymal cell types.

macrometastasis

A metastatic tumor of a size that allows it to be detected by a variety of clinically used imaging procedures and thus does not require microscopy for its detection. *See also* **micrometastasis**.

eosinophil, eosinophile

A motile phagocytic granulocyte that can migrate from blood into tissue spaces, displays cell surface IgE receptors, and plays a role, among other functions, in eliminating parasitic and bacterial infectious organisms.

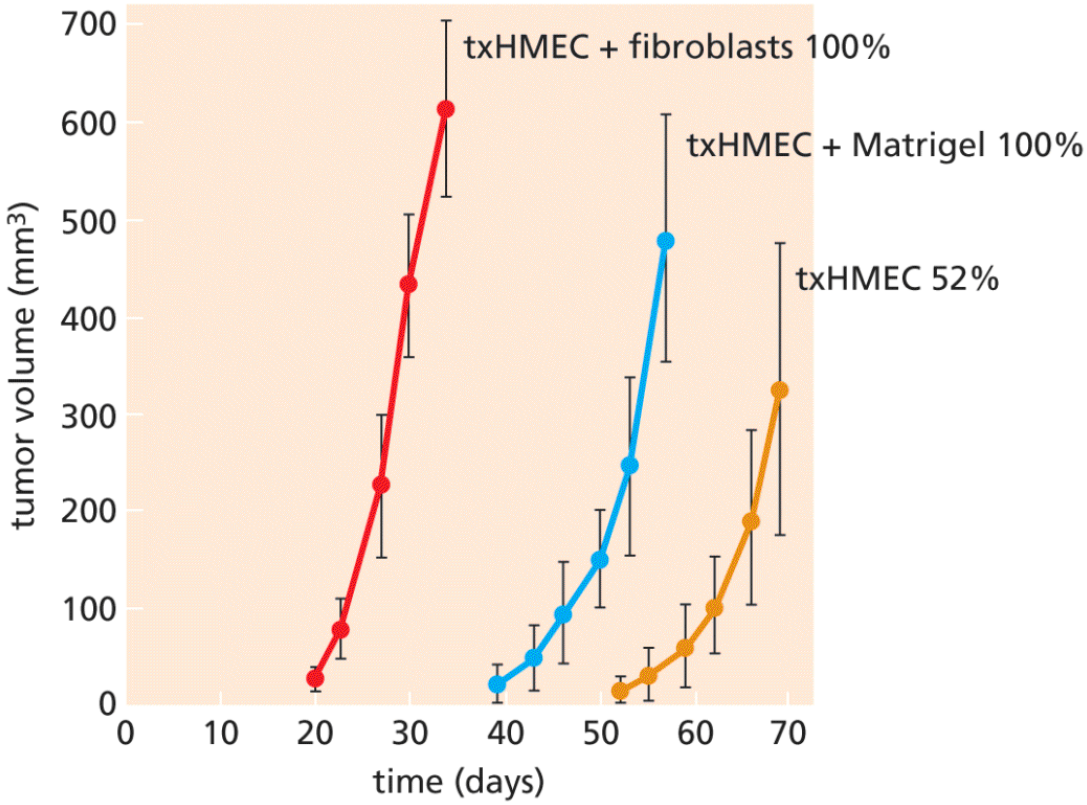
13.4 Experiments directly demonstrate that stromal cells are active contributors to tumorigenesis

Several biological experiments provide far more direct demonstrations of the profound influence that recruited stromal cells exert on epithelial cell tumorigenesis. In one study, previously non-tumorigenic, immortalized keratinocytes were forced to secrete PDGF at high levels (achieved through the introduction of a PDGF expression vector). The released growth factor had no effect on the proliferation of these epithelial cells *in vitro* because they do not display PDGF receptors on their surface. However, when these cells were implanted into host mice, they acquired the ability to form robustly growing tumors, clearly derived from the ability of the released PDGF to recruit and activate stromal cells. The stromal cells then reciprocated by driving the proliferation of the PDGF-secreting keratinocytes, eventually causing the latter to undergo malignant transformation.

The important role of stromal fibroblasts in supporting tumor growth can be demonstrated by yet another type of experiment: transformed, weakly tumorigenic human mammary epithelial cells (MECs) were found to require more than two months to form a tumor after being introduced into immunocompromised host mice (**Figure 13.21**). However, if these cancer cells were mixed with human mammary stromal fibroblasts (from normal breast tissue) prior to injection into hosts, the cells formed tumors in one-third the time. These admixed fibroblasts clearly obviated the need of the MECs to spend time recruiting fibroblasts from host mice—a process that usually requires many weeks’ time; in the absence of these fibroblasts, tumor growth could not take off.

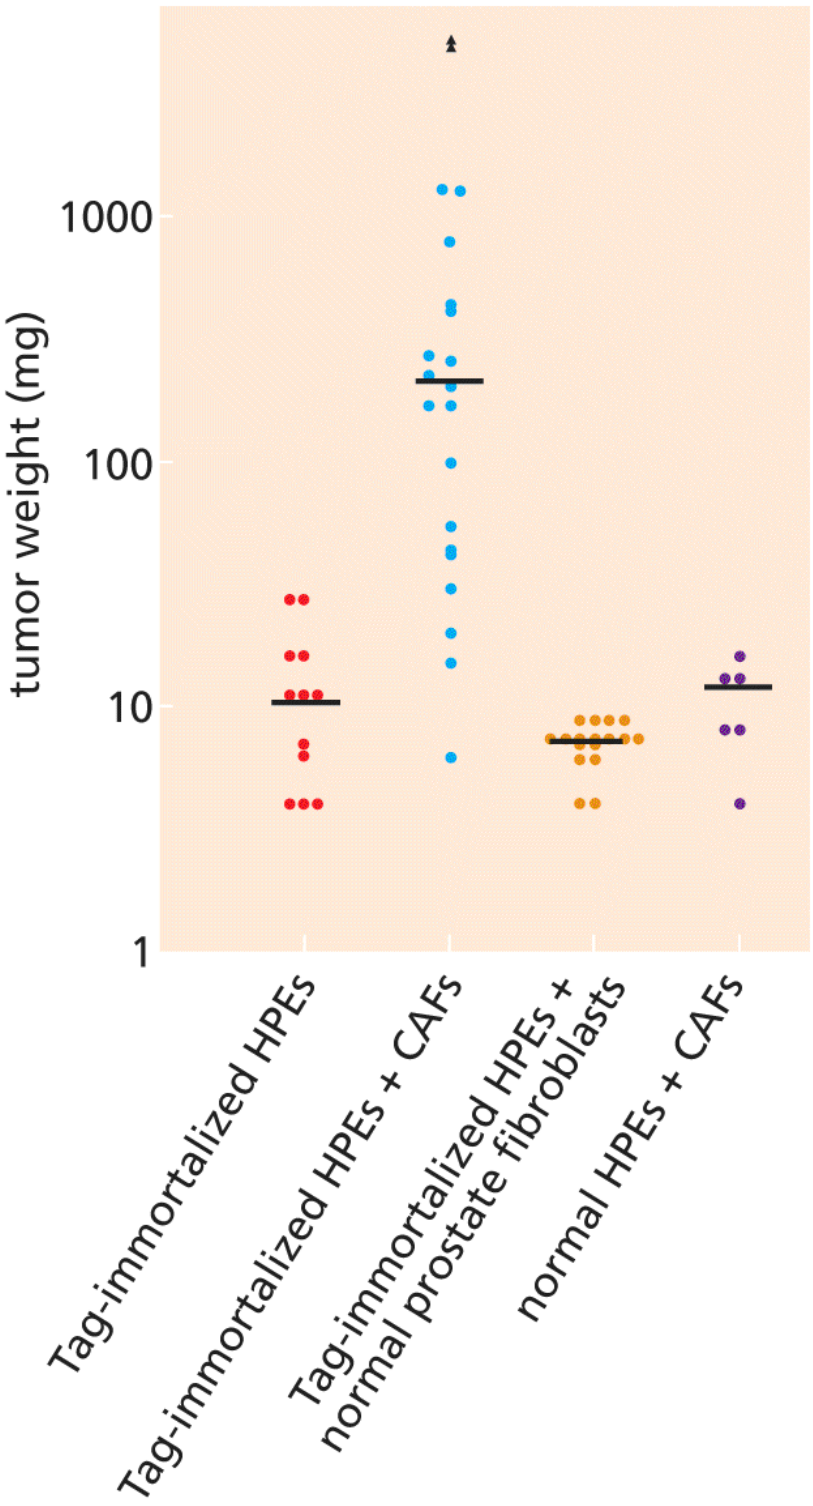


Experimental results, displayed as a line graph with tumor volume on the vertical axis and time on the horizontal axis. There are three curves. The curve for t x H M E C plus fibroblasts 100% begins at 20 days, 10 cubic millimeters and rises to 34 days, 610 cubic millimeters. The curve for t x H M E C plus Matrigel 100% begins at 39 days, 8 cubic millimeters and rises to 58 days, 480 cubic millimeters. The curve for t x H M E C 52% begins at 52 days, 6 cubic millimeters and rises to 70 days, 320 cubic millimeters.

Figure 13.21 Admixed fibroblasts and tumor growth When human mammary epithelial cells (HMECs) were transformed through the introduction of the SV40 early region, the *hTERT* gene, and a weakly expressed *ras* oncogene (see Section 11.9), the resulting transformed HMECs (txHMECs) formed tumors, albeit with a long lag time after injection, and then only in about half of the mice into which they had been injected (*orange curve*). When a preparation of extracellular matrix (Matrigel) produced by mouse sarcoma cells was mixed with the txHMECs prior to introduction into host mice (*blue curve*), this slow development was accelerated a bit and tumor-forming efficiency was doubled. However, when mammary stromal fibroblasts from a normal human breast were admixed to the transformed human MECs prior to injection, the cancer cells formed tumors rapidly and with 100% efficiency (*red curve*). This experiment illustrated that the recruitment of stromal fibroblasts (or similarly functioning mesenchymal cells) is an important

rate-limiting step in tumor formation. (From B. Elenbaas et al., *Genes Dev.* 15:50–65, 2001. With permission from Cold Spring Harbor Laboratory Press.)

This experiment did not address the issue of whether the stromal cells of normal epithelial tissues can accelerate tumor formation as effectively as the stromal cells of carcinomas. This possibility was addressed by comparing the actions of stromal fibroblasts extracted from a normal epithelial tissue with the carcinoma-associated fibroblasts (CAFs) prepared from carcinomas (in which myofibroblasts are abundant; for example, see Figure 13.18). In one set of experiments, fibroblasts were purified from the stroma of normal human prostate glands, and the CAFs were prepared from the stroma of human prostate carcinomas. Each cell population was then mixed with otherwise non-tumorigenic, SV40 large T antigen–immortalized human prostate epithelial cells and implanted in immunocompromised Nude mice. The results, summarized in **Figure 13.22**, showed dramatic differences in the growth of these mixed tissue grafts. In particular, the grafts containing CAFs plus immortalized prostate epithelial cells formed tumors that were as much as 500 times larger than those containing normal prostate fibroblasts plus immortalized prostate epithelial cells. (When injected alone, the CAFs formed no tumors at all.)

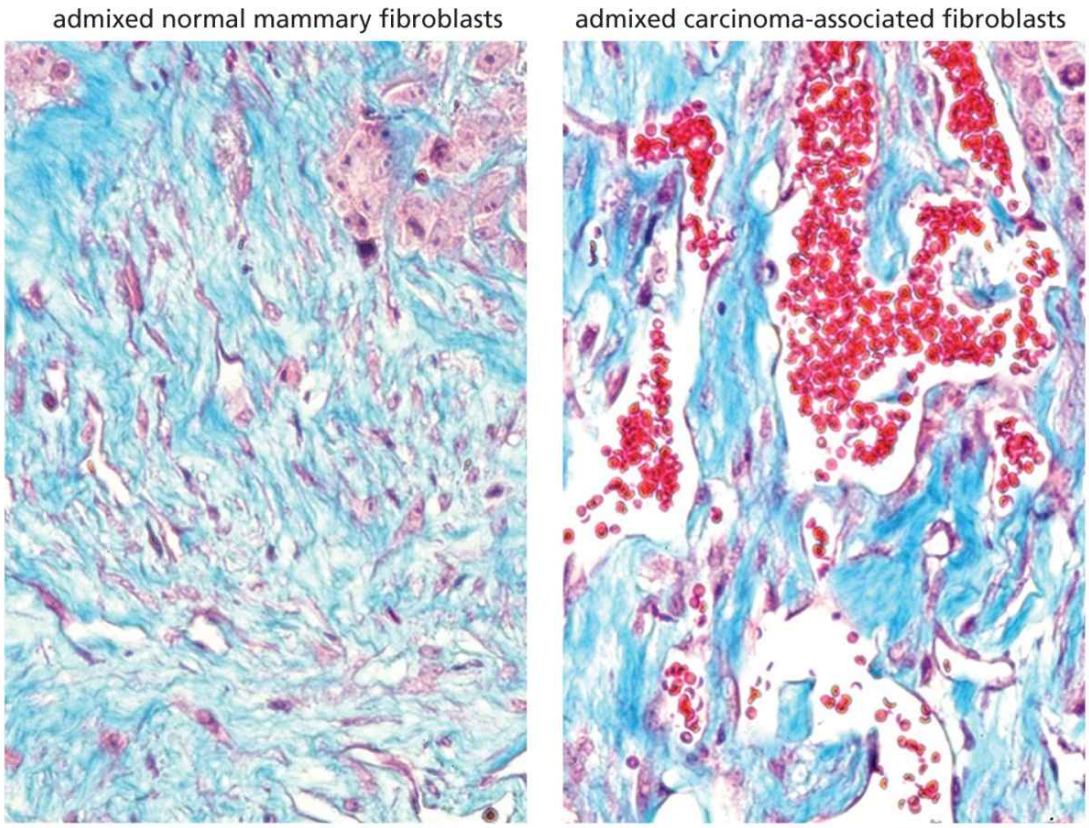


Data plot of tumor weights for four different cell types. For each type, there is a spread of weights. For Tag-immortalized H P E ease, Tag-immortalized H P ease plus normal prostate fibroblasts, and normal H P E ease plus C A effs, tumor weights range from 5 milligrams to 30, with 10 milligrams as a rough average. For

Tag-immortalized H P E ease plus C A effs, tumor weights range from 8 milligrams to over 1000, with 200 milligrams as a rough average.
Figure 13.22 Effects of prostatic stromal cells on immortalized prostatic epithelial cells When normal human prostate epithelial cells (HPEs) that had been immortalized by SV40 T antigen (Tag-immortalized HPEs) were introduced into Nude mice, they formed growths of ~10 mg after many weeks, not significantly larger than the initial inoculum (*red dots*), indicating that these cells were, when implanted on their own, non-tumorigenic. However, if these same cells were mixed with carcinoma-associated fibroblasts (CAFs) prepared from a human prostate carcinoma, tumors arose whose median weight was 10 times larger (Tag-immortalized HPEs + CAFs, *blue dots*). In contrast, when these Tag-immortalized HPEs were mixed with stromal fibroblasts from a normal human prostate, the median weight of the resulting growth was ~7 mg, possibly even less than the starting inoculum (*orange dots*). And if CAFs were mixed with normal HPEs prior to inoculation, the median weight after many weeks was, once again, only ~10 mg (*purple dots*). (From A.F. Olumi et al., *Cancer Res.* 59:5002–5011, 1999. With permission from American Association for Cancer Research.)

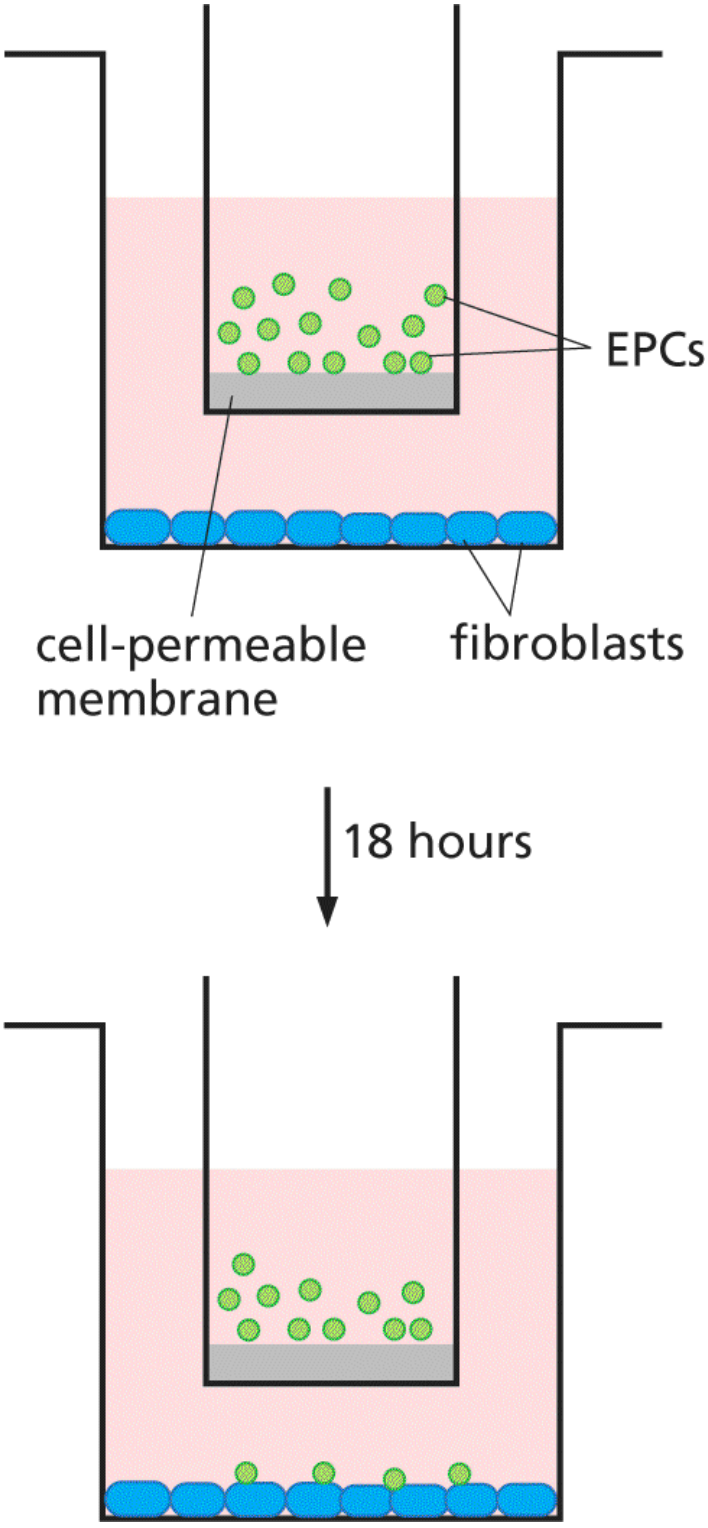
This experiment demonstrated that these CAFs were functionally very different from the stromal fibroblasts present in normal prostatic tissue. Stated differently, during the course of tumor progression, stromal cells become increasingly adept at helping their epithelial neighbors to survive and proliferate. Similar observations have since been made with CAFs extracted from human breast cancers.

Still, these experiments do not reveal precisely *how* the myofibroblast-rich CAF populations accelerate tumor growth. Once established within the tumor-associated stroma, the myofibroblasts, as mentioned earlier, confer multiple benefits on nearby epithelial cancer cells, the most important benefit possibly being angiogenesis. Myofibroblasts expedite angiogenesis through their ability to release stroma-derived factor-1 (SDF-1/CXCL12), a chemokine that recruits circulating endothelial progenitor cells (EPCs) and other myeloid cell types into the tumor stroma (**Figure 13.23**). The VEGF secreted by myofibroblasts then helps to induce some of these recruits to differentiate into the endothelial cells that form the tumor neovasculature (see Figure 13.8A). Because angiogenesis is usually a rate-limiting step in tumor formation, the tumor-stimulating effects of admixed CAFs may result largely from their ability to accelerate tumor angiogenesis. The neovascularization of a tumor can often be solved through unconventional means, as described in **Sidebar 13.5**.



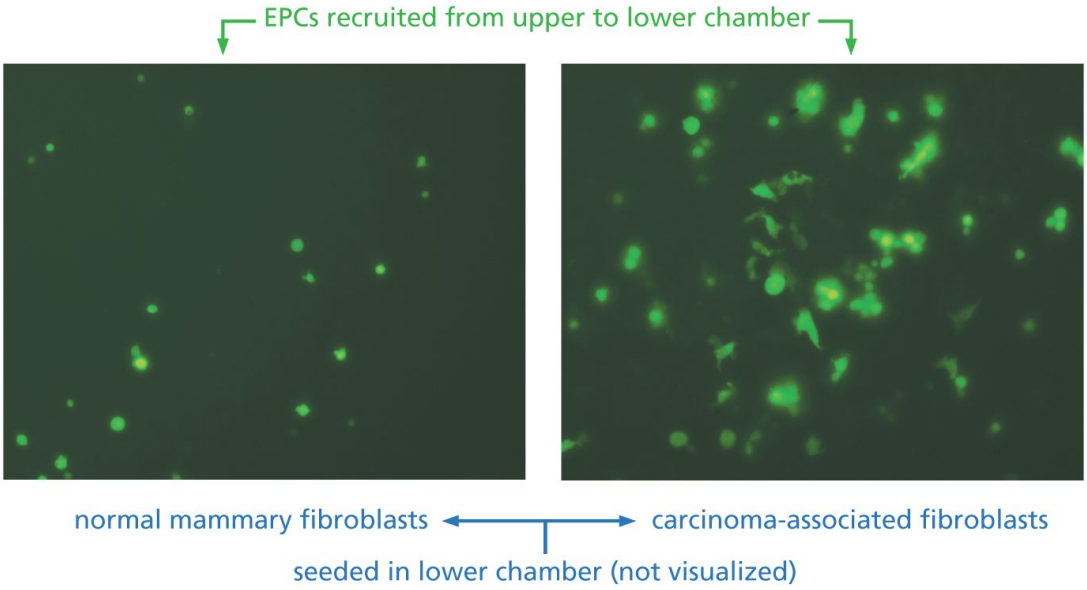
Two histology images. The left one, labeled admixed normal mammary fibroblasts, contains a mix of pink and blue cells. The right one, labeled admixed carcinoma-associated fibroblasts, looks similar but has voids occupied by clumps of round red cells.

(A)



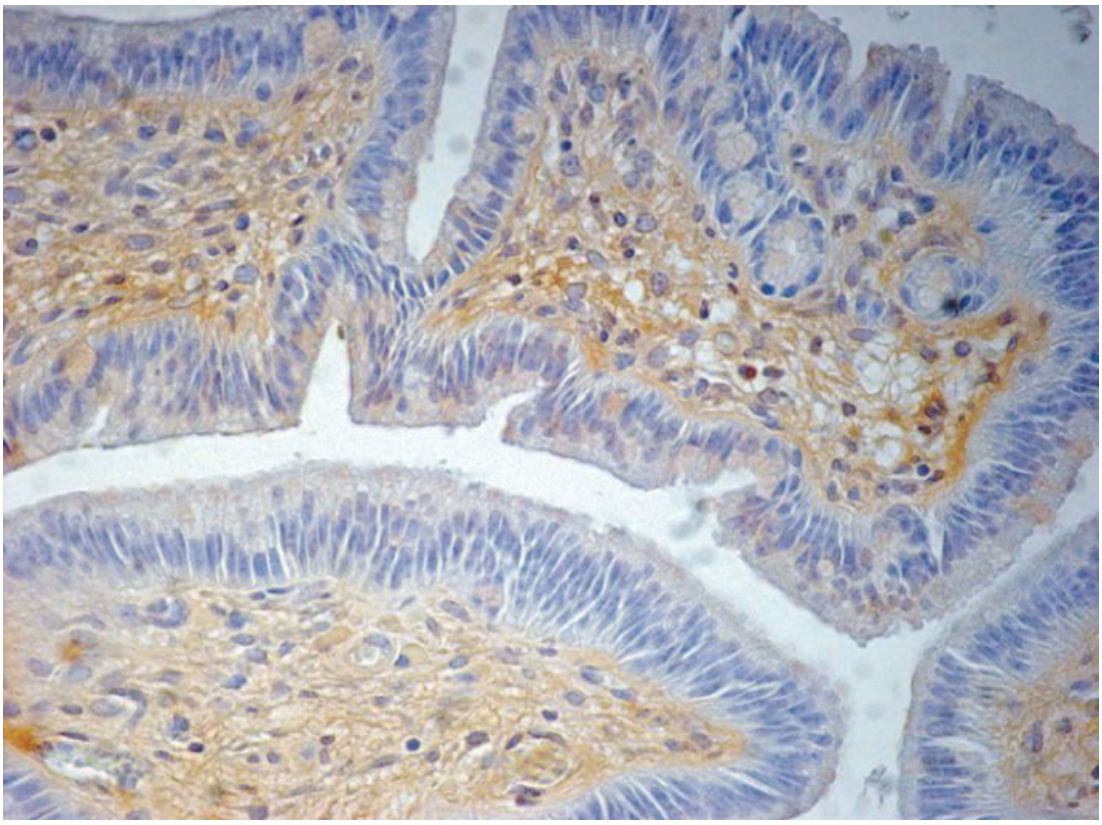
A diagram of an experiment. It begins with a chamber that has a layer of fibroblasts on the bottom and is filled with liquid. A second, smaller chamber, containing E P Sees, is lowered into the first one so that its bottom is submerged. This bottom is a cell-permeable membrane. After 18 hours, some

of the E P Sees have made their way out of the smaller chamber and lie among the fibroblasts at the bottom of the larger one.
(B)



Two images. The left one shows normal mammary fibroblasts as small, bright green dots. The right one shows carcinoma-associated fibroblasts as larger, more irregular bright green splotches. Both cell types are E P Sees recruited from the upper to the lower chamber and seeded in the lower chamber.

(C)



A histology image of gastric tumor tissue from a mouse. The purple epithelial cells surround tan stroma cells.

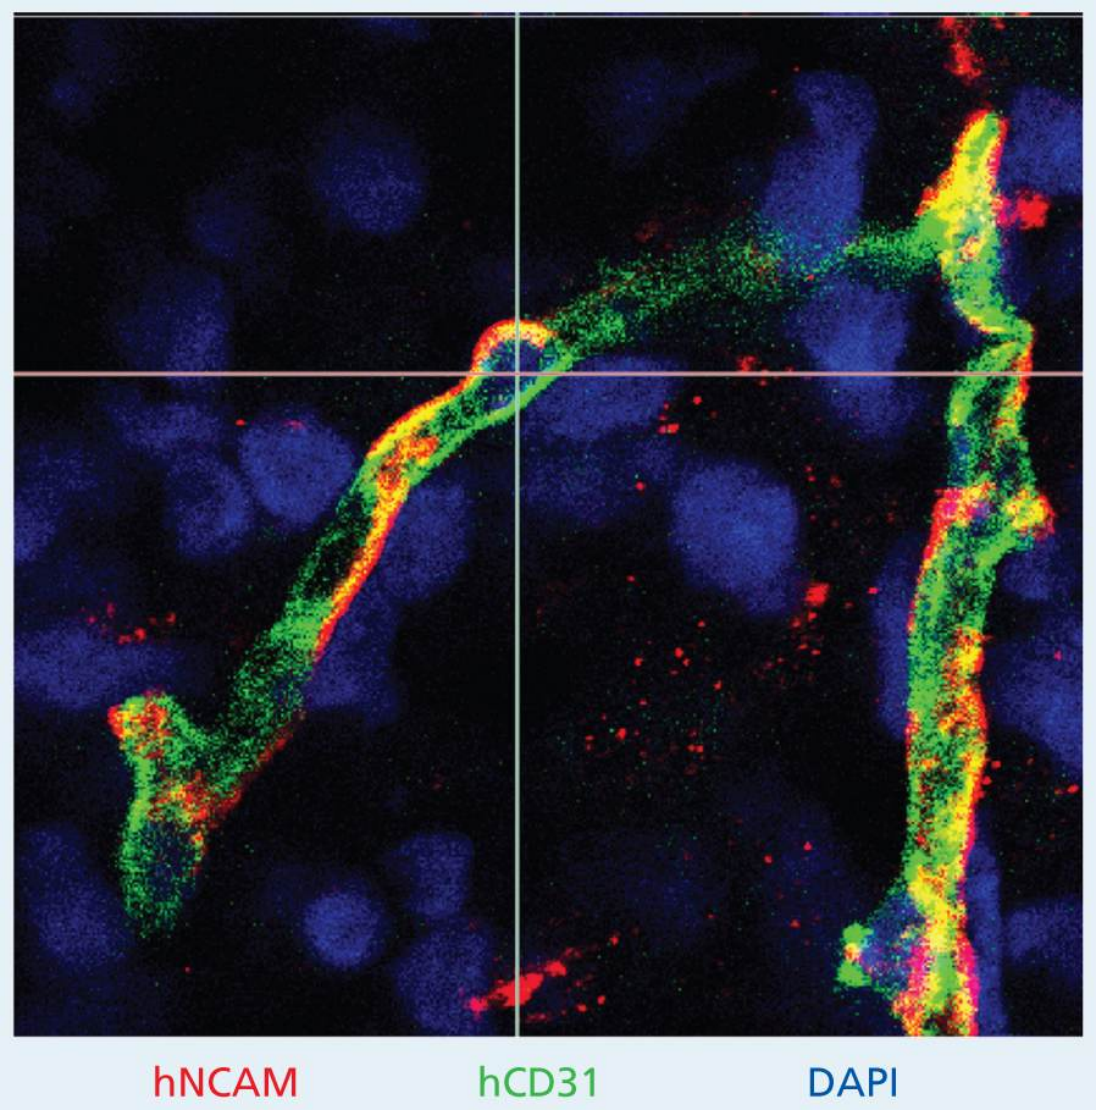
(D)

Figure 13.23 Recruitment of endothelial precursor cells and induction of their differentiation by CAFs (A) When normal human mammary stromal fibroblasts are admixed to cells of the human MCF7-ras breast cancer cell line (*left panel*), the resulting tumors show relatively small numbers of blood vessels (*pink-red*) amid the tumor-associated stroma (*blue*). However, admixture of carcinoma-associated fibroblasts (CAFs; *right panel*) results in highly vascularized tumors with large vessels and associated erythrocytes (*red*). The resulting access to the circulation is likely to greatly facilitate tumor growth. (B) The ability of the CAFs, which are largely myofibroblasts, to attract endothelial cells was demonstrated by an *in vitro* experiment, in which green fluorescent protein (GFP)–labeled bone marrow cells expressing surface antigens characteristic of endothelial progenitor cells (EPCs; *green*) were placed above a cell-permeable membrane (*light gray*) in a Boyden chamber. Either normal mammary stromal fibroblasts or CAFs from a breast cancer (*blue*) were placed on the bottom surface of the lower chamber. After 18 hours, the number of EPCs that had migrated through the filter and had been recruited to the bottom of the lower chamber was gauged by fluorescence

microscopy. (C) Analysis of the cells attached to the lower chamber indicated that the CAFs (*right panel*) are able to attract far more GFP-labeled EPCs than the normal mammary stromal fibroblasts (*left panel*). This recruitment could be reduced by 60% by placing antiserum that neutralized the SDF-1/CXCL12 chemokine released by the CAFs in these chambers, indicating its important role in mediating this recruitment. (D) In a mouse model of gastric carcinoma development, the myofibroblasts of the tumor-associated stroma are seen, by immunostaining, to express high levels of VEGF-A (*brown*), which induces differentiation of EPCs and the proliferation of resulting endothelial cells. (A and C, from A. Orimo et al., *Cell* 121:335–348, 2005. With permission from Elsevier. D, from X. Guo et al., *J. Biol. Chem.* 283:19864–19871, 2008. © 2008 ASBMB. This is an open access article distributed under the terms of the Creative Commons Attribution license.)

Sidebar 13.5 Alternative sources of tumor vascularization

The endothelial cells present in the tumor neovasculature have been widely assumed to derive from two sources—the proliferation of existing endothelial cells, including those present in adjacent normal tissue and, to a smaller extent, from the endothelial progenitor cells (EPCs) that originate in the marrow and arrive via the circulation into the tumor stroma. In 2010, two groups simultaneously reported a fully unexpected finding: within human glioblastomas (and the xenografts derived from these tumors), a significant portion of the endothelial cells in the tumor-associated neovasculature descend from the genetically mutant tumor cells, more specifically arising via the differentiation of glioblastoma stem cells (see Section 11.7) that are present in these tumors (**Figure 13.24**). Indeed, the glioblastoma CSCs are known to exhibit an ability to spawn a diverse array of more differentiated progeny, which is reflected in their proper name—glioblastoma multiforme (see Figure 2.8A). This finding was most unanticipated, because glioblastomas derive from the embryonic neuroectoderm, whereas the endothelial cells arise ultimately from the mesoderm and thus are members of cell lineages very distant from those forming the bulk of the brain.



A fluorescence microscopy image. Two bright streaks, with green, red and yellow in them, intersect. Dark blue cell nuclei are visible behind them.

Figure 13.24 Transdifferentiation of glioblastoma stem cells into tumor-associated endothelial cells The characterization of the endothelial cells formed in the neovasculature of human glioblastomas (GBMs), including those that are grown as xenografts in immunocompromised host mice, has revealed that many of these cells, while expressing a human endothelial cell–specific marker (CD31, *green*), can also be stained with antibodies that are specifically reactive with human NCAM antigen (*red*), which indicates cells of neuroectodermal origin. Overlapping staining between these two colors is seen here as *yellow.* Moreover, these apparent endothelial cells can be shown to carry the same genomic alterations as are present in the bulk of the neoplastic cells in these GBMs and to derive from the differentiation of glioblastoma stem cells. Cell nuclei are stained

blue. (From R. Wang et al., *Nature* 468:829–833, 2010. With permission from Nature.)

In fact, there is a second alternative source of tumor-associated microvasculature that had been recognized years earlier and has been termed vasculogenic mimicry. Thus, collections of neoplastic cells can form microvessels through which blood passes. These channels have the superficial appearance of capillaries but clearly are not lined by endothelial cells as usually defined. They may, however, express at least one protein that is a critical component of the endothelial cell-associated, normal microvessels: vascular-endothelial–cadherin (VE-cadherin), a member of the family of adhesion proteins that includes the widely expressed E-cadherin that is so critical to knitting together epithelial cell sheets (see Figure 13.14). Similarly, VE-cadherin enables the side-by-side associations of the endothelial cells in fully formed vessels, thereby creating a continuous tight barrier between the blood and parenchyma outside of the vasculature.

Glossary

neovasculature
: Vasculature that is newly developed, often by a growing tumor. *See also* **vasculature**.

vasculogenic mimicry
: The process that enables the neoplastic cells within a tumor to assemble into blood-carrying microvessels without these cells becoming *bona fide* endothelial cells.

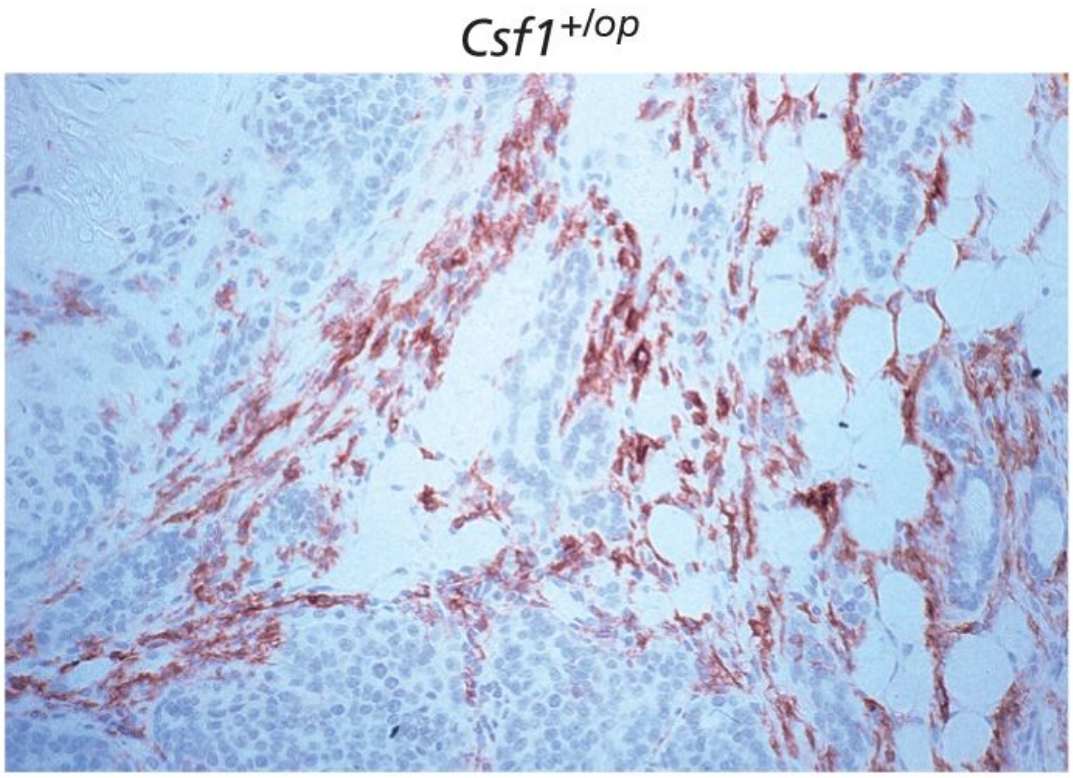
OceanofPDF.com

13.5 Macrophages and myeloid cells play important roles in activating the tumor-associated stroma

The active recruitment of macrophages into tumor masses would seem, at first glance, to be counterproductive for tumor formation, because macrophages are usually deployed by the immune system to scavenge and destroy infectious agents and abnormal cells, as we will explore in more detail in Chapter 15. However, increasing evidence indicates that these immune cells can also play important roles in *furthering* tumor development.

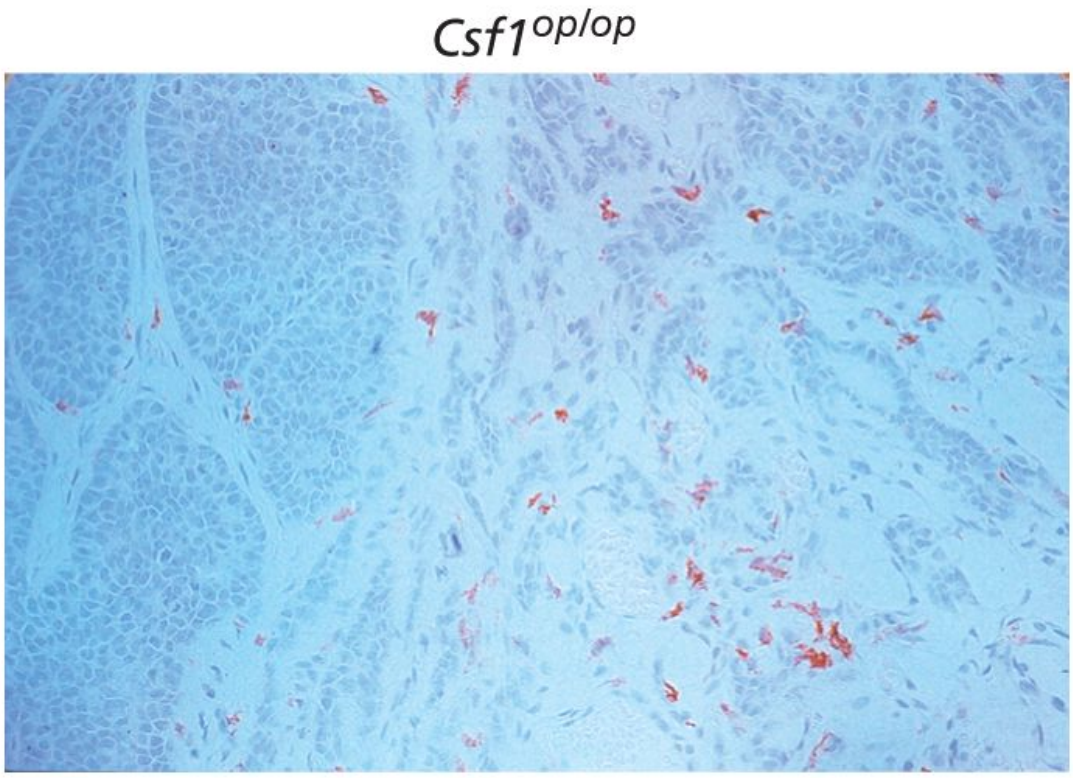
In more detail, monocytes from the myeloid lineage in the bone marrow enter into the general circulation, from which they are recruited by cancer cells into a tumor; once ensconced there, the monocytes are induced to differentiate into macrophages. This recruitment depends on attraction signals that are conveyed by chemotactic factors. By definition, these factors provide directional cues to motile cells rather than mitogenic stimulation. In the case of leukocytes (white blood cells such as monocytes), the relevant chemotactic factors are often called chemokines, that is, chemotactic cytokines.

The chemokine known as monocyte chemotactic protein-1 (sometimes called macrophage chemoattractant protein-1; MCP-1) is expressed in significant quantities by a wide range of neuroectodermal and epithelial cancer cell types. It appears to be a critical signal for attracting monocytes to some tumors and inducing their differentiation into macrophages. In other tumors, vascular endothelial growth factor (VEGF), colony-stimulating factor-1 (CSF-1; often called M-CSF, macrophage colony-stimulating factor), and the PDGF released by tumor cells also seem to help in this recruitment, while CSF-1 aids in stimulating the subsequent monocyte-to-macrophage differentiation (**Figure 13.25**).



A histology image of cells carrying one copy of the C S F-1 encoding gene and one null allele. The image is mostly blue, but there are areas streaked with red.

(A)



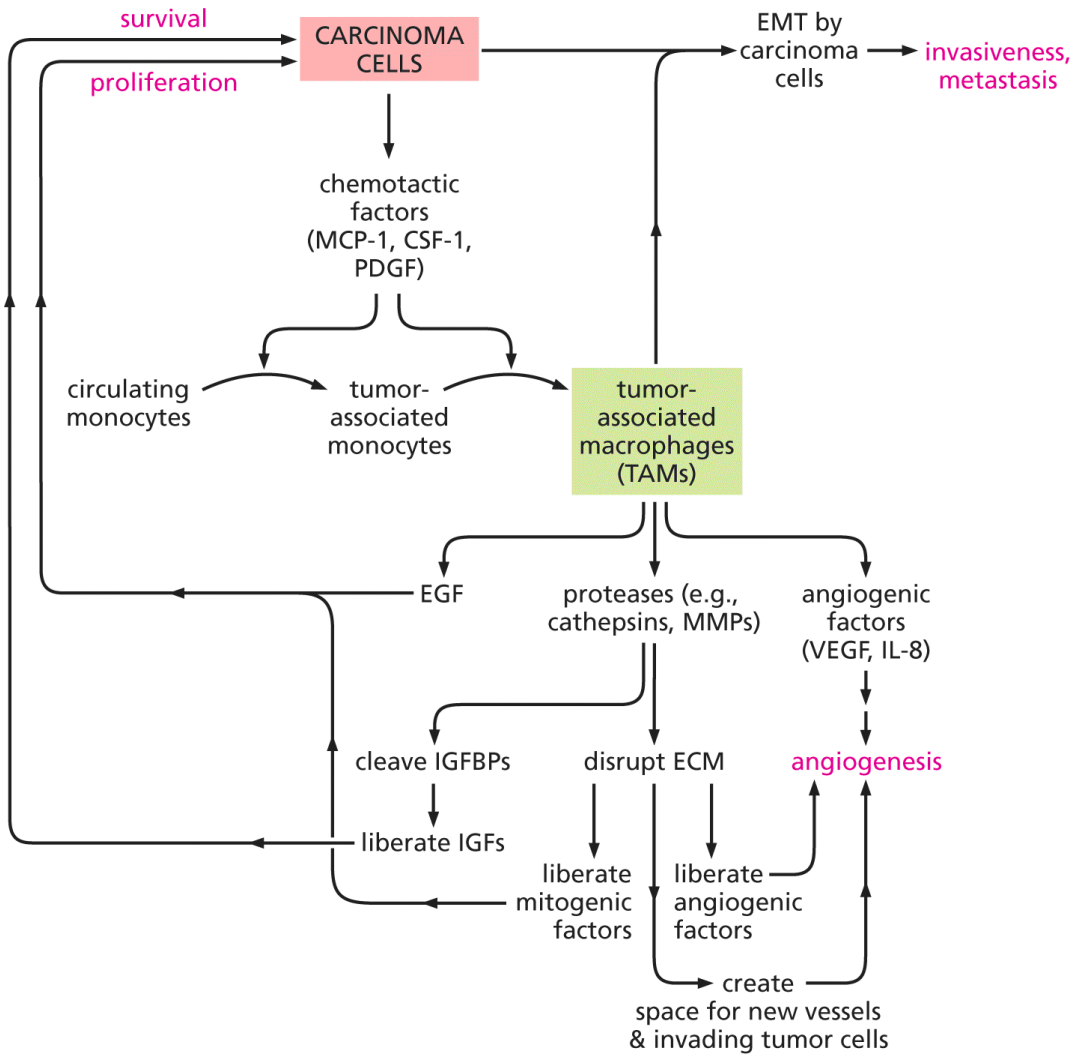
A histology image of cells carrying two null alleles. The image is blue, with hardly any red streaks–just a few flecks here and there.

(B)

Figure 13.25 Recruitment of macrophages by CSF-1 In some tumors, colony-stimulating factor-1 (CSF-1) released by tumor cells serves as the key attractant for monocytes and thus macrophages. In the transgenic mice studied here, mammary tumorigenesis was driven by a transgene, which was constructed from an MMTV (mouse mammary tumor virus) transcriptional promoter that drives expression of the polyoma middle T (PyMT) oncogene, doing so almost exclusively in mammary epithelial cells. (A) The tumor analyzed here arose in a transgenic MMTV-PyMT mouse that was heterozygous at the *Csf1* locus, because it carried one null allele of the CSF-1–encoding gene, and was therefore labeled $Csf1^{+/op}$. The presence of macrophages in the stroma of a tumor is revealed by a monoclonal antibody that detects macrophages (*reddish brown*). (B) This tumor arose in an MMTV-PyMT transgenic mouse that was genetically $Csf1^{op/op}$ and therefore lacked all CSF-1 activity. Consequently, the tumor cells arising in this mouse were unable to release this chemoattractant, resulting in a mammary tumor in which the macrophages are barely detectable. The absence of macrophages did not affect the growth of the primary tumor but strongly suppressed progression to an invasive and metastatic state, implicating macrophages in such tumor

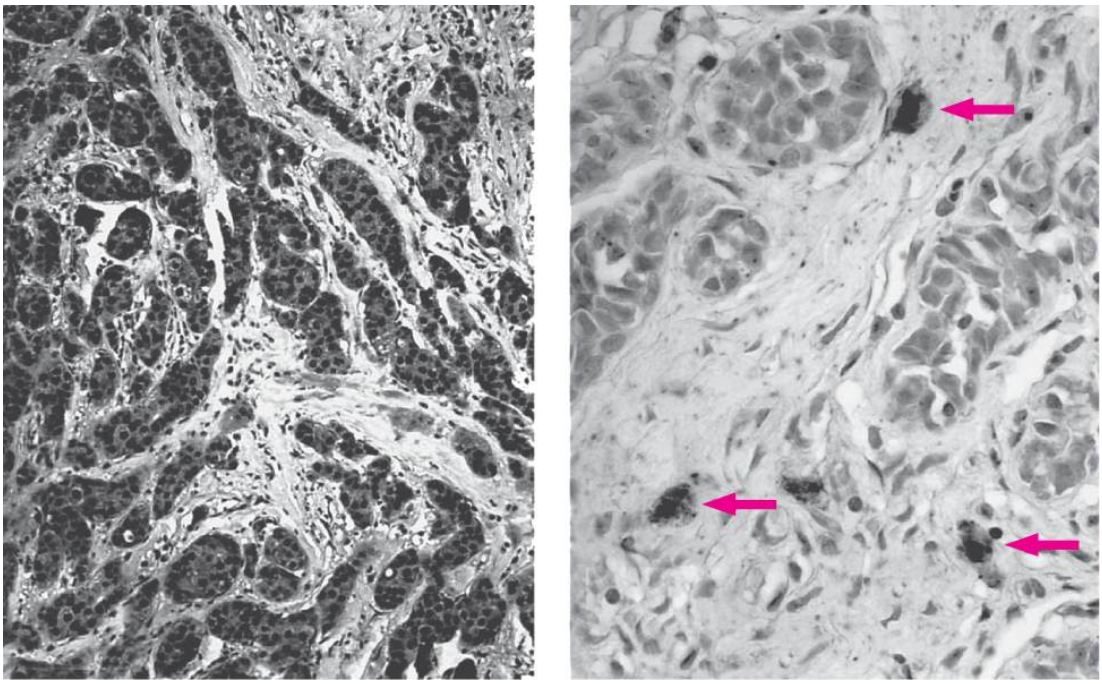
progression. (From E.Y. Lin et al., *J. Exp. Med.* 193:727–740, 2001. With permission from Rockefeller University Press.)

Once established in the tumor stroma, macrophages play important roles in stimulating angiogenesis (**Figure 13.26**). Thus, in some cancers, such as breast carcinomas, there is a direct correlation between the level of MCP-1 produced, the number of macrophages present, and the level of angiogenesis induced by the various tumors; in other tumors, the density of infiltrating tumor-associated macrophages (TAMs) is correlated with microvessel density (see Figure 13.26D); this density is gauged by counting the number of capillaries per microscopic field in a tumor section. Numerous reports suggest that macrophages play a major role in driving tumor progression by demonstrating a direct correlation between the presence of a high density of macrophages in tumor masses and a poor prognosis for cancer patients. This correlation has been documented for gliomas and for carcinomas of the breast, ovary, prostate, cervix, bladder, and lung.



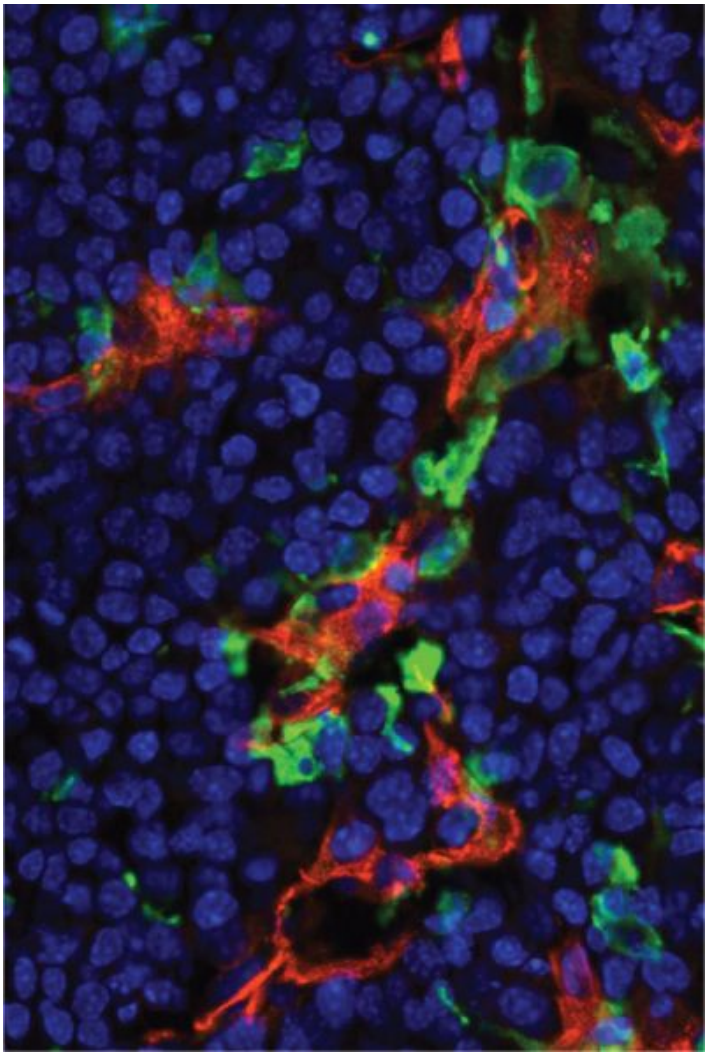
A flowchart showing how carcinoma cells and tumor-associated macrophages, or T A ems, coordinate to promote E M T by the carcinoma cells, leading to invasiveness and metastasis. Carcinoma cells use chemotactic factors (M C P-1, C S F-1, P D G F) to turn circulating monocytes into tumor-associated monocytes and then into T A ems. T A ems, in turn, initiate a complex series of events that result in angiogenesis and the survival and proliferation of the carcinoma cells.

(A)



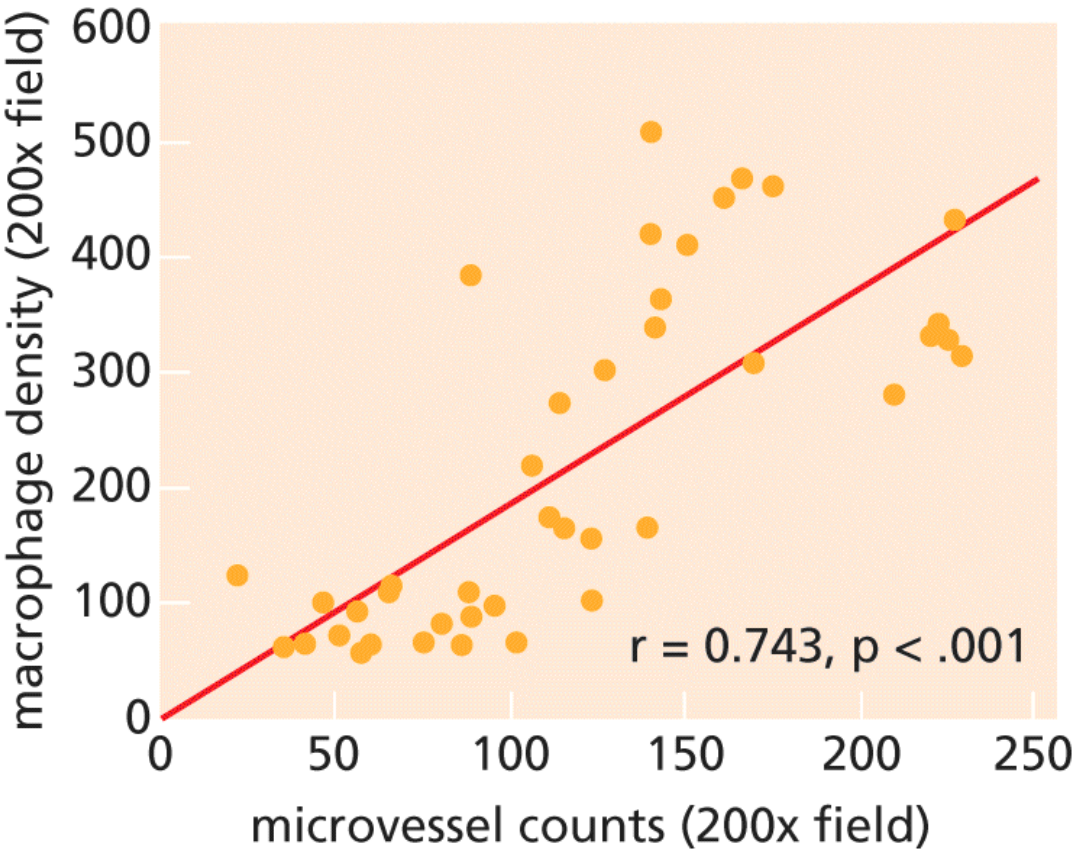
Two black and white images of tissue samples. In the left one there are many dark nodules, while in the right one there are only three dark spots, indicated by arrows.

(B)



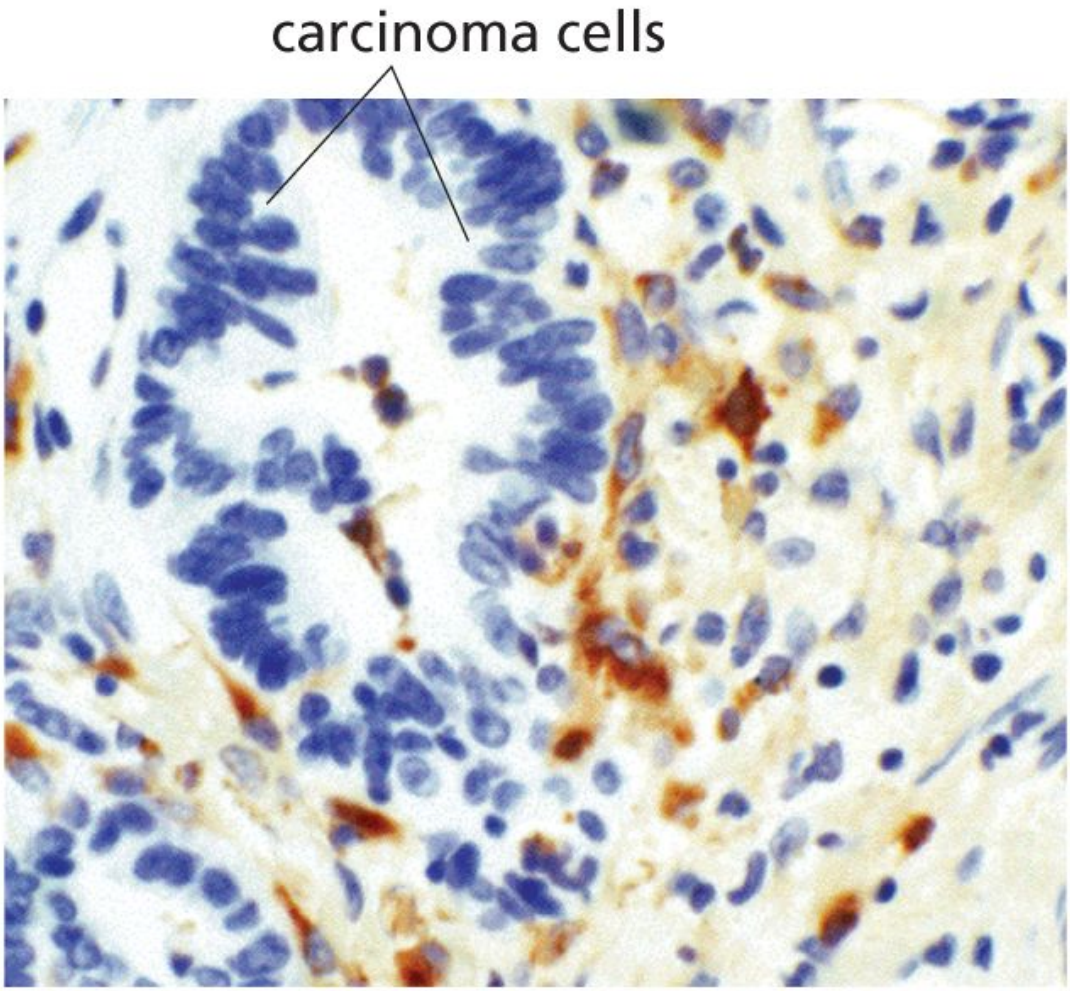
A fluorescence microscopy image with many dark blue nuclei, a few splotches of bright green, and a few streaks of red.

(C)



A scatter plot with macrophage density on the vertical axis and microvessel counts on the horizontal axis. The trendline runs from the origin up to the point 250, 470. The r statistic is 0.743. p is less than 0.001.

(D)



A histology image with blue nuclei and brown flecks appearing within otherwise white tissue. Cells that appear dark blue due to densely packed nuclei in a columnar cell arrangement are labeled carcinoma cells.

(E)

Figure 13.26 Macrophage involvement in angiogenesis (A) Macrophages play a major role in releasing mitogenic factors for carcinoma cells as well as reorganizing the tumor-associated stroma in order to facilitate angiogenesis and, in some tumors, carcinoma cell invasiveness. MMPs, matrix metalloproteinases. (B) In certain breast tumors (*left panel*), the cancer cells synthesize the potent angiogenic factor VEGF (vascular endothelial growth factor), revealed here (*dark areas*) by staining with an anti-VEGF monoclonal antibody. However, in other breast tumors (*right panel*), VEGF production originates in isolated macrophages within the tumor-associated stroma (*red arrows*). (C) In a variety of tumor types, including the pancreatic islet tumors of Rip-Tag mice (see Figure 13.35) analyzed

here, macrophages (*green*) can be found in large numbers next to the tumor-associated neovasculature (*red*). Cell nuclei are stained *blue*. Yet other work (see Figure 13.36B) reveals that such macrophages, working together with recruited mast cells, contribute actively to the process of angiogenesis in the tumor stroma. (D) In a series of human non-small-cell lung carcinoma (NSCLC) specimens, each represented here by a point on the graph, the density of tumor-associated macrophages (TAMs) per microscope field has been plotted vs. the density of microvessels (i.e., capillaries). Such correlations add further weight to the notion that TAMs play a key role in fostering tumor-associated angiogenesis. (E) Macrophages in the stroma of a human colorectal adenocarcinoma produce matrix metalloproteinase-9 (MMP-9; *brown spots*), a key enzyme in angiogenesis that acts by liberating angiogenic factors from the ECM. (A, update courtesy of J. Joyce. B, from R.D. Leek et al., *J. Pathol.* 190:430–436, 2000. With permission from John Wiley & Sons. C, courtesy of V. Gocheva and J. Joyce. D, from J.J.W. Chen et al., *J. Clin. Oncol.* 23:953–964, 2005. With permission from American Society of Clinical Oncology. E, from B.S. Nielsen et al., *Int. J. Cancer* 65:57–62, 1996. With permission from John Wiley & Sons.)

Such evidence, however, is only *correlative*. More compelling evidence of the *causal* role of macrophages, at least in tumor angiogenesis, comes from experiments in which cancer cells are forced to express higher levels of MCP-1. The expression of this chemokine allows the cancer cells to attract more macrophages, which proceed to secrete important angiogenic factors, notably VEGF and interleukin-8 (IL-8), resulting in marked increases in angiogenic activity and the formation of more extensive tumor-associated neovasculature. In addition, when lung cancer cells are exposed *in vitro* to factors that have been secreted by cultured macrophages, the cancer cells respond by producing IL-8 and several other proteins that promote angiogenesis and cell invasiveness.

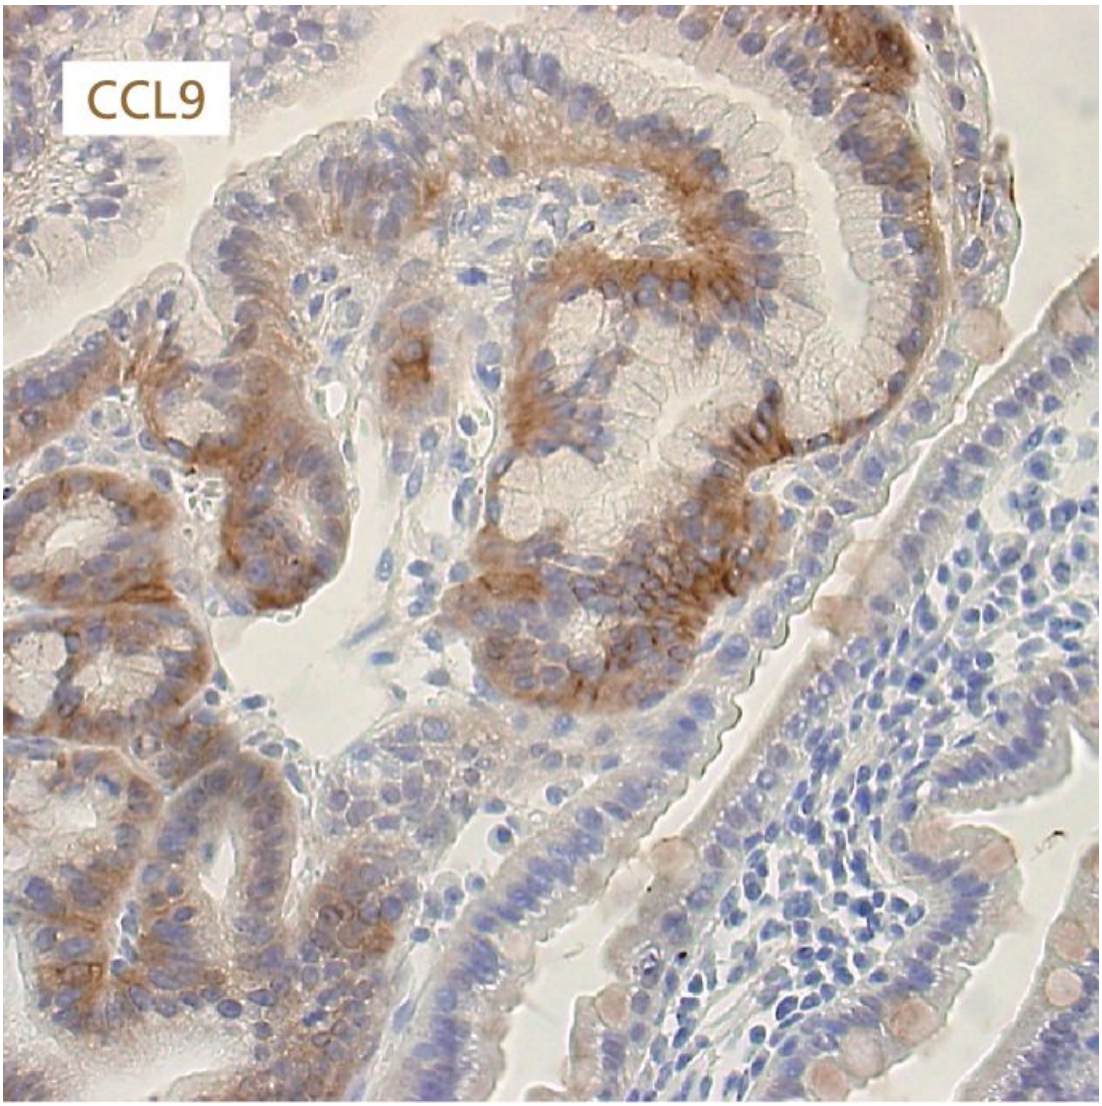
Hypoxic areas within tumors attract macrophages, which appear to tolerate hypoxia quite well. Once established in hypoxic regions of tumors, these inflammatory cells begin to secrete significant amounts of VEGF (see Figure 13.26A), which reduces the hypoxia by bringing in endothelial cells, capillaries, and thus oxygen-rich blood. Hypoxic areas of tumors often remain poorly vascularized, which indicates that the recruited macrophages, on their own, are unable to fully cure local defects in angiogenesis. Thus, in rapidly growing tumors, the macrophages and the vasculature that they induce cannot keep pace with the rate of tumor expansion, and large areas within a tumor mass eventually become necrotic (that is, filled with dead and dying cells) as a consequence (to be described in Section 13.6).

Like myofibroblasts, macrophages are adept at secreting matrix metalloproteinases (MMPs; see Table 13.1). MMP-9, prominently involved in cancer progression, is

produced by tumor-associated macrophages (TAMs; see Figure 13.26E) and, once activated, proceeds to cleave a number of important protein substrates in the extracellular space. In certain invasive carcinomas, including those of the breast, bladder, and ovary, TAMs have proven to be the major source of this enzyme. It contributes to tumor progression by enhancing angiogenesis, by disrupting existing tissue structure, thereby carving out space for expanding tumor masses, and by liberating critical mitogens that have been immobilized through tethering to proteoglycans of the ECM. MMP-9 can also cleave IGFBPs (insulin-like growth factor–binding proteins), which normally sequester IGF molecules in the extracellular space (see Section 9.14). This cleavage liberates the IGFs, notably IGF-1, which then provide survival signals to nearby cells, including cancer cells. In advanced breast cancers, TAMs are also able to help the carcinoma cells directly because they are the major source of the epidermal growth factor (EGF) that drives the proliferation of EGF-R–expressing carcinoma cells.

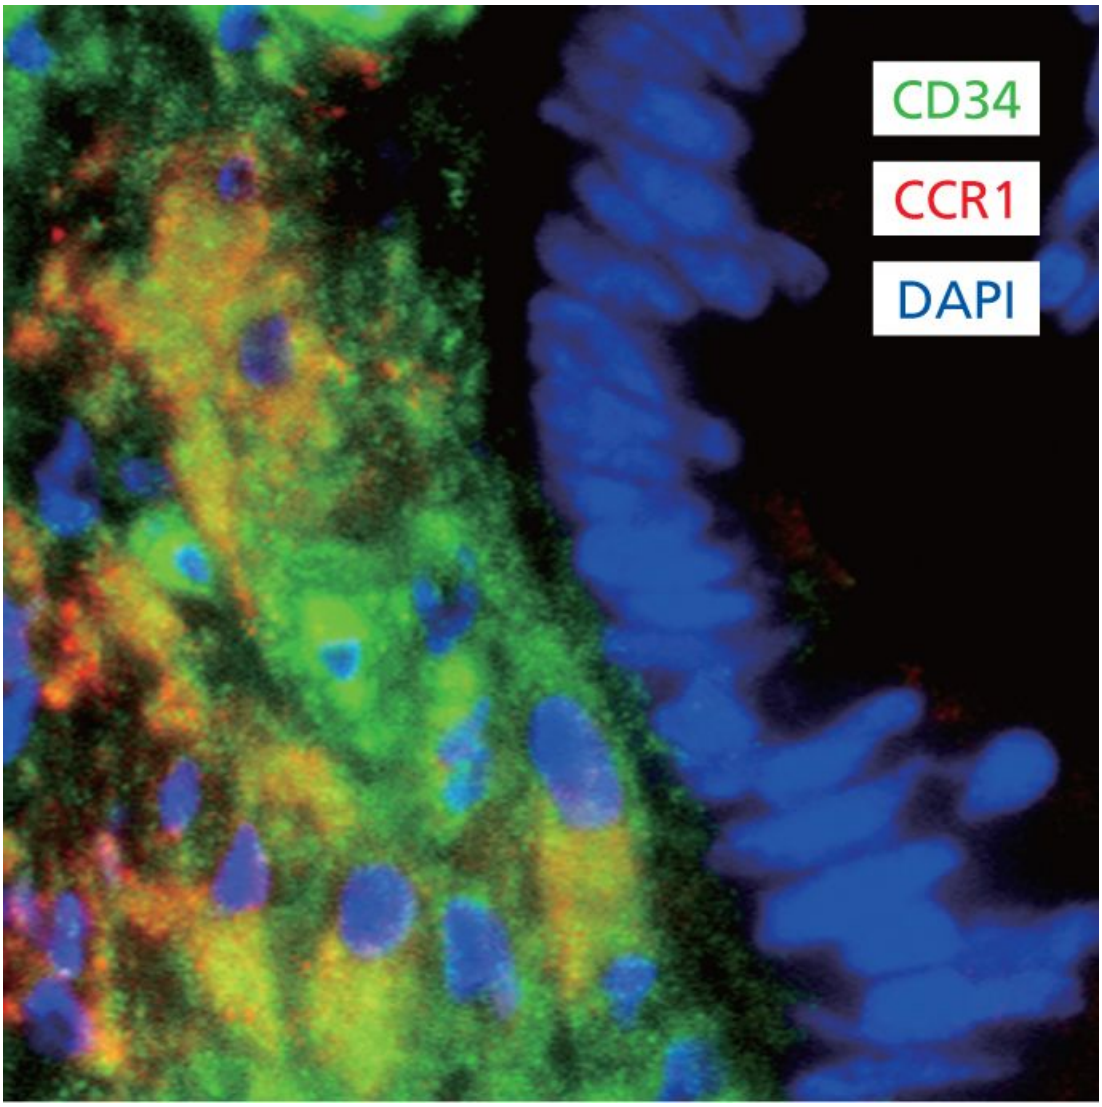
Although there is abundant evidence implicating some macrophages as active collaborators in tumor progression, it is also clear that another, distinct subset of macrophages, by acting as deputies of the immune system, can detect and kill cancer cells. Yet they clearly fail to do so in many types of tumors. Thus, some cancer cells acquire the ability to inactivate or blunt the tumoricidal (cancer-killing) actions of this second class of macrophages, while leaving intact the functions of the first type that are involved in aiding tumor progression. As we will learn in Chapters 15 and 16, these two classes of macrophages, termed M1 and M2, can either facilitate or blunt the immune attacks on tumors.

Yet another cell type in the myeloid lineage can also contribute to tumor invasiveness. *Immature myeloid cells* (iMCs) have been best characterized in mouse models of colorectal carcinogenesis. For example, when the genotype of human colorectal carcinomas is modeled in the mouse by inactivating both the *Apc* and *Smad4* genes (see Sections 7.10 and 11.3)—Smad4 being critical to TGF-β signal transduction (see Figure 6.22D)—the resulting adenoma and adenocarcinoma cells release the chemokine CCL9, which recruits iMCs originating in the bone marrow. The iMCs congregate at the invasive front of these tumors, secrete matrix metalloproteinases MMP-2 and MMP-9, and thereby facilitate invasion by the carcinoma cells into underlying tissue layers (**Figure 13.27**). Other research has shown that without MMP-2 and MMP-9, the iMCs cannot foster invasion and metastasis by the colorectal mouse tumors, and that the ability of cancer cells in the primary tumors to metastasize depends on recruitment of iMCs to these tumors.



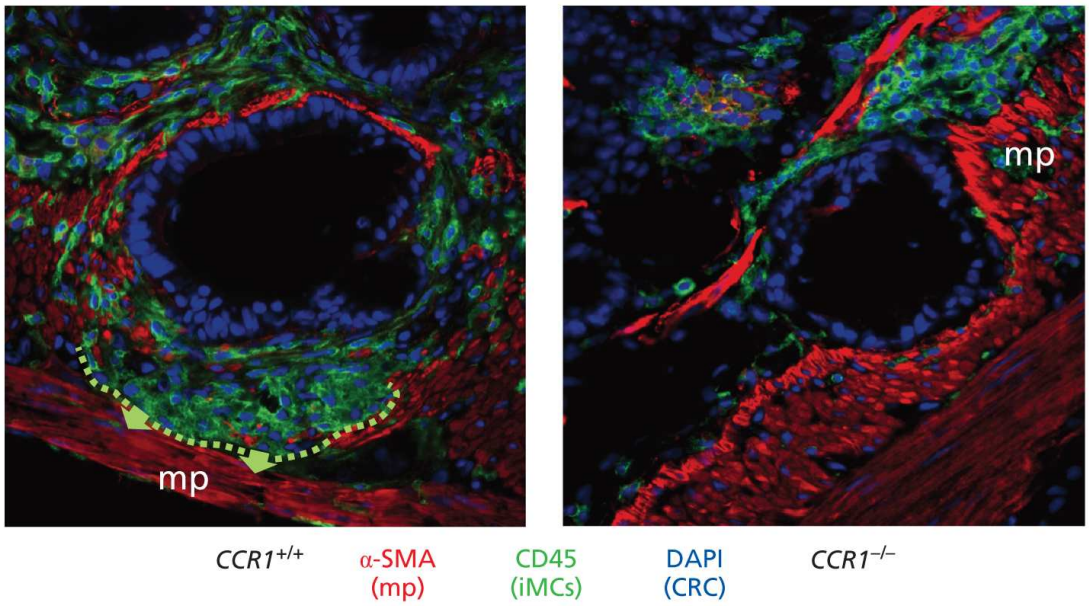
A histology image labeled C C L 9. It shows a clump of cells with pale blue nuclei and brown cytoplasms.

(A)



A fluorescence microscopy image, showing C D 34 in green, C C R 1 in red, and D A P I in blue. The left part of the image shows significant amounts of C D 34, with C C R 1 on the left edge, while the right side is dominated by D A P I.

(B)



Two fluorescence microscopy images, showing alpha S M A (m p) in red, C D 45 (i M Sees) in green, and D A P I (C R C) in blue. The left image, labeled C C R 1 homozygous positive, shows a front of green cells that form a semicircle around a round region of blue cells. The green cells are advancing into an area of red cells labeled M P. The right image, labeled C C R 1 homozygous negative, shows no such activity.

(C)

Figure 13.27 Immature myeloid cells promote colorectal carcinoma progression In a mouse model of colorectal (CRC) carcinogenesis, epithelial cells that have lost both Apc and Smad4 function—thereby mirroring the state of many human colorectal carcinomas (see Figure 11.11)—recruit a type of immature myeloid cell (iMC) of bone marrow origin into the tumor stroma. (A) The chemokine CCL9 (*brown*) is already released early in tumor progression by the cells in adenomas, which are precursors to frank carcinomas. Normal tissue, stained with DAPI (*light blue nuclei*), is seen in the *lower right*. CCL9 then acts as an attractant to recruit immature myeloid cells (iMCs) into the tumor stroma. (B) The cognate receptor of CCL9, termed CCR1 (*red-orange*), is displayed by many of the $CD34^+$ iMCs that are being recruited into the tumor stroma (*green*). DAPI (*blue*) stains all nuclei. (CD34 is a marker of hematopoietic precursor cells.) (C) When displaying the CCR1 receptor of CCL9 (*left panel*), large numbers of $CD45^+$ iMCs (*green*) congregate (*below*) near colorectal carcinoma cells (*blue nuclei*), and this mixed cell population begins to invade in a broad front (*green dotted line*) the underlying α-smooth muscle actin–expressing *muscularis propria* (mp, *red*). (CD45 is a marker of all types of hematopoietic cells.) However, when

the gene encoding the CCR1 receptor is knocked out in the genome of the tumor-bearing host (*right panel*), such $CD45^+$ iMCs are essentially absent and the depth of invasion is reduced 10-fold (*not shown*). The nature of the thin stripe of α-SMA-positive cells above the carcinoma cells is not known. (From T. Kitamura et al., *Nat. Genet.* 39:467–475, 2007. With permission from Nature.)

Interestingly, a certain class of immature myeloid cells have been shown to play an important role in tumor immunology, as discussed in Chapters 15 and 16. In that context, they are often termed myeloid derived suppressor cells (MDSCs) because of their strongly immunosuppressive powers that can be mustered by tumor cells to help protect themselves against various types of immune attack. As a class, immature myeloid cells represent a diverse and poorly characterized set of cell types whose precise contributions to tumor biology are still being explored.

OceanofPDF.com

Glossary

leukocyte
: A nonpigmented white blood cell such as a lymphocyte, monocyte, macrophage, neutrophil, or mast cell.

chemokine
: (1) A polypeptide that serves as an attractant for motile cells, notably leukocytes, via chemotaxis. (2) More narrowly, a member of a family of low–molecular-weight (8–10 kD) secreted proteins, most of which contain four cysteine residues in evolutionarily conserved sites. *See also* **chemotaxis**.

necrotic
: Referring to a region of a normal or neoplastic tissue in which the cells have died.

tumoricidal
: Able to kill cancer cells and/or destroy a tumor.

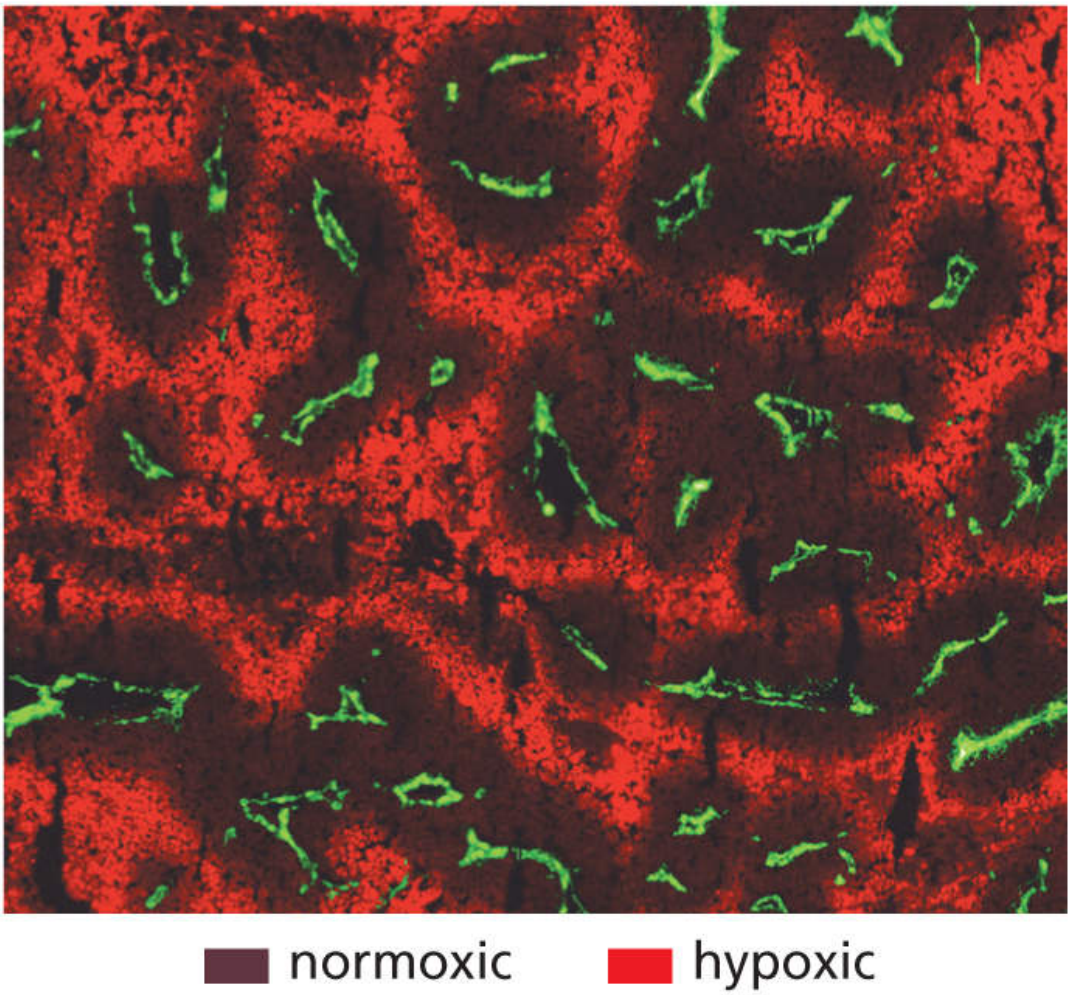
myeloid derived suppressor cell
: Relatively undifferentiated cell of myeloid origin, deriving from cells of the granulocytic or monocytic lineages, that exerts potent immunosuppressive functions on other immune cells of both the innate and adaptive arms of the immune system.

chemotaxis (adj., **-tactic**)
: Movement of a cell toward high concentrations of a soluble attractant such as a chemokine or growth factor. *See also* **chemokine**, **haptotaxis**.

OceanofPDF.com

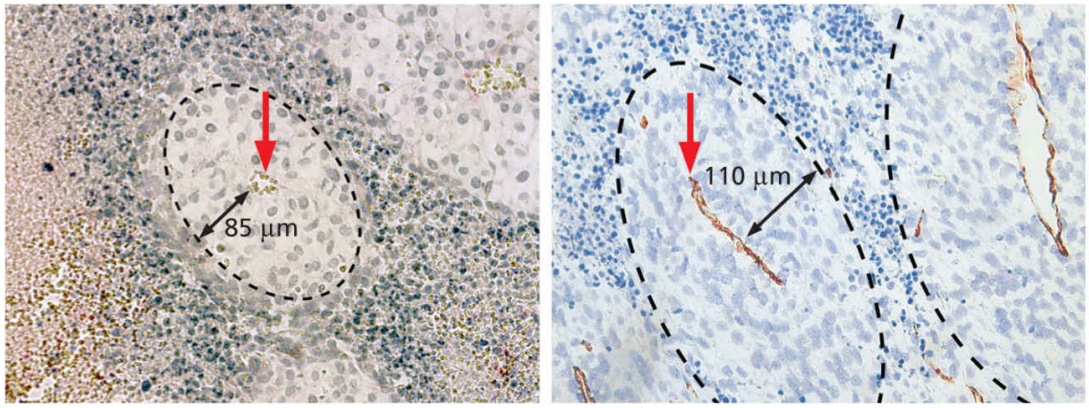
13.6 Endothelial cells and the vessels that they form ensure tumors adequate access to the circulation

The most obvious stromal support required by tumors has already been cited repeatedly in this chapter: like normal tissues, tumors require access to the circulation in order to grow and survive. As early as the mid-1950s, pathologists noted that cancer cells grew preferentially around blood vessels (**Figure 13.28A**). Those tumor cells that were located more than about 0.2 mm away from blood vessels were found to be nongrowing, and others even farther away were seen to be dying (Figure 13.28B).



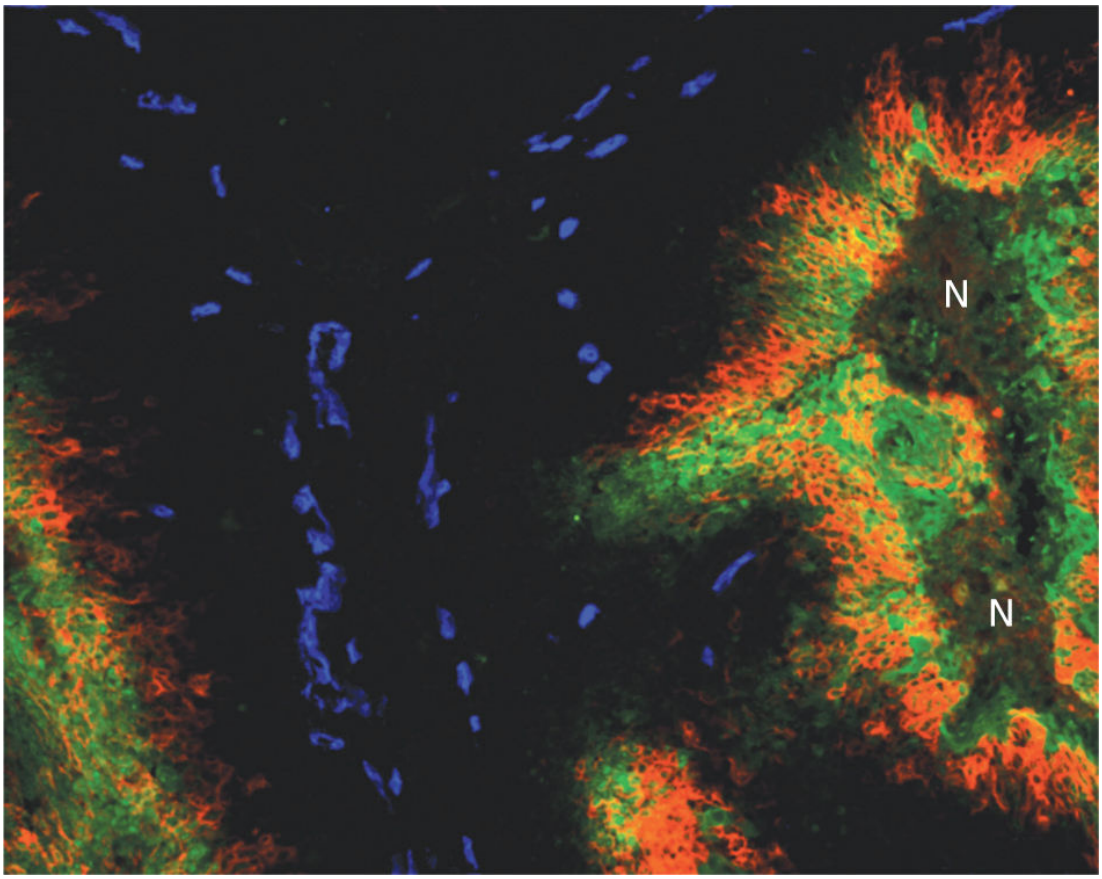
A fluorescence microscopy image. Islands of bright green dots are surrounded by dark cells which a legend identifies as normoxic. Between these islands are areas of bright red cells identified by the legend as hypoxic.

(A)



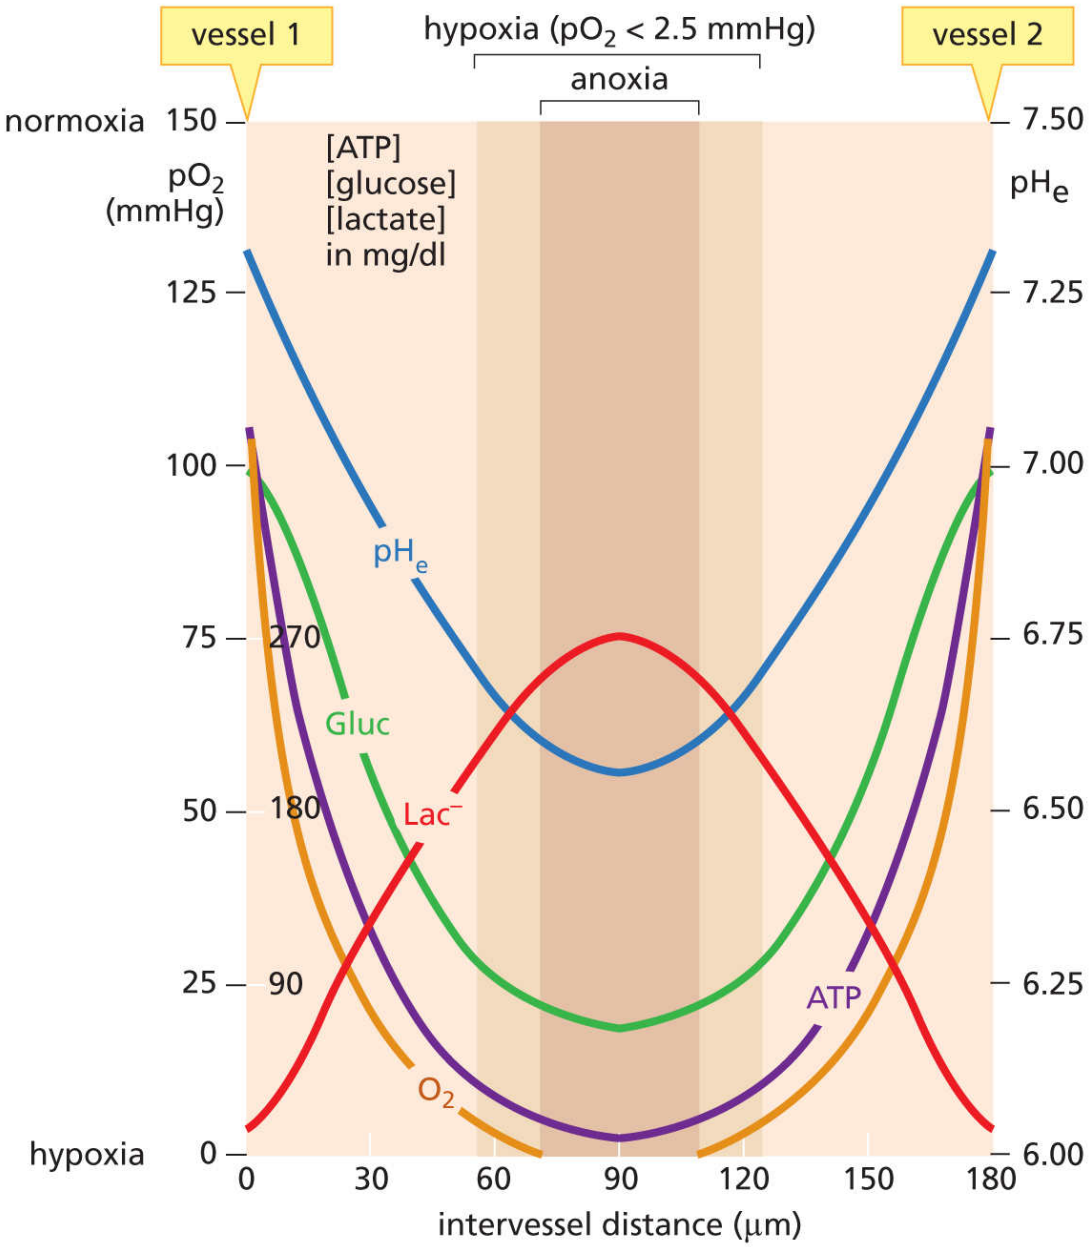
Two histology stain images. In the left one, a light colored area of human melanoma tissue is measured as having a radius of about 85 micrometers from a capillary; beyond that distance, the tissue is darker. In the right image, a light colored area of rat prostate cancer tissue is measured as having a radius of about 110 micrometers from a capillary; beyond that distance, the tissue is darker.

(B)



A fluorescence microscopy image containing regions of bright green, red and yellow to the left and right, and in the middle a dark region in which only blue nuclei are visible. The center of the brightly colored region on the right is darker and is marked n.

(C)

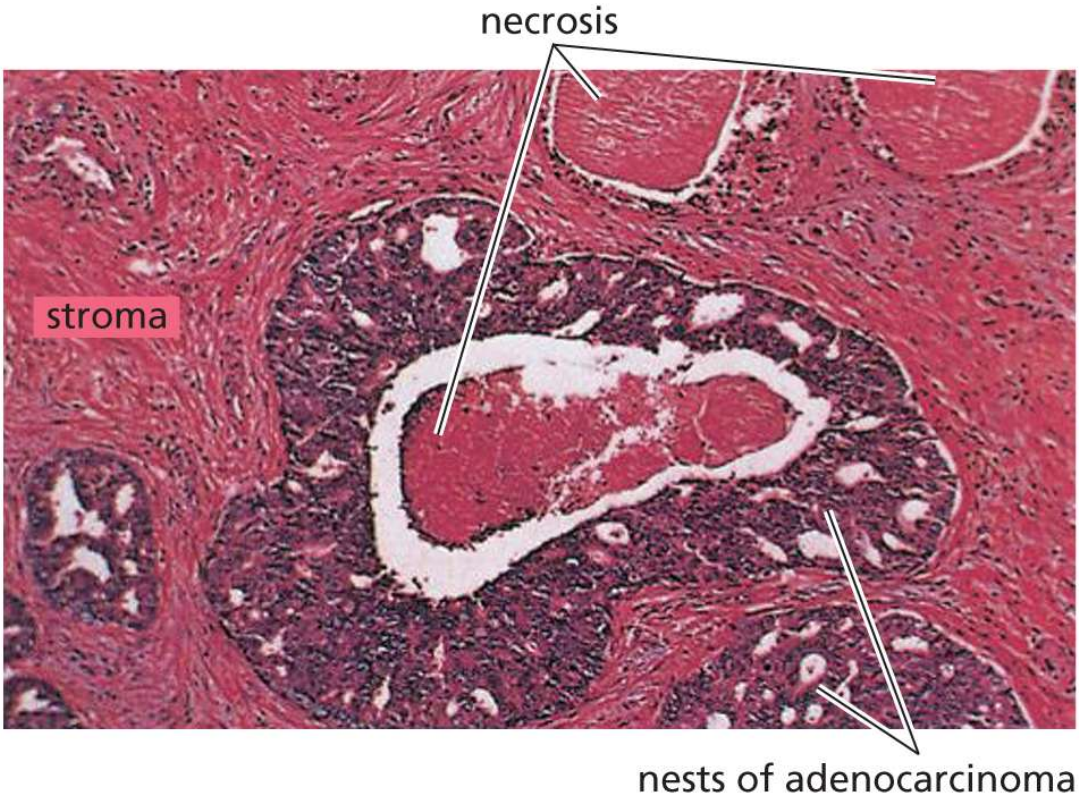


A graphic reporting the values of five parameters across a 180 micrometere gap between two blood vessels. p H e, glucose, A T P and oxygen concentrations are all high near each vessel and low in the middle of the gap

between them. The concentration of lactate, by contrast, is low near the vessels and high in the middle of the gap. The middle 40 micrometers or so of the gap are a region of anoxia. The middle 70 micrometers are a region of hypoxia, with Oxygen pressure less than 2.5 m m H g.
(D)

Figure 13.28 Hypoxia and necrosis of cells in poorly vascularized sections of tissues Various techniques have been used to demonstrate hypoxia and necrosis in regions of tissues surrounding capillaries. (A) This micrograph reveals capillaries (*green*) and the degrees of oxygenation in the surrounding tumor parenchyma. Immunostaining using an antibody reactive with EF5, a molecule that localizes to hypoxic regions of tissues, reveals hypoxic areas (*red*) at some distance from the capillaries, whereas those cells that are well oxygenated are unstained and therefore appear *dark brown*. (B) These sections of a human melanoma and a rat prostate carcinoma have been immunostained with an anti-CD31 antibody, which reveals capillaries (*red arrows*). Immediately around each capillary is a region of healthy cells (*inside the dashed line*), beyond which necrosis is apparent. The necrotic regions (*granular areas*) begin as close as 85 μm from the melanoma capillary (*left*) and 110 μm from the prostate carcinoma capillary (*right*). This necrosis reveals the limitations of diffusion in conveying oxygen and nutrients from capillaries to cells in the parenchyma of a tumor. (C) The dynamics of oxygenation on a larger scale are apparent in this human head-and-neck squamous cell carcinoma (HNSCC). Where blood vessels (*blue spots*) provide good oxygenation, the tumor appears *black*. In contrast, in areas of poor vascularization and moderate hypoxia, a carbonic anhydrase enzyme is expressed (*red-orange*), whereas in areas of extreme hypoxia, the pimonidazole dye is detectable (*green*). Overlap between these two markers appears *orange*. Areas of necrosis, located even further away from the tumor vasculature, are indicated by “N.” (D) Measurements of five parameters indicate the dramatic changes that occur with increasing distance from microvessels within tumors. Parameters have been calculated from two arterioles running in parallel, 180 μm apart. pH_e represents the pH of extracellular fluid. These measurements in aggregate explain why cells that are situated at some distance from a microvessel experience a sub-optimal environment that often leads to their death by necrosis. (A, courtesy of B.M. Fenton. B, left, from C.M. Croce et al: Holland Frei Cancer Medicine, 9th ed. Hoboken, N.J.: John Wiley & Sons, 2017. With permission from John Wiley & Sons. B, right, from L. Hlatky, P. Hahnfeldt and J. Folkman, *J. Natl. Cancer Inst.* 94:883–893, 2002. With permission from Oxford University Press. C, from J.H. Kaanders et al., *Cancer Res.* 62:7066–7074, 2002. With permission from American Association for Cancer Research. D, from P. Vaupel, *Semin. Radiat. Oncol.* 14:198–206, 2004. With permission from Elsevier.)

We now realize that this threshold of approximately 0.2 mm represents the distance that oxygen can effectively diffuse through living tissues. Cells located within this radius from a blood vessel can rely on diffusion to guarantee them oxygen; those situated further away suffer from moderate or severe hypoxia and low pH (see Figure 13.28B–D). Tissues suffering from hypoxia are in danger of becoming necrotic as illustrated in **Figure 13.29**, an alternative form of cell death that does not depend on apoptosis. Apoptotic death triggered by p53 also threatens hypoxic cells (see Chapter 9), and the inactivation of the p53 signaling system often enables cancer cells to survive beyond the small perimeter surrounding each capillary. Newly arising tumors must negotiate these constraints, doing so in the context of the rules that govern normal angiogenesis (Supplementary Sidebar S13.6).

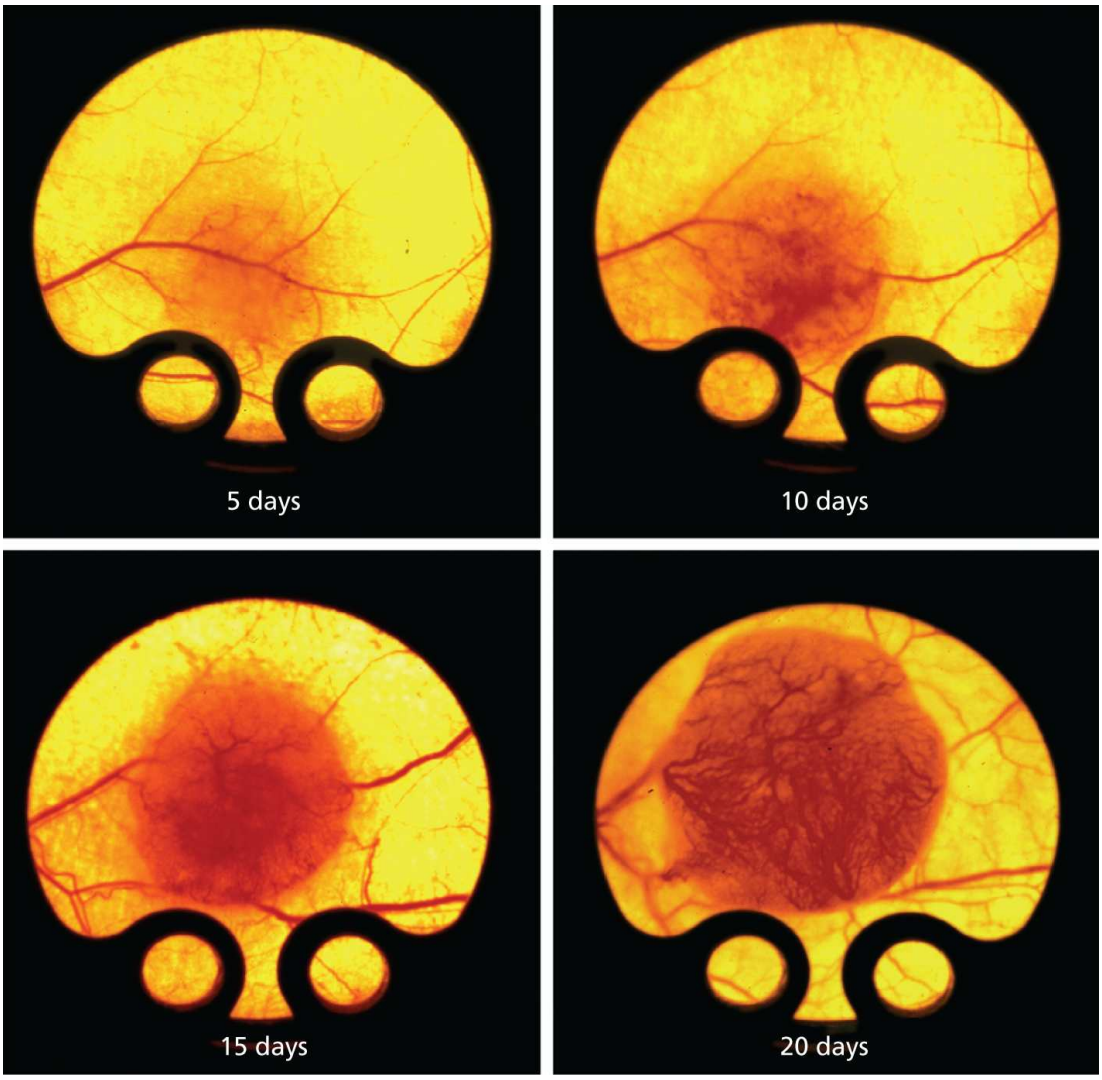


A histology image of prostate cancer. Nests of adenocarcinoma are surrounded by stroma. Three regions represent necrosis. One of these is at the center of an adenocarcinoma nest.

Figure 13.29 Large-scale necrosis within a tumor The inability of large sectors of a tumor to gain access to the vasculature in the stroma is evident in this high-grade adenocarcinoma of the prostate. As seen in the growth in the *center*, a nest of adenocarcinoma cells (*dark red*) is surrounded by extensive stroma (*light red*). In the middle of the nest of adenocarcinoma cells is a large clump of necrotic

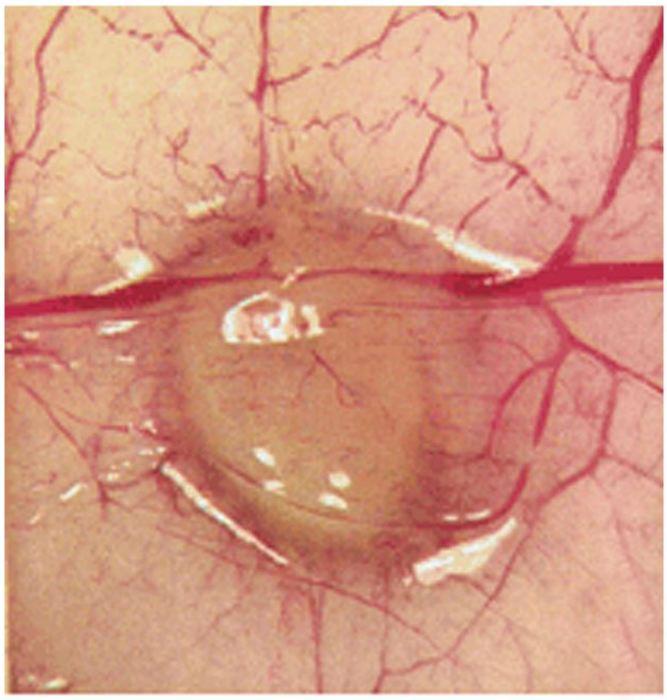
tissue (*light red*) that has shrunk away from the viable adenocarcinoma cells that surround it; the latter thrive because they have more direct access to the stroma and its associated vasculature. (From M.A. Weiss and S.E. Mills, Atlas of Genitourinary Tract Disorders, London: Gower Medical Publishing, Ltd., 1988. With permission from Elsevier.)

The existence and powers of angiogenic factors were first revealed by implanting small chunks of tumor on the cornea or the ears of laboratory animals such as rabbits. Within days, dense networks of capillaries and larger vessels were seen to emerge from preexisting capillary beds and to converge on the implanted tumor chunks. Images like these (**Figure 13.30**) have strongly influenced our thinking about the behavior of tumors and their vasculature, because they demonstrate so vividly that tumors actively recruit blood vessels into their midst.



Four images show the growth and increasingly thick vascularization of a tumor, with micrographs at 5, 10, 15, and 20 days.

(A)



control

+ VEGF-R2 inhibitor

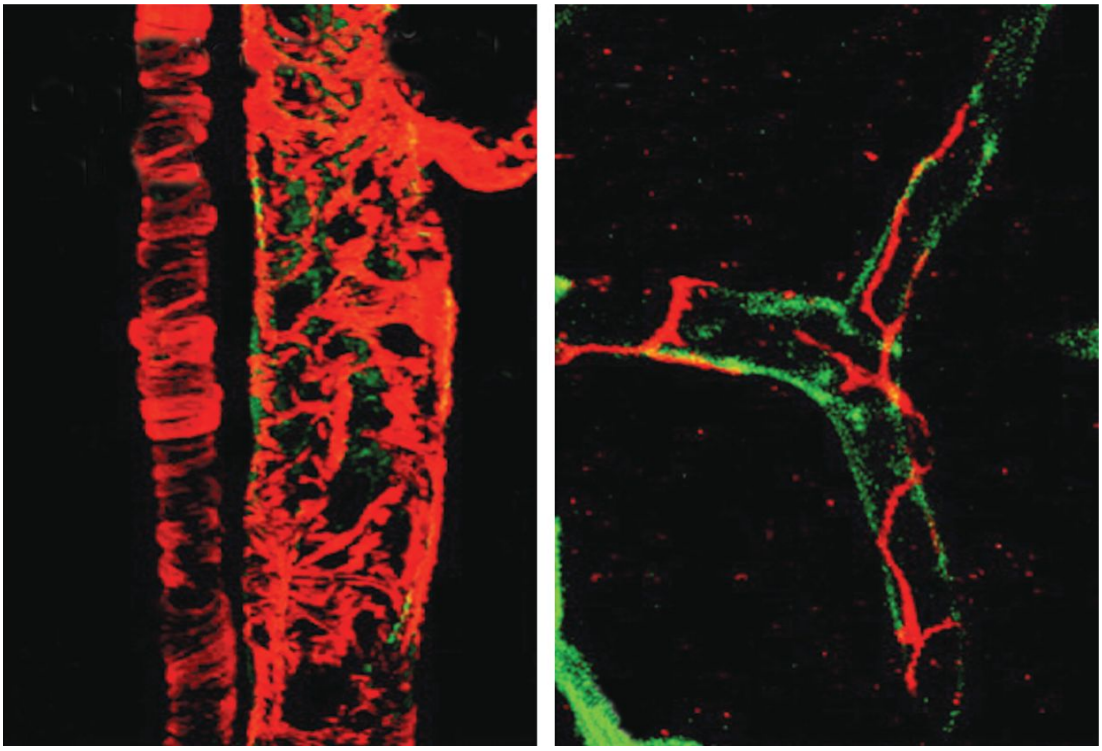
Two photographs. In the upper one, labeled control, a tumor appears covered with and surrounded by pink tissue and is fairly well vascularized. In the lower one, labeled plus V E G F-R 2 inhibitor, the tissue covering and surrounding the tumor is yellow, and the tumor is poorly vascularized.

(B)

Figure 13.30 Recruitment of capillaries by an implanted tumor (A) Shown is the growth of a small group of subcutaneously implanted human colorectal adenocarcinoma cells over a period of 20 days. The growth of the tumor-associated vessels (*red*) was observed through a window inserted above the tumor in the skin of the host mouse. (B) Such vascularization can be suppressed by antagonists of the VEGF receptor. Seen here are the effects of ZD6474 (also termed vandetanib), a low–molecular-weight inhibitor of the tyrosine kinase of the VEGF receptor-2, in mice bearing subcutaneously implanted human adenocarcinoma cell xenografts. The widespread *pink* background in the untreated control mouse is indicative of numerous capillaries, and the number of major vessels entering into a tumor mass (*above*) is strongly decreased in the presence of the drug (*below*). (A, from M. Leunig et al., *Cancer Res*. 52:6553–6560, 1992. B, from S.R. Wedge et al., *Cancer Res.* 62:4645–4655, 2002. Both with permission from American Association for Cancer Research.)

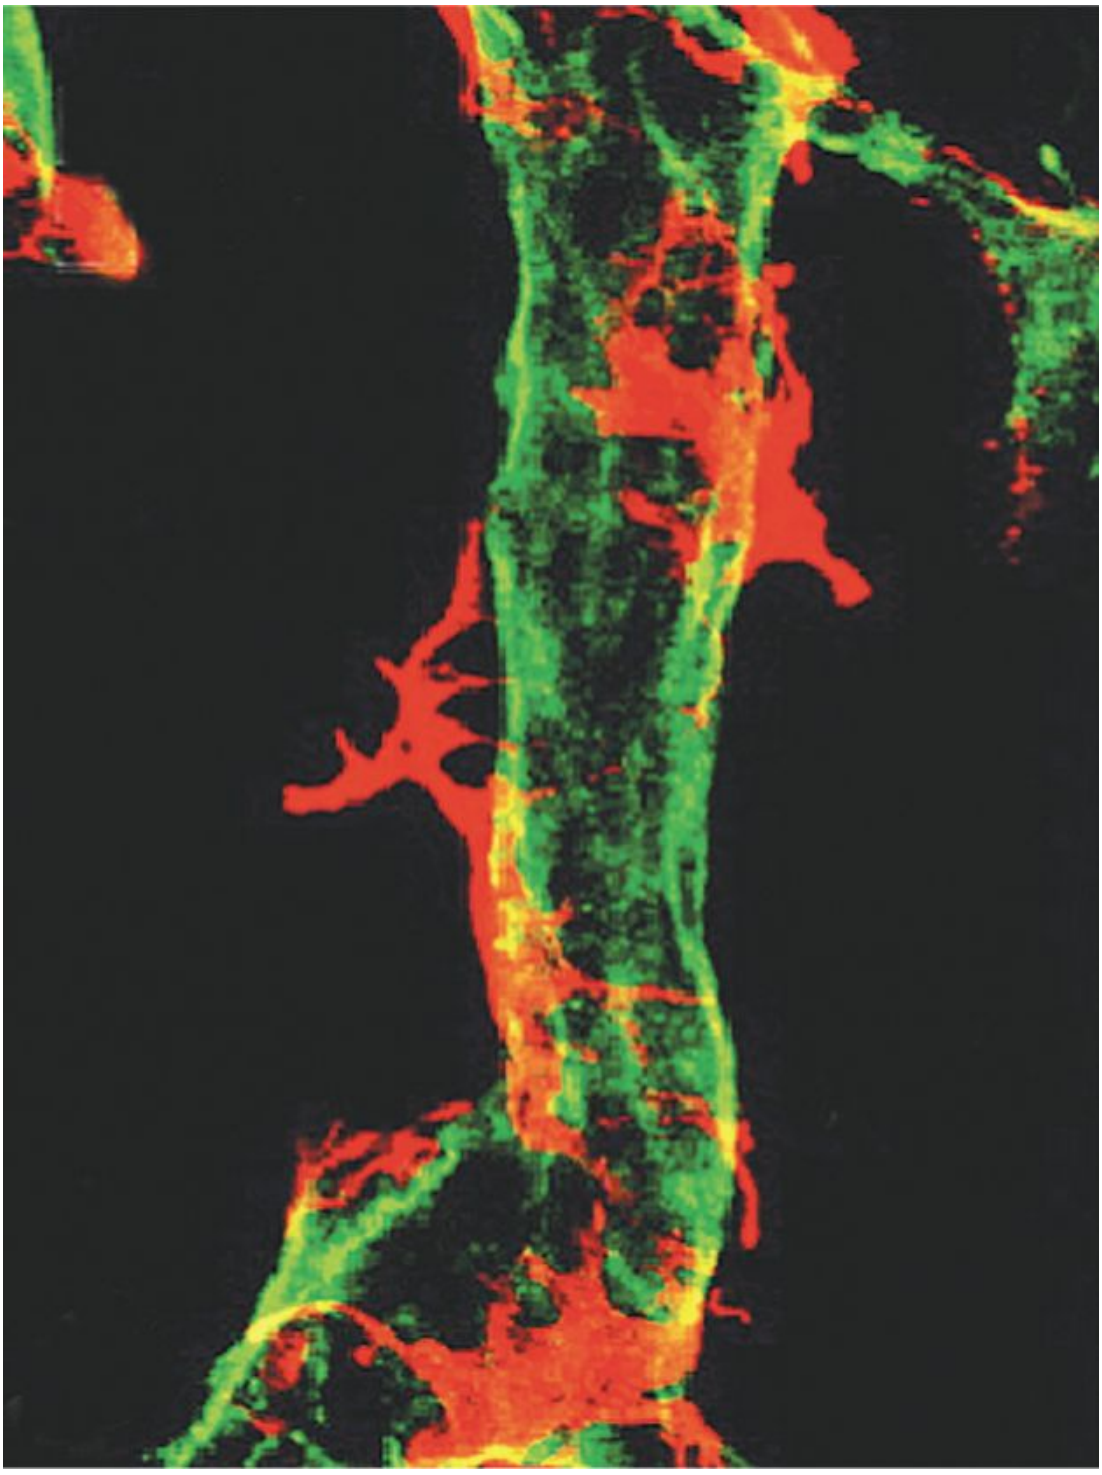
Angiogenesis is actually far more complicated than is suggested by the above discussion. Thus, this complex morphogenetic process involves many other factors in addition to the VEGFs, which clearly play a major role in attracting blood vessels to tumors. These other factors include several forms of TGF-β, basic fibroblast growth factors (notably FGF2), interleukin-8 (IL-8), angiopoietin, angiogenin, and PDGF. Also, several distinct cell types in addition to endothelial cells contribute to the construction of capillaries and larger vessels. Recall that the endothelial cells form the lumen of a capillary; these cells, in turn, are surrounded by the mural pericytes and vascular smooth muscle cells (see Figure 13.8A and B), which are absent from small lymph ducts.

The systematic covering of capillaries by pericytes seen in normal tissues can be contrasted with their chaotic dispersion near tumor-associated capillaries (**Figure 13.31**). Capillaries in tumors typically have diameters that are three times greater than their normal counterparts. In addition, the overall layout of blood vessels around and within tumor masses is quite chaotic (**Figure 13.32**). Often vessels stop abruptly in dead-end pouches or circle back and attach to themselves.



Two immunofluorescence micrographs. On the left, two medium-sized vessels, appearing in green, are almost entirely covered in tightly clinging red fibers. On the right, a capillary, again in green, has bits and pieces of red clinging tightly to its exterior.

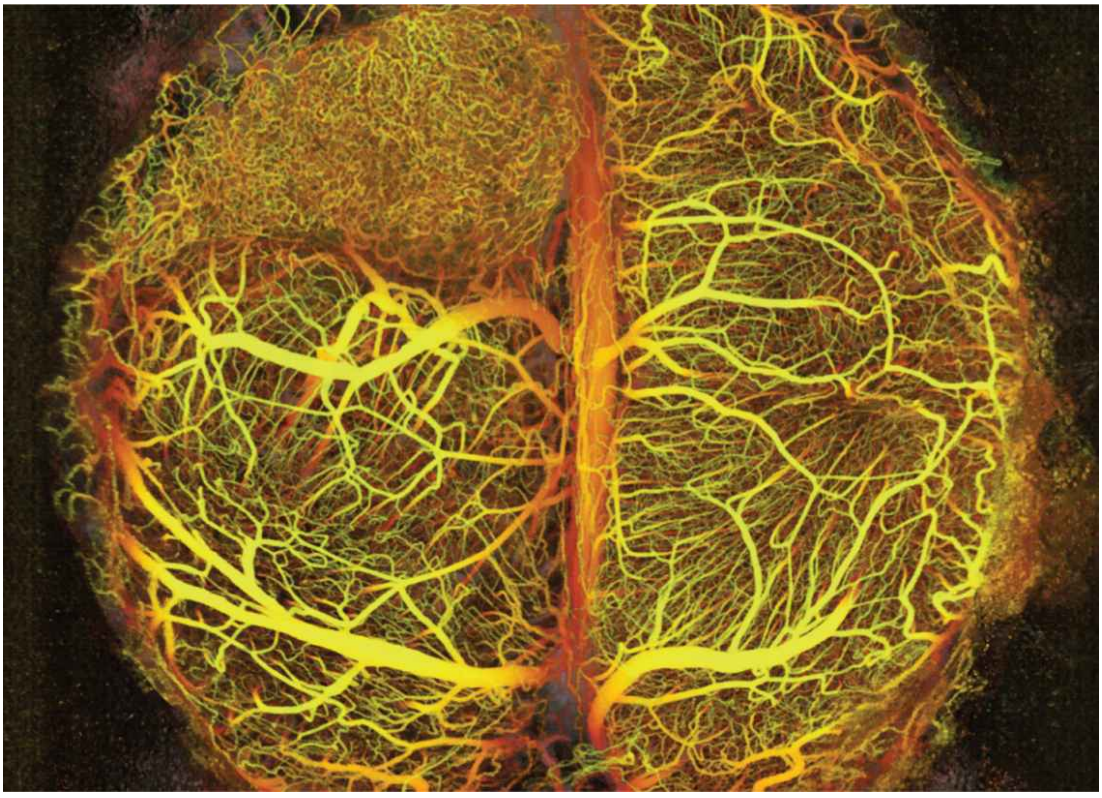
(A)



A capillary, in green, has chunks of red loosely attached to its exterior.

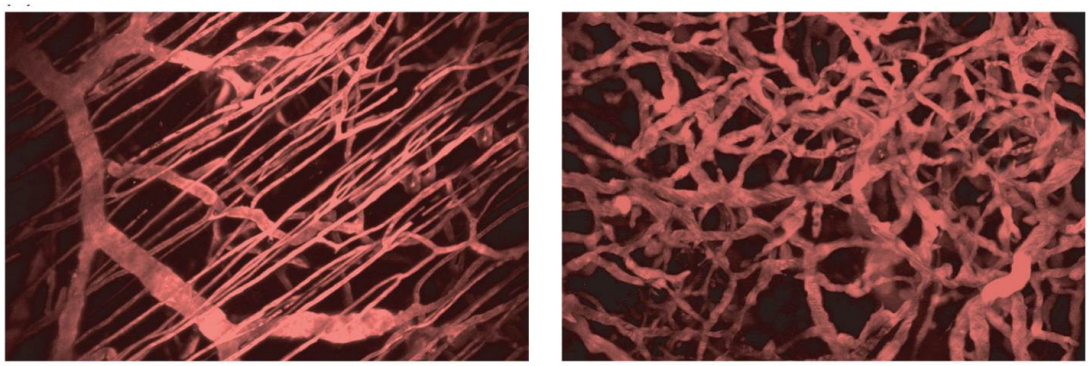
(B)

Figure 13.31 Pericytes in normal and tumor-associated vessels (A) This immunofluorescence micrograph shows that pericytes and smooth muscle cells (*both red-orange*) coat the outside of the tubes of endothelial cells (*green*), forming normally structured venules and arterioles (*left panel*). Pericytes and smooth muscle cells often cover these medium-sized vessels so completely that it is difficult to see the underlying endothelial cells. In contrast, in the smaller diameter capillaries (*right panel*), the pericytes are more sparsely disposed, but are nonetheless tightly attached to the endothelial cells. (B) This micrograph reveals the structure of a tumor-associated microvessel, in this case a vessel formed in a mouse by Lewis lung carcinoma (LLC) cells. The endothelial cells forming the lumen of this vessel (*green*) are only partially overlain by pericytes and smooth muscle cells (*red-orange*). The loose attachment of pericytes to the capillaries can be contrasted to their tight attachment seen in Figure 13.8A and B and panel A of this figure. (From S. Morikawa et al., *Am. J. Pathol.* 160:985–1000, 2002. With permission from American Society for Investigative Pathology.)



An image of what looks like a giant red and yellow ball of roots, oddly spherical but otherwise such as might be found under a bush or tree. Vessels ir the upper left corner of the image are much smaller than the rest, giving the impression of finer-textured tissue.

(A)



Two images contrast the linearity and parallel orientation of fine vessels on the left with the randomness and comparative coarseness of vessels on the right.

(B)

Figure 13.32 The chaotic organization of tumor-associated vasculature
Different techniques of imaging vessels in living tissues (sometimes termed *intra-vital* imaging) reveal at different levels of resolution the starkly contrasting organization of normal and neoplastic vasculature. (A) Intra-vital multiphoton microscopy allows the imaging of living tissues at multiple depths, in this case, the microvasculature of an implanted human glioblastoma multiforme growing as a xenograft in the mouse brain (*upper left*). Note the absence of the well-organized hierarchy of major and minor vessels that is apparent in normal brain tissue. (B) Two-photon microscopy has generated this higher-resolution image of the detailed organization of normal vs. neoplastic microvessels. Note the differing overall organization of the microvascular beds in the normal versus tumor tissue as well as the increased diameters of the tumor-associated capillaries. (A, from B.J. Vakoc et al., *Nat. Med.* 15:1219–1223, 2009. B, from R.K. Jain, *Nat. Med.* 9:685–693, 2003. Both with permission from Nature.)

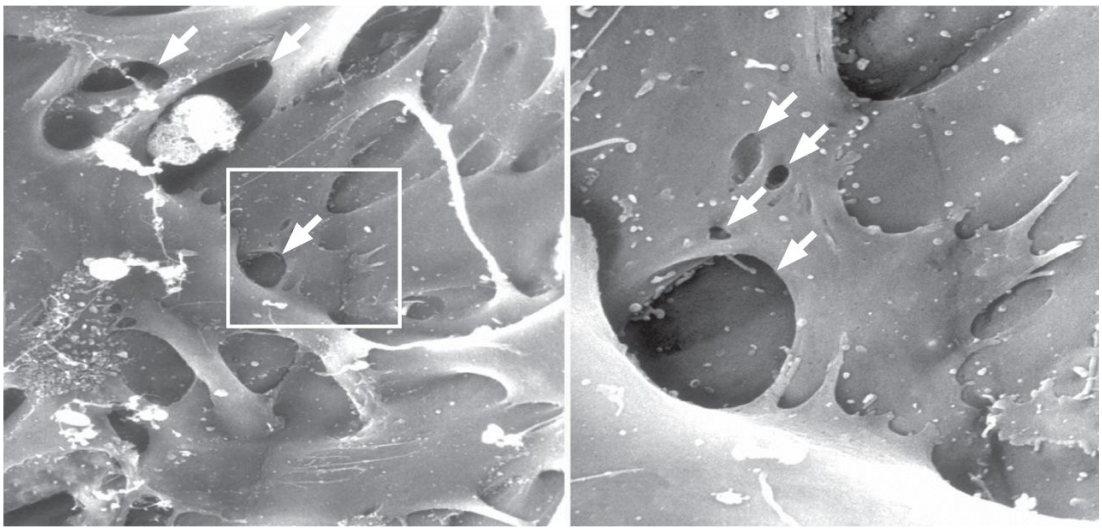
The precise reasons that capillaries and larger vessels within tumors are so haphazardly constructed are unclear. One possible factor is likely attributable to the imbalance between two mutually antagonistic growth factors, angiopoietin-1 and -2. Whereas VEGF is responsible for initiating the growth of capillaries by attracting and stimulating endothelial cells, a mix of angiopoietin-1 and -2 induces endothelial cells to recruit the pericytes and smooth muscle cells that enable newly formed capillaries to mature into properly assembled vessels containing appropriate proportions of these three cell types. An imbalance of these two angiopoietins, together with the greatly

elevated levels of VEGF within tumors, is suspected to be responsible for much of the defective construction of the vasculature within neoplasms. Indeed, some experiments indicate that most of the morphological abnormalities of tumor-associated microvessels can be mimicked simply by local overexpression of VEGF-A, the main pro-angiogenic factor.

At the submicroscopic level, it is also apparent that the capillaries in tumor masses are assembled haphazardly. This arrangement arises because the plasma membranes of adjacent endothelial cells do not contact one another to form a seamless lining around the capillary lumen but instead leave gaps, often several microns wide (**Figure 13.33A and B**), which allow direct access of the blood plasma to the cells surrounding the capillary. The resulting leakage (Figure 13.33C) seems to be responsible for the deposition of fibrin in the tumor parenchyma described earlier (see Figure 13.17).

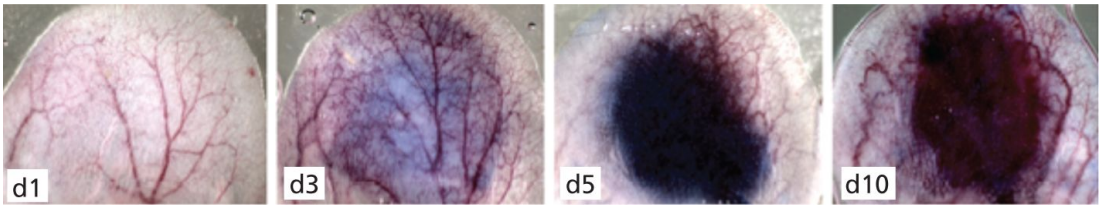
A scanning micrograph of a rippled, and sometimes bubbled, surface of cells tightly adhering to one another, without gaps.

(A)



Two scanning micrographs, the second a close-up of the first, showing a surface of cells tethered to one another haphazardly and with voids between, indicated by arrows.

(B)



A series of four photographs of a mouse’s ear, taken on day 1, day 3, day 5, day 10. On day 1, the ear looks fairly normal, pale with red veins. On day 3, it has a light purple bruise. And on days 5 and 10, it looks like one big, dark purple bruise.

(C)

Figure 13.33 Gaps in the tumor microvasculature and resulting leakage (A) This scanning micrograph reveals the tight seals between endothelial cells forming the luminal wall of this venule in a normal mouse mammary gland; these cell–cell junctions, indicated here by *white arrowheads*, do not overlap and block essentially all leakage of fluid from the lumen of the microvessel into the tissue parenchyma. The *black arrows* indicate bulges in the luminal surface deriving from underlying endothelial cell nuclei (see Figure 13.8A). (B) This scanning electron micrograph reveals that the sheets of endothelial cells fail to form a continuous uninterrupted surface in the wall of a capillary within a tumor. Instead, the tumor-associated endothelial cells overlap one another and, as indicated here

(*arrows*), show gaps of significant size between them. The box in the *left panel* is shown at higher magnification in the *right panel*. Such gaps permit the seepage of plasma fluids into the interstitial spaces between the cancer cells in the tumor parenchyma, contributing to the high hydrostatic pressure in these spaces. (C) The role of VEGF in inducing capillary permeability is illustrated here in an experiment in which an adenovirus gene expression vector encoding VEGF-A was infected into the ears of mice. At the indicated days thereafter, Evans Blue dye was injected into the general circulation of the mice and the ears were imaged 30 minutes later. With increasing time after initial VEGF-A expression, the microvessels became increasingly permeable, resulting in leakage of the dye molecules from the circulation into the parenchymal tissue of the ear. (A and B, from H. Hashizume et al., *Am. J. Pathol.* 156:1363–1380, 2000. With permission from American Society for Investigative Pathology. C, from J.A. Nagy et al., *Lab. Invest.* 86:767–780, 2006. With permission from Nature.)

Quantitative measures indicate that the walls of capillaries in tumors are about 10 times more permeable than those of normal capillaries. Much of this leakiness is attributable to the defective assembly of capillary walls noted here, which seems, in turn, to result from the deregulated production of VEGF by cancer cells and by macrophages and fibroblasts in the tumor-associated stroma. We know this because when an antibody that neutralizes VEGF is introduced into the circulation of tumor-bearing mice, the permeability of the walls of the tumor-associated capillaries is substantially reduced. In fact, a mysterious extracellular factor—vascular permeability factor (VPF)—was first described in 1979, but its biochemical nature only became clear a decade later with the cloning of its gene, which was thereafter termed the VEGF. This permeability of tumor-associated microvessels can have dramatic effects on other processes, such as certain forms of anti-cancer therapy (**Sidebar 13.6**).

Sidebar 13.6 Vessel permeability governs one childhood cancer treatment

Medulloblastomas are childhood tumors of the cerebellum and are encountered in four forms in the pediatric oncology clinic, distinguished by various somatically mutated genes. Three forms are treated with various degrees of success, whereas the fourth type, termed WNT-medulloblastomas, is almost invariably curable. The cancer cells of this subtype, which exhibit hyperactive Wnt signaling caused by their expression of mutant β-catenin (see Figure 6.19B), secrete large amounts of Wnt inhibitors into the extracellular space. These inhibitors block normal Wnt signaling, which is critical for the proper formation of capillaries in the brain. Consequently, these tumors develop microvessels that carry many large gaps, termed fenestrations, that result in as much as a 300-fold increase in the transport of drugs from the circulation into the tumor parenchyma. This permeability of tumor-associated microvessels renders these tumors

highly curable, in that relatively low drug concentrations that have few toxic side effects on the treated children succeed in eliminating these tumors, while having little effect on the other three forms of medulloblastoma. (The four types of medulloblastoma cells are equally susceptible to killing by cytotoxic drugs when propagated in tissue culture.)

As mentioned, the leakiness of tumor-associated capillaries leads to the accumulation of substantial amounts of fluid in the interstitial spaces within a tumor. In normal tissues, these fluids are drained continuously by the lymphatic vessels (see Figure 13.8C), which eventually empty their contents into the venous circulation (**Sidebar 13.7**). However, within solid tumors, the ongoing expansion of cancer cell populations exerts physical pressure on those few lymphatic vessels that do succeed in forming, causing their collapse (**Figure 13.34**). (Blood capillaries are more capable of resisting this pressure because of their own significant internal hydrostatic pressure, which lymphatic vessels lack.) The resulting defective lymphatic drainage within the cores of solid tumors further exacerbates the elevated accumulation of fluid caused by capillary leakage, generating relatively high fluid pressure in the nonvascular parts of tumors.

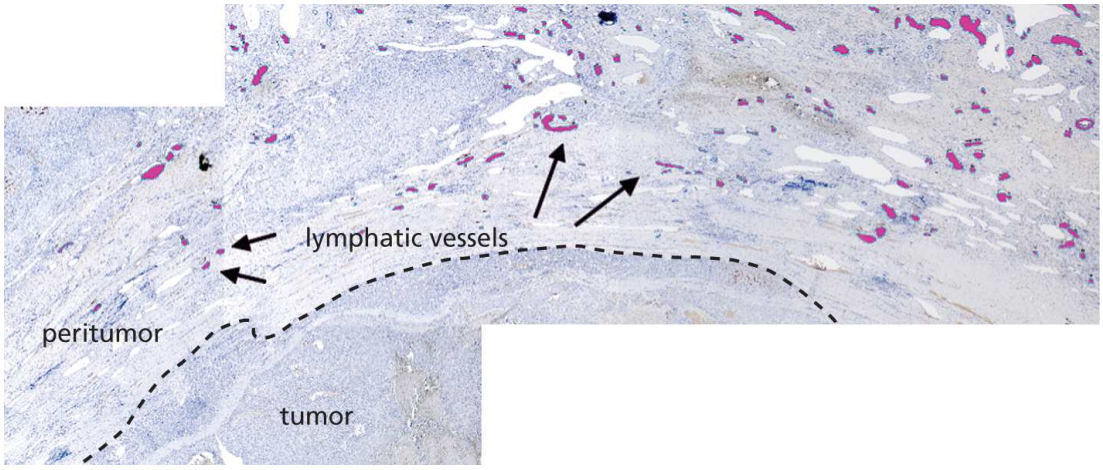
Sidebar 13.7 Endothelial cells also construct lymph ducts

Lymph ducts have two major functions in normal physiology. They drain fluid from the interstices between cells and empty this fluid into the venous circulation. In addition, they allow antigen-presenting cells of the immune system to convey antigens from various tissues to the lymph nodes, where immune responses are often initiated (to be described in Chapter 15).

Interestingly, lymph ducts are assembled from endothelial cells originating in the same embryonic stem cell population that yields the endothelial cells of capillaries and larger blood vessels. During embryonic development, lymphatic vessels can often be observed to bud from developing capillaries before they separate and construct their own parallel network of interconnecting vessels (see Figure 13.8C). In addition, the factors that stimulate lymphangiogenesis—vascular endothelial growth factors C and D (VEGF-C and VEGF-D)—are homologous to VEGF-A and -B, which play a major role in stimulating the angiogenesis that creates the blood vasculature.

As might be expected, the receptor for VEGF-C and VEGF-D displayed by lymphatic endothelial cells—VEGF receptor 3 (VEGF-R3)—is structurally related to the dominant VEGF receptor of blood capillaries, VEGF-R2. In addition, there is clear evidence that VEGF-D, which is mainly responsible for driving lymphangiogenesis, may also help stimulate angiogenesis by binding and activating VEGF-R2. So these two systems—the blood and lymphatic networks—derive from common evolutionary

roots, develop from common precursors in the embryo, and continue to interact with one another in complex ways within adult tissues. Of note, there are even more ancient evolutionary connections between the mechanisms guiding the growth of capillaries and those guiding nerve axon growth (to be described in Section 13.10.)



A histology image in which a tumor is surrounded by lighter-colored peritumor tissue. The peritumor tissue contains red specks representing lymphatic vessels. The tumor itself contains no red specks.

Figure 13.34 Absence of lymphatic vessels within solid tumors Analysis of a section of a hepatocellular carcinoma (HCC; liver cancer) reveals (via specific antibody staining) that lymph ducts (*dark red*) are present in the normal tissue above the tumor margin (*dotted line*) but are absent within the tumor mass itself. This absence may be attributed (1) to the lack of formation of these ducts during tumor growth or (2) to the collapse and degeneration of these ducts because of the high hydrostatic pressure within solid tumors; both mechanisms are likely to operate. (From C. Mouta Carreira et al., *Cancer Res.* 61:8079–8084, 2001. With permission from American Association for Cancer Research.)

Yet another mechanism conspires to maintain high hydrostatic pressure within tumors: the large amounts of PDGF that are released by many types of carcinoma cells induce contraction of stromal myofibroblasts, resulting in the squeezing out ("expression") of interstitial fluid. Hence, at least three mechanisms—lymphatic vessel collapse and resulting loss of fluid drainage, weeping by capillaries, and fibroblast contraction—contribute to high intra-tumoral hydrostatic pressure. This pressure, in turn, greatly complicates the administration of anti-cancer therapeutic drugs, because it prevents the formation of the steep pressure gradient leading from the capillary lumen down to the parenchyma that is needed for the efficient passive transfer of drugs from the circulation into the extravascular spaces of the tumor (**Supplementary Sidebar 13.7**).

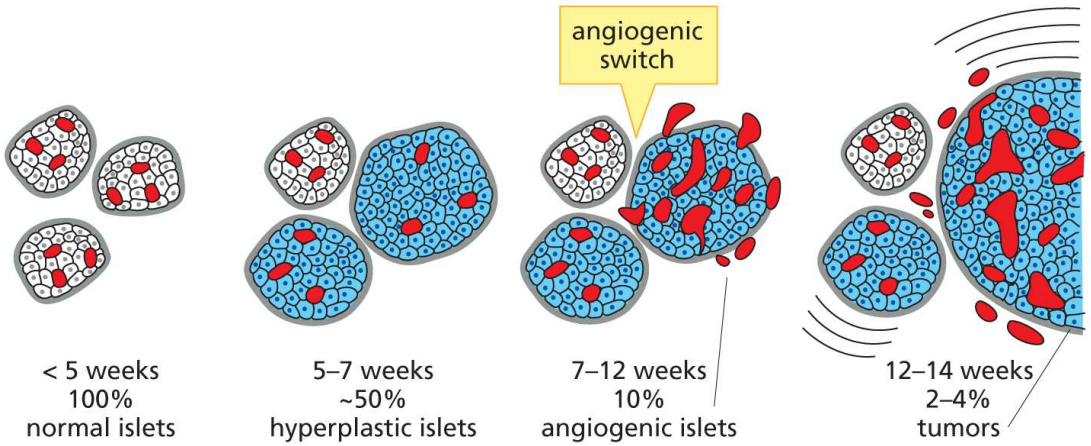
13.7 Tripping the angiogenic switch is essential for tumor expansion

The descriptions of angiogenesis given above would seem to suggest that the release of angiogenic factors is virtually automatic: whenever groups of cells, including cancer cells, suffer hypoxia, they release angiogenic factors and thereby provoke the growth of capillaries into their midst. This sequence of steps cures the hypoxia and results in an appropriate density of capillaries in the tissue harboring these cells.

In fact, the ability to attract blood vessels seems to be a trait that many tumor cell populations initially lack and must acquire as tumor progression proceeds. This idea was first suggested by the observation, cited above, that in certain tumors, cancer cells thrive near capillaries, but those that are located further than 0.2 mm from capillaries stop growing and may enter apoptosis or become necrotic (see Section 13.6). So, even though these cancer cells experience hypoxia, they lack the ability to induce the formation of nearby capillaries.

We know much about these dynamics from detailed study of experimental models of tumorigenesis. The most informative of these has been the Rip-Tag transgenic mouse. It carries a transgene in its germ line, in which the concomitant expression of the SV40 large T antigen (see Sections 8.5 and 9.1) and small T antigen (see Sidebar 11.9) is driven by the promoter of the insulin gene. This promoter ensures expression of these viral oncoproteins in the β cells that form the islets of Langerhans in the pancreas (in which insulin is normally produced).

Tumor progression in the 400 or so islets of the mouse pancreas can be easily followed, because these islets can readily be distinguished from the surrounding tissue of the exocrine pancreas, which is involved in manufacturing and secreting digestive enzymes. As many as half of these islets in a Rip-Tag mouse form hyperplastic nodules by 10 weeks of age, and 8 to 12% of the hyperplastic islets eventually progress to become angiogenic, that is, they acquire the ability to recruit new blood vessels. By 12 to 14 weeks, about 3% of the initially formed hyperplastic islets finally progress to form carcinomas (**Figure 13.35**).



An illustration of a progression, in four stages. Stage 1, labeled less than 5 weeks, 100 percent normal islets, shows three normal-sized islets, each containing three normal-sized capillaries. Stage 2, labeled 5 to 7 weeks, roughly 50 percent hyperplastic islets, shows two of the islets now oversized, but all capillaries still normal in size and number. Stage 3, labeled 7 to 12 weeks, 10 percent angiogenic islets, shows that the angiogenic switch has occurred in one of the two oversized islets. It now has a dozen capillaries, many irregular in shape and some lying outside the body of the islet. Stage 4, 12 to 14 weeks, 2 to 4 percent tumors, shows the angiogenic islet growing rapidly, with capillaries proliferating both inside and around it.

Figure 13.35 The Rip-Tag model of islet cell tumor progression Multi-step tumorigenesis in the Rip-Tag transgenic mouse model proceeds in distinct stages. Normal pancreatic islets (also known as islets of Langerhans; *left*) carry a small number of capillaries (*red*) to support, among their other cellular constituents, the β cells, which are responsible for synthesizing and secreting insulin into the circulation. By 5–7 weeks of age, about half of these islets become hyperplastic, but the density of blood vessels is not increased. At 7–12 weeks, about 10% of the hyperplastic islets become angiogenic, as indicated by the greatly increased density of capillaries in the surrounding, nearby exocrine pancreas. Finally, by 12–14 weeks of life, 2–4% of the initially formed hyperplastic islets have become invasive carcinomas that grow rapidly and invade the surrounding exocrine pancreas. The exocrine pancreas, in which these islets are embedded, is not illustrated here. (From D. Hanahan and J. Folkman, *Cell* 86:353–364, 1996. With permission from Elsevier.)

Early in tumor progression in the Rip-Tag mice, the hyperplastic pancreatic islets begin to expand slightly to a small diameter of about 0.1–0.2 mm and then halt their forward march (see Figure 13.35), at least for a while. In these small nests of tumor

cells, cell division continues unabated, being driven by the oncogenic SV40 transgene. However, the overall size of the tumor cell population within each islet remains constant because of a compensating attrition of cells occurring through apoptosis. This mouse model suggests that in humans, small tumor nests may also remain in such a dynamic but nongrowing state for many years, unable to break through the barriers that are holding them back.

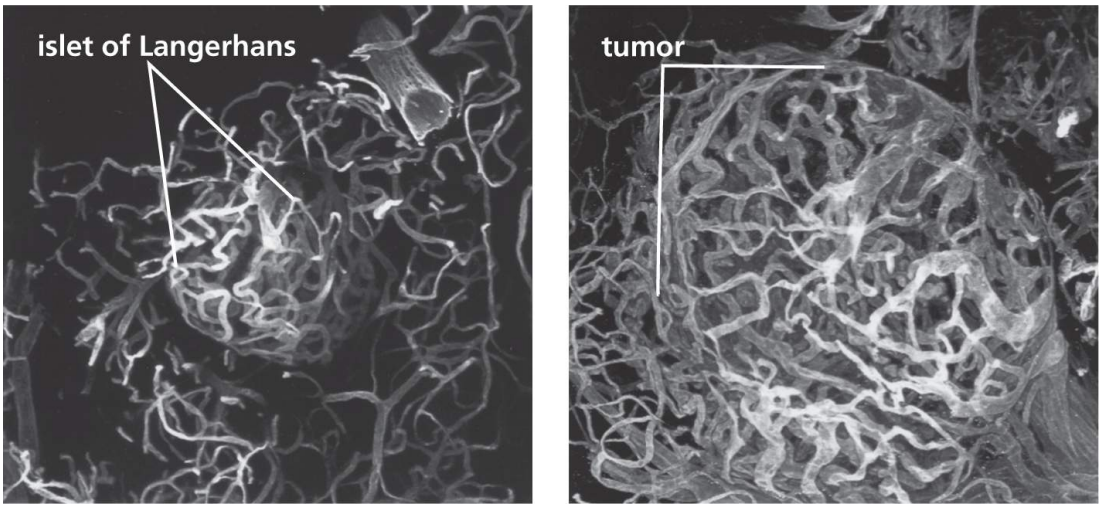
In principle, a critical barrier constraining the expansion of the tumor cell nests might be a physical one—lack of adequate space within the tissue for these cancer cells to multiply. But detailed histological analysis of these small nests of cancer cells reveals something quite different. Because these cells have not yet become angiogenic, they lack vasculature. The resulting hypoxia that they experience triggers apoptosis, which explains their high rate of attrition. (It is possible that other sub-optimal conditions within these poorly vascularized cell nests, including inadequate nutrient supply, high levels of carbon dioxide and metabolic wastes, and low pH caused by lactic acid accumulation, also contribute to the death of these cells; for example, see Figure 13.28D).

At some point in time, however, small clusters of these pre-neoplastic islet cells suddenly acquire the ability to provoke neoangiogenesis (see Figure 13.35). Once these cells learn how to induce capillaries to form nearby, they and their descendants seem to be liberated from the major constraint that has been holding back their multiplication. This sudden, dramatic change in the behavior of the small tumor masses is said to reflect the operations of the mechanism termed the angiogenic switch.

These phenomena suggest an interesting idea, really a speculation: the body purposefully denies its cells the ability to readily induce angiogenesis. By doing so, the body erects yet another impediment to block the development of large neoplasms. According to such thinking, the angiogenic switch—a clearly important step in tumor progression—represents the successful breaching of this defensive barrier and the acquisition by cancer cells of a forbidden fruit: the ability to induce blood vessel growth at will.

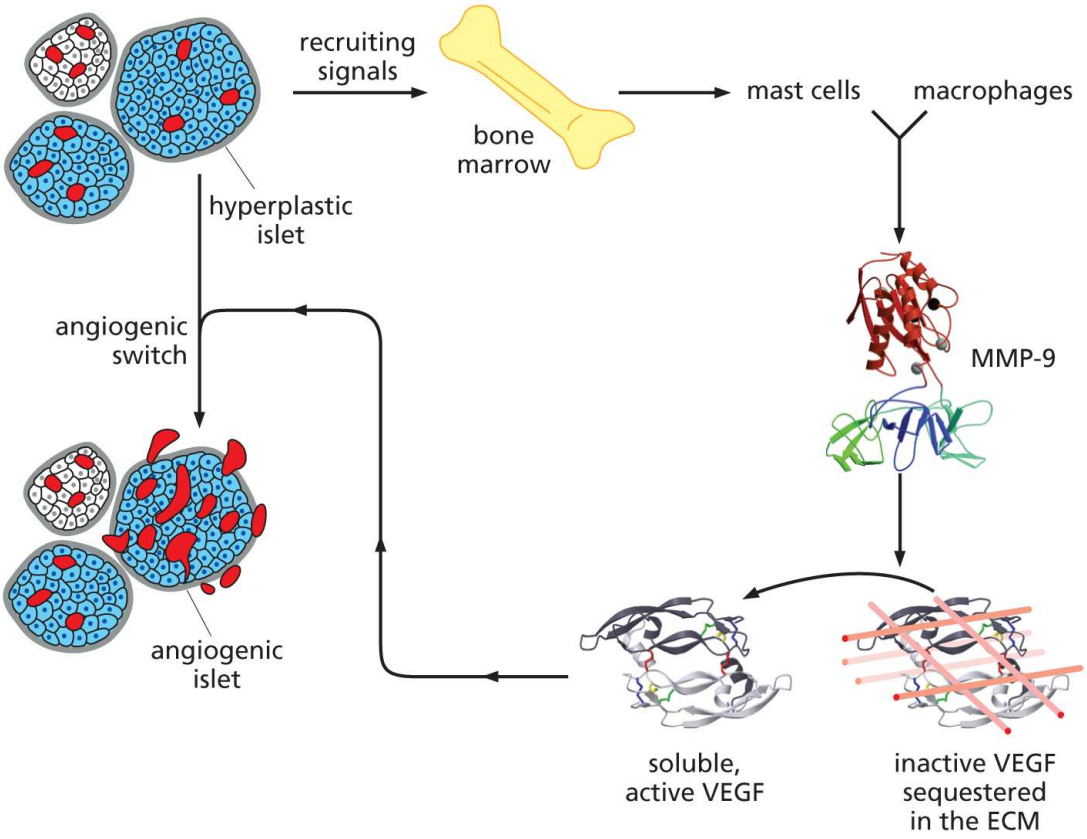
One might conclude that the angiogenic switch in these transgenic mice is driven by the premalignant β cells' suddenly acquiring the ability to express and release VEGFs. Actually, these cells have been making large amounts of VEGFs long before the angiogenic switch occurs, as do fully normal pancreatic islets. However, the VEGF molecules secreted by these β cells are efficiently sequestered by the surrounding extracellular matrix (ECM). As a consequence, the VEGF molecules are functionally inactive and thus unable to stimulate angiogenesis.

This sequestered state of the VEGF explains why the angiogenic switch in the Rip-Tag pancreatic islets is accompanied by the sudden appearance of substantial amounts of matrix metalloproteinase-9 (MMP-9; see Table 13.1). MMP-9 acts in a targeted fashion to cleave specific structural components of the ECM, thereby releasing VEGF for active signaling to nearby endothelial cells (**Figure 13.36**). This MMP-9 is synthesized and released by inflammatory cells—mast cells and macrophages—that have been attracted to the premalignant islets. Hence, in this particular tumor model, tripping of the angiogenic switch ultimately depends on an acquired ability to recruit inflammatory cells.



Two micrographs of blood vessels. The first is of a normal islet of Langerhans. The second is of one taken over by a tumor, which is significantly denser.

(A)



A flowchart. A hyperplastic islet of Langerhans sends recruiting signals that cause bone marrow to produce mast cells, which together with macrophages produce M M P-9, which convert inactive V E G F sequestered in the E C M into soluble, active V E G F. That trips the angiogenic switch, causing the hyperplastic islet to become an angiogenic islet.

(B)

Figure 13.36 The angiogenic switch and recruitment of inflammatory cells
(A) The normal islet of Langerhans (*oval area, center of left panel*) is poorly vascularized and is sustained largely through diffusion from the microvessels surrounding it. Following tripping of the angiogenic switch, there is an increase in the number of cells within the islet, caused by tumor expansion and, as seen here, a dramatic induction of vessel formation with vessels now threading their way through the islet (*right panel*). Imaging was achieved by whole-mount microscopy of lectin-perfused vessels. (B) According to the scheme presented here, a pre-angiogenic, hyperplastic islet sends signals to the bone marrow or circulation, or both (*not illustrated*), that lead to the recruitment of mast cells and macrophages. Once in the vicinity of the islet, these cells release metalloproteinases, notably MMP-9. MMP-9 then cleaves extracellular matrix (ECM) components (*light orange, orange, lower right*), liberating vascular endothelial growth factor

(VEGF) from its sequestered state. The solubilized VEGF proceeds to induce angiogenesis around the islet, thereby tripping the angiogenic switch. (A, courtesy of G. Bergers, D. Hanahan, and L.M. Coussens. See also G. Bergers, D. Hanahan and L.M. Coussens, *Int. J. Dev. Biol.* 42:995–1002, 1998. B, adapted from data in G. Bergers et al., *Nat. Cell Biol.* 2:737–744, 2000. Image of VEGF in B, from Y.A. Muller et al., *Proc. Natl. Acad. Sci. USA* 94:7192–7197, 1997. With permission from National Academy of Sciences, U.S.A.)

If the gene encoding VEGF is selectively deleted from the islet cells through genetic engineering, the islets survive and the early steps of tumor progression still proceed normally, but the angiogenic switch is never tripped. This observation reinforces the conclusion that VEGF molecules of islet cell origin play a critical role in triggering the onset of angiogenesis and that recruited stromal cells cannot compensate for this absence of VEGF by bringing in some of their own.

This scenario (see Figure 13.36B) involves heterotypic interactions among three distinct cell types: (1) the release of still-unidentified signals from the premalignant islet cells that recruit mast cells (**Sidebar 13.8**) and, quite possibly, macrophages; (2) the release of MMP-9 by these inflammatory cells to activate previously latent VEGF made by the premalignant islet cells; and (3) the proliferative response of endothelial cells to the activated VEGF. In fact, yet other cell types are likely to be partners in islet cell neoangiogenesis. Thus, the cells creating the walls around microvessels (formed by pericytes and smooth muscle cells) may be formed by progenitor cells originating in the marrow.

Sidebar 13.8 A proof that mast cells from the bone marrow play a key role in the angiogenic switch

Rip-Tag mice carrying the insulin SV40 transgene in their germ line can be bred with others that lack the Kit growth factor receptor. Kit serves as the receptor for stem cell factor (SCF), an important growth factor that triggers the development of certain subclasses of hematopoietic cells. Among other deficits, $Kit^{-/-}$ mice lack the ability to form mast cells. In Rip-Tag mice lacking Kit receptor, islet cell tumors are initiated at rates routinely observed in standard Rip-Tag mice. However, these tumors never succeed in becoming angiogenic, and the rate of cell proliferation in these small growths is compensated by an equal rate of apoptotic death. Consequently, these tumors remain very small (0.1–0.2 mm diameter).

If these mice are provided with a bone marrow transplant containing wild-type hematopoietic precursor cells, which cures their mast cell deficit, angiogenesis is initiated in the pancreatic islets, tumor cells in the islets are no longer lost through

apoptosis, and large, life-threatening neoplasms appear soon thereafter. This outcome demonstrates that the ability to provoke angiogenesis in Rip-Tag tumors depends on the actions of at least one nonendothelial component of the tumor-associated stroma—the mast cells originating in the bone marrow.

Importantly, the Rip-Tag model does not typify the angiogenic mechanisms occurring during the formation of all types of tumors. For example, in some tumors, angiogenesis appears to increase progressively, as if a controlling rheostat is gradually being turned, which contrasts with the behavior described here, in which a binary, on–off switch seems to be tripped.

Other tumors may depend on different angiogenic factors to provoke angiogenesis. For example, when transformed mouse embryonic stem (ES) cells are deprived of both copies of the VEGF-A–encoding gene, they lose almost all their power to make malignant teratomas. In contrast, transformed adult mouse dermal fibroblasts remain highly tumorigenic after they have been deprived of both copies of this gene. And the sarcomas generated by these transformed fibroblasts continue to grow even when the mice bearing them have been treated with an antibody that binds and inactivates VEGF-R2 (the primary endothelial cell receptor that confers responsiveness to both VEGF-A and VEGF-B). This lack of response is likely explained by the fact that transformed dermal fibroblasts can make a complex *mixture* of angiogenic factors—including VEGF-B, acidic, and basic fibroblast growth factors (aFGFs and bFGFs), and transforming growth factor-α (TGF-α). More generally, the deployment of multiple angiogenic factors (**Table 13.3**), often observed in advanced human cancers, complicates the development of anti-angiogenesis cancer therapies. Moreover, certain classes of tumor-associated microvessels appear to arise independently of the VEGF-driven capillary formation.

Table 13.3 Important angiogenic factors

Name	**Mol. wt. (kD)**
vascular endothelial GFs (VEGFs)	40–45
basic fibroblast growth factor (bFGF)	18
acidic fibroblast growth factor (aFGF)	16.4

Name	Mol. wt. (kD)
angiogenin	14.1
transforming growth factor-α (TGF-α)	5.5
transforming growth factor-β1 (TGF-β1)	25
tumor necrosis factor-α (TNF-α)	17
platelet-derived growth factor-B (PDGF-B)	45
granulocyte colony-stimulating factor (G-CSF)	17
placental growth factor	25
interleukin-8 (IL-8)	40
hepatocyte growth factor (HGF)	92
proliferin	35
angiopoietin	70
leptin	16

Glossary

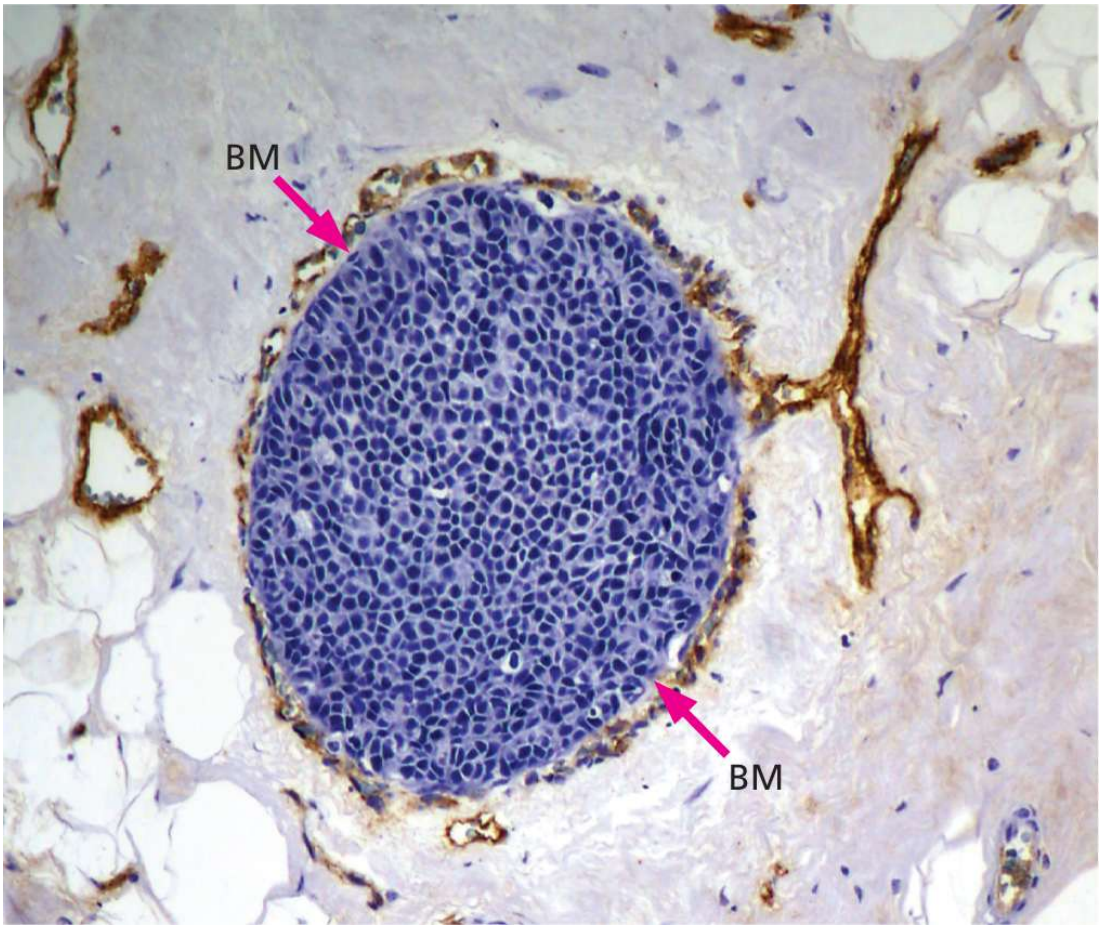
exocrine
: Referring to a gland that secretes fluids via a duct, often into the gastrointestinal tract or to the surface of the skin, rather than into the bloodstream. *Compare* **autocrine**, **endocrine**, **intracrine**, **juxtacrine**, **paracrine**.

angiogenic switch
: Shift by a mass of tumor cells from a state in which they are unable to induce neovascularization to one in which they exhibit this ability.

OceanofPDF.com

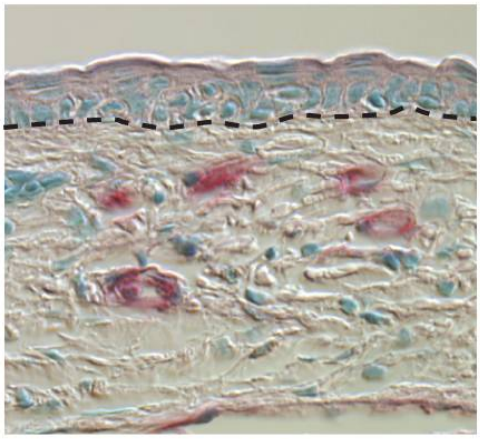
13.8 The angiogenic switch initiates a highly complex process

Angiogenesis begins in the stroma surrounding the Rip-Tag tumors long before the basement membrane has been broken down. This behavior typifies that of many tumors in both mice and humans (**Figure 13.37**). Somehow, angiogenic signals are dispatched by benign cancer cells through the porous basement membrane (BM) in order to encourage increased angiogenesis on the stromal side of this membrane. Nevertheless, this early angiogenesis is circumscribed, and it is clear that intense angiogenesis can begin only when cancer cells become invasive, penetrate the basement membrane, and acquire direct, intimate contact with stromal cells (**Figure 13.38**). This suggests that tumor invasiveness and intense angiogenesis are often tightly coupled processes. We will study tumor invasiveness in detail in the next chapter.

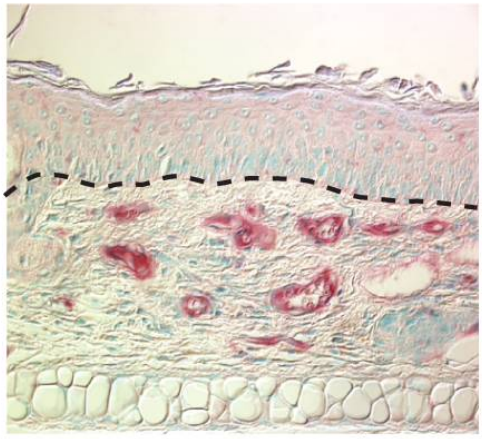


A histology image of a tumor, which is dark blue with densely packed nuclei. It is tightly contained within a basement membrane that separates the tumor from normal, lighter colored, surrounding tissue.

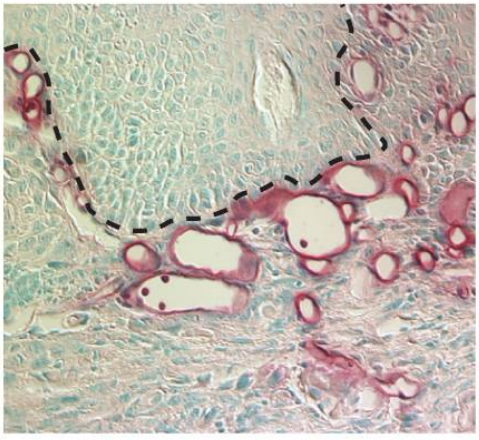
(A)



normal skin



hyperplasia



dysplasia

A sequence of histology images, labeled normal skin, hyperplasia, and dysplasia. In normal skin the epithelial layer is comparatively thin; in hyperplasia it is thickened, and in dysplasia it has become irregular, forcing the basement membrane to take on an irregular shape, as well.

(B)

Figure 13.37 Signaling through the basement membrane early in tumor progression (A) A human ductal carcinoma *in situ* (DCIS) of the breast contains a collection of carcinoma cells (*purple-blue*) that are noninvasive and therefore have not yet breached the basement membrane (BM, *arrows*) that surrounds them and separates them from the mammary stroma. As is apparent, this DCIS has nonetheless succeeded in transmitting angiogenic signals through the BM into the nearby stroma that have resulted in the growth of a small vessel (*dark brown*) that surrounds the tumor mass but does not penetrate into the tumor itself because of the continued integrity of the BM. (B) In this transgenic mouse model of skin carcinogenesis, the oncoprotein-encoding human papillomavirus (HPV) 16 early region is expressed under the control of a keratin-14 gene promoter, which ensures its expression specifically in keratinocytes of the skin (*upper panel*). In the early hyperplastic stage of tumor progression (*middle panel*), the noninvasive carcinoma cells on the epithelial side of the BM (*above*) are able to transmit signals through the BM (*dashed line*) that provoke angiogenesis on the stromal side (*below*), as evidenced by the increased density of capillaries (*red*), detected in this case through their display of the CD31 antigen. Dysplastic tissue, in which the BM (*dashed line*) has not yet been breached, shows even more intensive angiogenesis in the nearby stroma. (A, courtesy of A.L. Harris. B, from L.M. Coussens et al., *Genes Dev.* 13:1382–1397, 1999. With permission from Cold Spring Harbor Laboratory Press.)

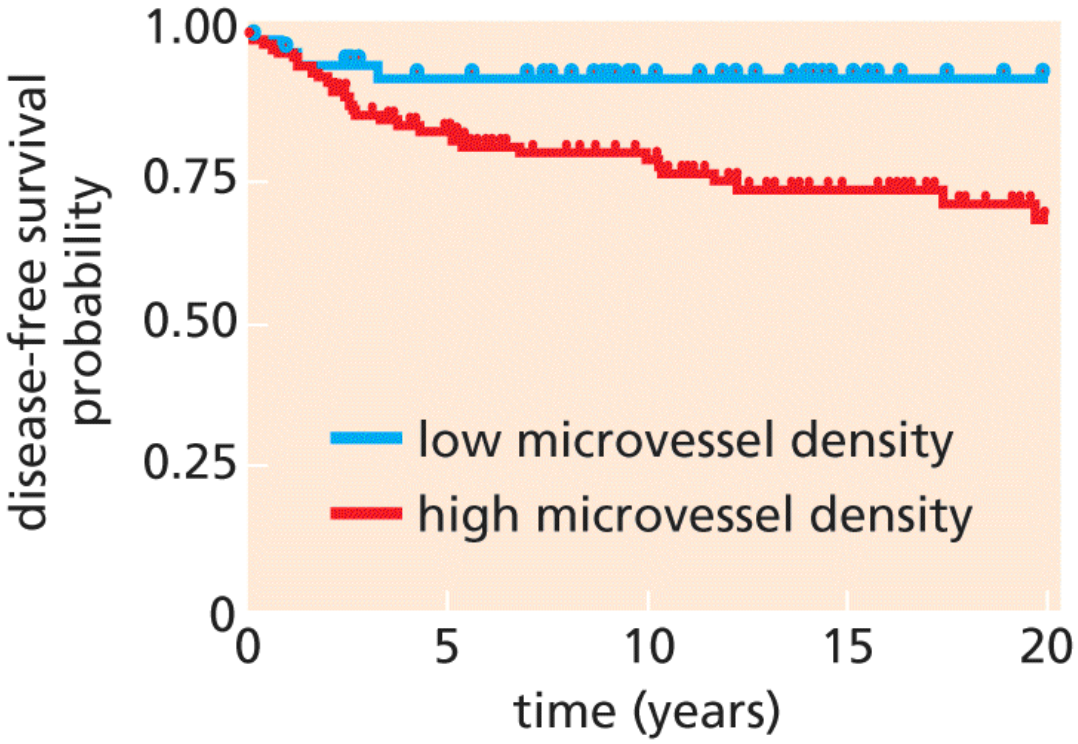
Two histology images of breast cancer–in situ on the left and invasive on the right.

(B)

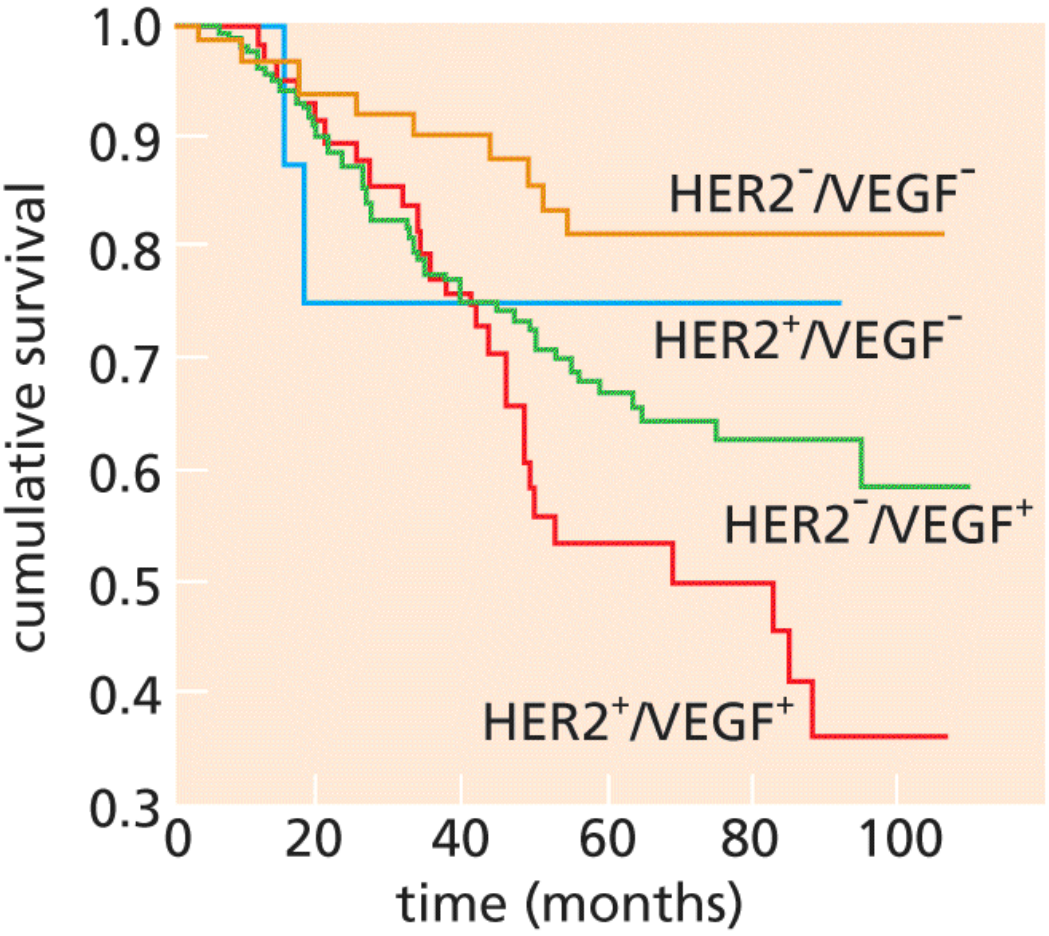
Figure 13.38 Angiogenesis before and after acquisition of invasiveness Tumor angiogenesis is circumscribed as long as human carcinomas remain benign. However, once they become invasive, the intensity of angiogenesis increases, leading to a higher density of capillaries (*brown*) threading their way through tumors. (A) The capillaries ringing a benign prostatic intraepithelial neoplasia (PIN) lesion (*left*) are far fewer than those in an invasive prostate carcinoma (*right*). (B) Similarly, those in a benign ductal carcinoma *in situ* (DCIS) of the human breast (*dark red, left panel*) are far fewer than those in an invasive ductal carcinoma (*right panel*). (Courtesy of J. Folkman.)

In many human tumor types, the density of capillaries per microscope field increases in lockstep with increasing degrees of malignancy. For example, among human breast carcinomas that have already grown to a considerable size, those that have managed to attract dense networks of capillaries into their midst are indicative, on average, of a far worse prognosis than those that are poorly vascularized (**Figure 13.39A**). Moreover, patients whose breast tumors that express large amounts of VEGF (in addition to HER2; see Figure 4.3) fare especially badly following initial diagnosis and treatment (Figure 13.39B). Altogether, these correlations suggest that the angiogenic switch is only the first of many shifts that enable tumors to become progressively more angiogenic and hence increasingly vascularized, enabling their highly aggressive behavior.



A graph of disease-free survival probability over time. With low microvessel density, the probability declines from 100% to 90% over 5 years and then remains at 90%. With high microvessel density, the probability declines from 100% to 75% within 10 years and continues to decline out to 20 years to abou 72%.

(A)



A graph of cumulative survival over time, with lines for four different genotypes that all start at 1 at time zero. The line for H E R 2 positive, V E G F negative drops abruptly from 1 to 0.75 just before the 20 month mark and then is level at 0.75. The other three lines drop more gradually. The line for H E R 2 negative, V E G F negative drops steadily to 0.8 at 50 months and then is level. The line for H E R 2 negative, V E G F positive drops steadily to less than 0.6 at 100 months. The line for H E R 2 positive, V E G F positive drops steadily to less than 0.4 at 100 months.

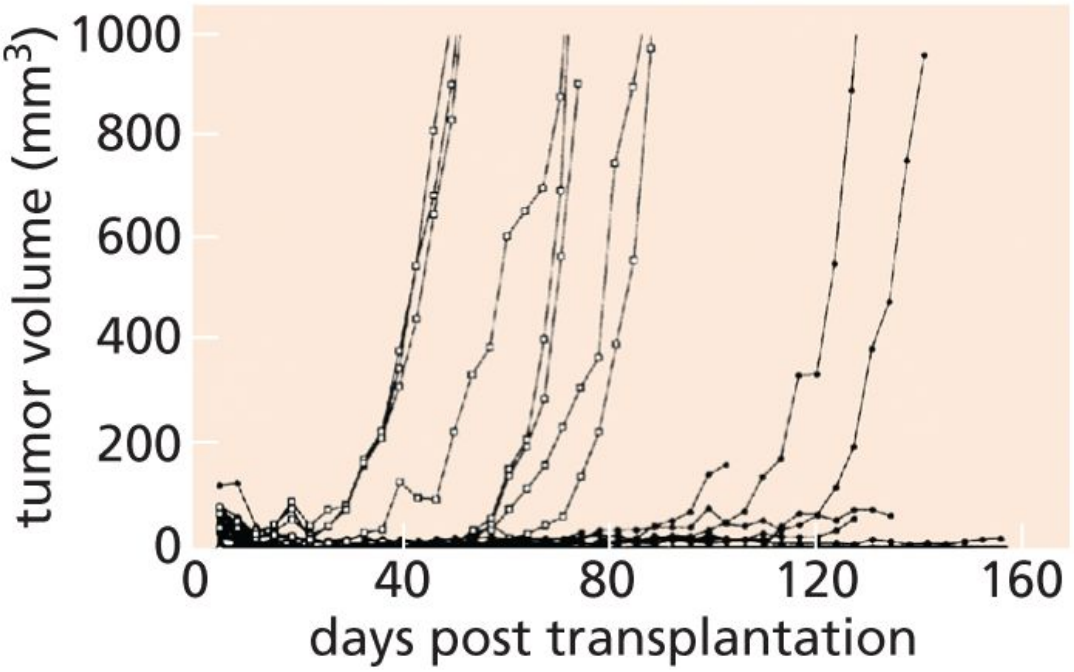
(B)

Figure 13.39 Clinical outcomes and the intensity of angiogenesis (A) Breast carcinomas were analyzed for the density of capillaries, which was determined as the number of microvessels per microscopic field. This Kaplan–Meier graph demonstrates that those patients whose tumors had a high microvessel count (*red curve*) had a markedly lower probability of disease-free survival in the 20 years following initial diagnosis than those whose tumors had a low microvessel count (*blue curve*). (B) As indicated earlier (see Figure 4.3), breast cancer patients

whose tumors overexpress HER2/Neu have a markedly poorer prognosis than those whose tumors do not. In the group analyzed here, all patients showed metastatic cancer cells in one or more of the lymph nodes draining the breast. The differences in survival are even more dramatic when the levels of VEGF produced by their tumors are also considered. In this relatively small clinical study, more than 80% of patients whose tumors expressed low, basal levels of both HER2/Neu and VEGF ($HER2^{-}$ $VEGF^{-}$) were alive 8 years after diagnosis; in contrast, only about 35% of the patients whose tumors expressed elevated levels of both HER2/Neu and VEGF ($HER2^{+}$ $VEGF^{+}$) survived this long. (A, from R. Heimann and S. Hellman, *J. Clin. Oncol.* 16:2686–2692, 1998. With permission from American Society of Clinical Oncology. B, from G.E. Konecny et al., *Clin. Cancer Res.* 10:1706–1716, 2004. With permission from American Association for Cancer Research.)

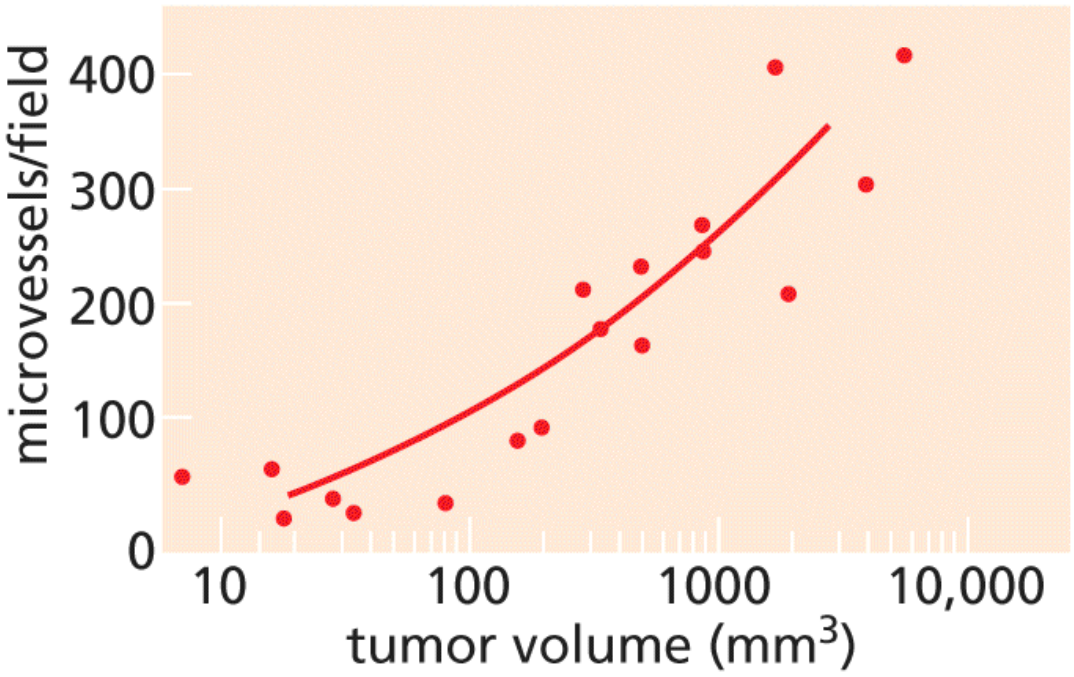
These striking correlations are actually susceptible to two alternative interpretations. It is possible that intense vascularization enables cancer cells to grow more aggressively, thereby leading to poor clinical outcomes. Alternatively, intense angiogenesis might be only a reflection of an underlying aggressive phenotype but not be causally involved in driving high-grade malignancy. Available clinical data do not allow a clear resolution between these alternatives.

We have spoken of the angiogenic switch without knowing which carcinoma cells within a tumor drive this shift; it might represent a concerted shift of all cells within a tumor or, alternatively, the actions of a small number of especially aggressive cells. In fact, analyses of cells isolated from explanted human tumors indicate great heterogeneity in the angiogenic powers of different subpopulations of cancer cells within a given tumor, with some cancer cells being highly angiogenic, whereas others are poorly so. Even within tumor cell lines, individual cancer cell subpopulations show greatly differing angiogenic and tumorigenic powers when engrafted *in vivo* (**Figure 13.40A**). The strong positive correlation between the microvessel density and tumor volume (Figure 13.40B) provides additional evidence, albeit of a correlative nature, that neoangiogenesis is a critical driving force in tumor growth. Also, these observations introduce yet another idea into our thinking: that within a tumor mass, long after the tripping of the angiogenic switch, the weakly angiogenic cancer cells rely on help from their friends—their strongly angiogenic neighbors—in order to acquire adequate microvasculature.



A graph with tumor volume in cubic millimeters on the vertical axis and days post-transplantation on the horizontal axis. Curves representing roughly exponential growth rise steeply at a range of times–as early as 40 days post-transplantation and as late as 130 days. Most of these curves achieve roughly 1000 cubic millimeters.

(A)



A scatter plot with microvessels per field on the vertical axis and tumor volume in cubic millimeters on the logarithmically scaled horizontal axis. The regression curve through the plotted points is slightly curved upward. It begins at the point 100, 100 and ends at the point 3000, 350.

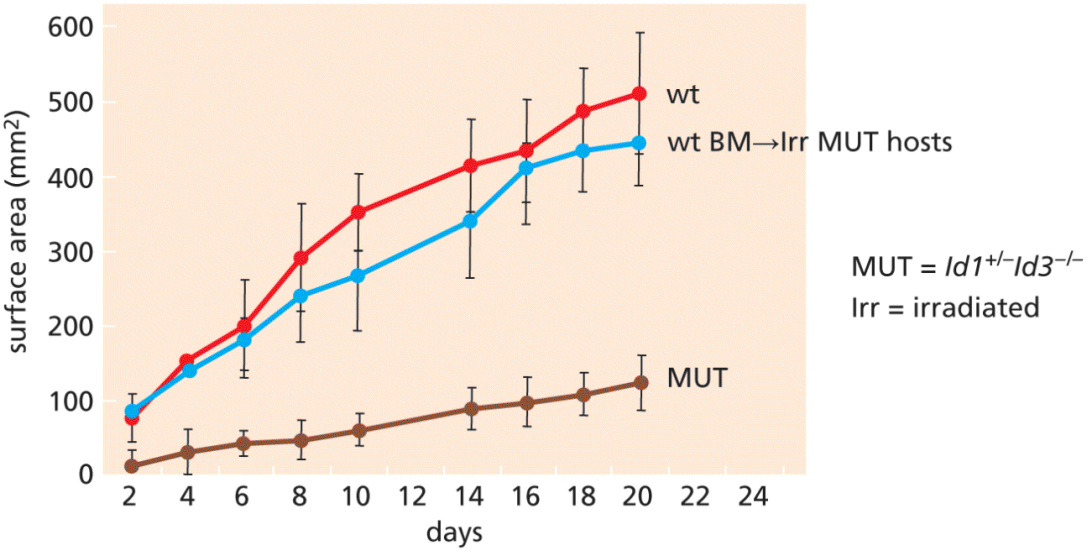
(B)

Figure 13.40 Heterogeneous degrees of vascularization within a tumor cell population (A) When a population of cells in a human liposarcoma cell line was subjected to single-cell cloning (in which all the cells in each resulting cell clone derive from a single common ancestor), the various cloned cell populations show greatly differing abilities to form tumors (*individual curves*) when implanted into immunocompromised host mice. (B) When the resulting tumors were analyzed for microvessel density (microvessels per microscopic field) and tumor volume, plotted logarithmically here, it appears that they have greatly differing angiogenic capabilities and that angiogenesis behaves as if it were a rate-limiting determinant of overall tumor growth. (From E.G. Achilles et al., *J. Natl. Cancer Inst.* 93:1075–1081, 2001. With permission from Oxford University Press.)

The angiogenic switch is associated with processes that extend far beyond the immediate vicinity of a tumor. Thus, as mentioned earlier, neovascularization relies in part on the recruitment of endothelial progenitor cells (EPCs) that originate in the marrow and travel via the circulation to the tumor. In fact, VEGF released into the

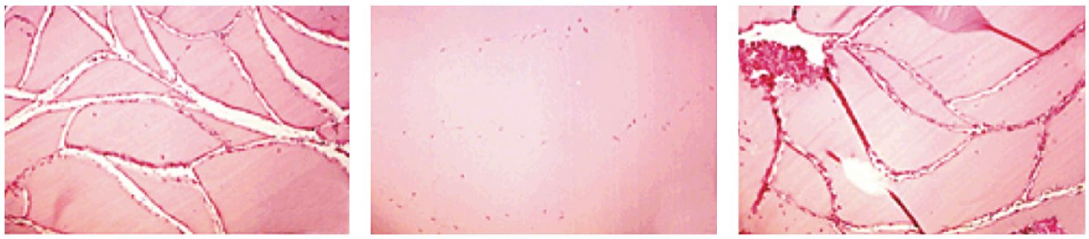
circulation by a tumor stimulates the production of EPCs in the bone marrow and their release into the general circulation; in addition, it helps to attract circulating EPCs to the tumor mass. Detailed analyses have shown that the proportion of endothelial cells derived from circulating EPCs (versus those arising from nearby capillaries) varies greatly from one type of tumor to another.

The importance of EPC recruitment is dramatically illustrated by the behavior of mice that lack one copy of the *Id1* gene and both copies of the *Id3* gene. These *Id* genes encode transcription factors regulating differentiation of a variety of cell types, often inhibiting development of tissue-specific differentiation programs (see Figure 8.25C). Many of these mutant mice survive to adulthood and show a very peculiar phenotype: they are defective in neoangiogenesis and will not permit several types of engrafted tumors to grow (**Figure 13.41A**).



A line graph describing surface area as a function of time in days for three different populations of mice. In wild-type mice, tumors grow from zero surface area at time zero to 500 square millimeters in 20 days. In mutant mice, tumors grow to only about 120 square millimeters in 20 days. In mutant mice with transplanted, wild-type mice bone marrow, tumors grow to about 450 square millimeters in 20 days.

(A)



A visual comparison of vascularization in three types of mice. In mutant mice there is no vascularization to be seen. In wild-type mice and in mutant mice with wild-type bone marrow, there is visible vascularization in the sample.

(B)

Figure 13.41 Defective tumor angiogenesis in *Id1*$^{+/-}$*Id3*$^{-/-}$ mice Mutant mice (Id MUT), which lack three of four *Id* gene copies (and have an *Id1*$^{+/-}$*Id3*$^{-/-}$ genotype), show impaired mobilization of endothelial precursor cells (EPCs) from the bone marrow and thus impaired recruitment of circulating EPCs into tumors that these mice may carry. (A) Wild-type (wt) mice bearing Lewis lung carcinoma (LLC) cells develop rapidly growing tumors (*red curve*), whereas those of the mutant strain (Id MUT) are unable to support vigorous tumor growth (*brown curve*). This defect is essentially reversed if the bone marrow (BM) of the mutant mice is eliminated by irradiation and replaced with transplanted wild-type bone marrow (*blue curve*, wt BM → Irr MUT), indicating that the recruitment of bone marrow–derived cells is defective in the mutant mice and is responsible for the inability of the tumor to grow in them. (B) This defective recruitment can be further localized by the use of plugs of Matrigel (an extracellular matrix material) that have been impregnated with VEGF and are then implanted subcutaneously. These plugs are able to recruit neovasculature when implanted in wild-type mice (*left*) but not in the mutant mice (*center*). However, if the mutant mice receive a graft of wild-type bone marrow cells, the defect is cured and now angiogenesis within these plugs is comparable to that seen in wild-type mice (*right*). (From D. Lyden et al., *Nat. Med.* 7:1194–1201, 2001. With permission from Nature.)

The defect in these *Id1*$^{+/-}$*Id3*$^{-/-}$ mice can be cured by transplanting wild-type hematopoietic stem cells into their bone marrow. Alternatively, the subset of bone marrow stem cells whose production is normally spurred by high levels of circulating VEGF can be harvested from a wild-type mouse and transplanted into the bone marrow of *Id1*$^{+/-}$*Id3*$^{-/-}$ mice. These mice soon generate large numbers of endothelial precursor cells (EPCs) in their circulation and, following implantation of cancer cells, develop rapidly growing tumors. Taken together, these observations indicate that these

tumors rely on VEGF to mobilize EPCs from the bone marrow (Figure 13.41B) and to recruit the resulting circulating cells into the tumor stroma. These findings, as well as others demonstrating the recruitment of myofibroblast precursors into tumor stroma (see Section 13.3), show that primary tumors can extend their reach throughout the body long before they metastasize.

13.9 Anti-angiogenesis therapies have been employed to treat cancer

In finely tuned physiological processes, the actions of positive effectors must be counterbalanced by negative regulators. We have read much about the positive effectors of angiogenesis, such as VEGF and bFGF, as well as a variety of others that conspire to promote the assembly of normal vasculature (see Table 13.3). However, their antagonists have remained offstage until now.

Anti-angiogenic mechanisms clearly play key roles in the creation and maintenance of the normal vasculature. During the process of wound healing, for instance, the burst of angiogenesis that is required to repair the wound site must be shut down once the newly formed capillaries have reached a density that suffices to support normal tissue function. This shutdown is achieved, at least in part, by reducing the ongoing hypoxia-induced production of VEGF. In addition to the decline of pro-angiogenic factors, there are also a host of naturally anti-angiogenic proteins that reside within normal tissue and aid in actively shutting down angiogenesis. Their origins and mechanisms of action are described in detail in **Supplementary Sidebar 13.8**. At least two dozen anti-angiogenic molecular species involved in regulating various steps of vascular morphogenesis have been identified, as described in this Supplementary Sidebar.

The equilibrium created by the counterbalancing pro- and anti-angiogenic factors in each tissue ensures that tissues are supplied with the proper density of microvessels required to sustain their physiological activities. For those researchers intent on developing new types of anti-cancer therapeutics by inhibiting neoangiogenesis, this complexity offers multiple targets for intervention. Thus, highly targeted therapies may be devised to inhibit the several cell types that participate in angiogenesis as well as the multiple signaling channels through which they intercommunicate. Because tumors depend absolutely on angiogenesis to grow above a certain size (~0.2 mm diameter; see Figure 13.28), any successes in blocking angiogenesis or in undoing the products of angiogenesis should represent a highly effective strategy for treating cancer. Microscopic tumors should be prevented from growing larger, and larger tumors should collapse once their already-established blood supply disintegrates.

In principle, anti-angiogenesis therapies have a major advantage over those directed at the neoplastic cells within tumors. As we will learn in Chapter 17, one of the great frustrations of anti-cancer drug development is that, sooner or later, tumors that initially respond to a drug treatment become refractory (resistant) to further treatment by the drug. Almost always, these relapses can be traced to the emergence of drug-

resistant genetic variants within tumor cell populations (see Figure 11.16); these variants arise at an almost-predictable frequency and proceed to proliferate and regenerate aggressively growing tumor masses. The emergence of these drug-resistant variants seems to be one of the consequences of the highly unstable genomes of cancer cells (described in Chapter 12) and their resulting ability to spawn mutants at high frequency.

In contrast, many anti-angiogenesis therapies are directed at killing the genetically *normal* cells that have been recruited into tumor masses and co-opted by the cancer cells to do their bidding. There is every reason to believe that the endothelial cells within tumors possess normal, stable genomes and are therefore stable phenotypically. Hence, drug therapies directed against these cells—attractive targets of anti-angiogenic therapies—are unlikely to select for the outgrowth of drug-resistant genetic variants, and tumors should not, in theory, become refractory to anti-angiogenic drug therapy.

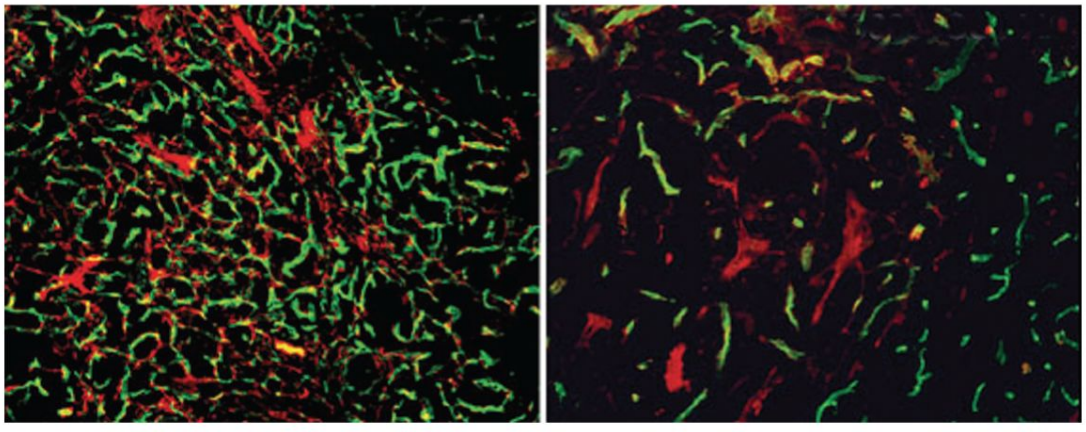
This interest in treating tumor-associated endothelial cells is further heightened by the peculiar biology of these cells. They are continually being formed and lost within tumor masses, with lifetimes measured as short as a week, whereas their counterparts that line normal blood vessels elsewhere in the body rarely divide and have lifetimes that are measured in hundreds of days, some being as long as seven years. Cycling cells (that is, cells racing around the active cell cycle) are, almost always, far more sensitive to drug-induced killing than are quiescent cells. For this reason, cytotoxic therapies directed against endothelial cells should have drastic effects on the tumor-associated neovasculature, while leaving blood vessels located elsewhere in the body unscathed.

An experiment reported in 1991 provided one of the earliest indications of the promise of another type of anti-angiogenic therapy. In this work, cancer cells were engineered to release a modified basic fibroblast growth factor, which greatly increased their tumorigenicity in mice, simply because this bFGF strongly enhanced the angiogenic powers of these cells. Use of a monoclonal antibody that specifically bound and neutralized this modified bFGF (but had no effect on the endogenous bFGF of the mouse) blocked the angiogenesis by tumor cells and led to a dramatic reduction in tumor volume. Within two years, a similar experiment was performed with an anti-human–VEGF monoclonal antibody. It succeeded in blocking the proliferation of two human sarcoma cell lines as well as a glioblastoma in Nude (immunocompromised) mouse hosts.

An even more effective version of this therapy came a decade later with the use of a monoclonal antibody that binds and neutralizes VEGF-A, which blocks new vessel formation and destabilizes recently formed ones. This antibody, termed variously Avastin or bevacizumab, showed significant efficacy in certain large-scale clinical trials. For example, patients with metastatic colon carcinoma who were treated with

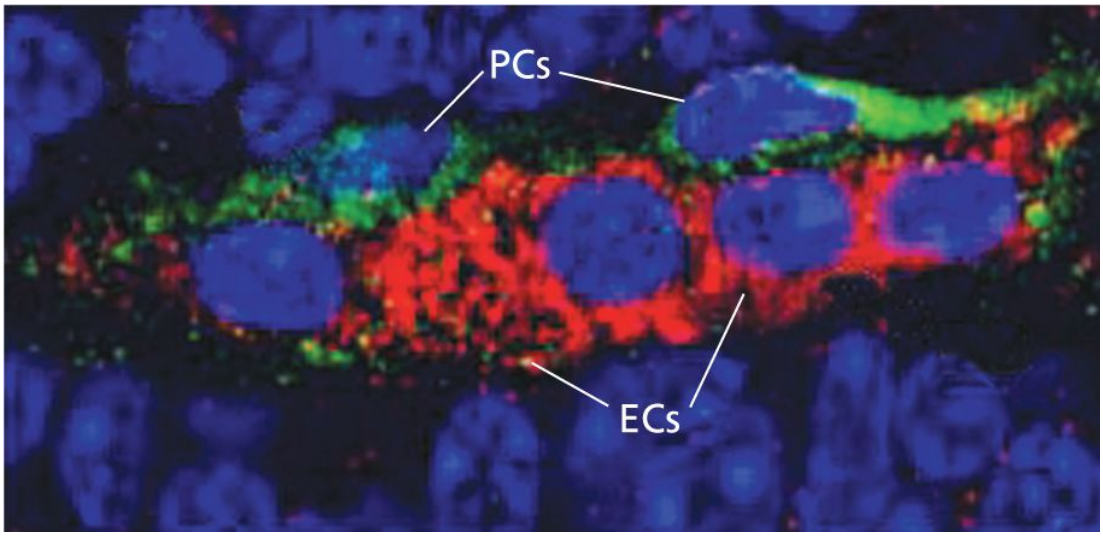
this antibody plus chemotherapy (the drug 5-fluorouracil) survived, on average, four months longer than patients treated with chemotherapy alone, and the addition of Avastin to conventional chemotherapy extended the survival of patients with non-small-cell lung carcinoma (NSCLC) by about two months. Similarly, Avastin could retard the progression of renal cell carcinomas in patients, but in the end had no effect on their long-term survival. It is plausible that the widely observed synergistic effects of Avastin with conventional chemotherapeutic drugs derive from the ability of this VEGF-A inhibitor to normalize tumor-associated vasculature (see **Supplementary Sidebar 13.7**), thereby greatly facilitating the delivery of drugs to the tumor parenchyma. By 2020, 3.5 million cancer patients worldwide had received this monoclonal antibody as part of their therapy, a stunning testimonial to its widely recognized powers in treating diverse types of human tumors. For many of the cancer types where it is currently being employed, addition of Avastin to existing approved chemotherapeutic regimens leads to a significant slowing of disease progression. It often extends survival, but it does not significantly increase overall survival.

The most informative preclinical studies of angiogenic inhibitors have come from using synthetic receptor inhibitors in the transgenic Rip-Tag model of pancreatic islet tumorigenesis described in Figure 13.35. Two types of low–molecular-weight synthetic compounds have been used in attempts to block various stages of islet tumor progression (**Figure 13.42**). One of these drugs is directed against the VEGF-R2, which is the main receptor driving angiogenesis. By inhibiting the tyrosine kinase of this RTK, the agent termed SU5416 should mimic the effects of Avastin, that is, both should be able to shut down VEGF signaling. Drugs of a second class, such as an agent termed SU6668, are directed primarily against the tyrosine kinase of the PDGF receptor. Recall from Section 13.1 that the role of PDGF in recruiting pericytes and smooth muscle cells to growing capillaries indicated that these mural cells are highly important for consolidating and strengthening recently formed capillaries.



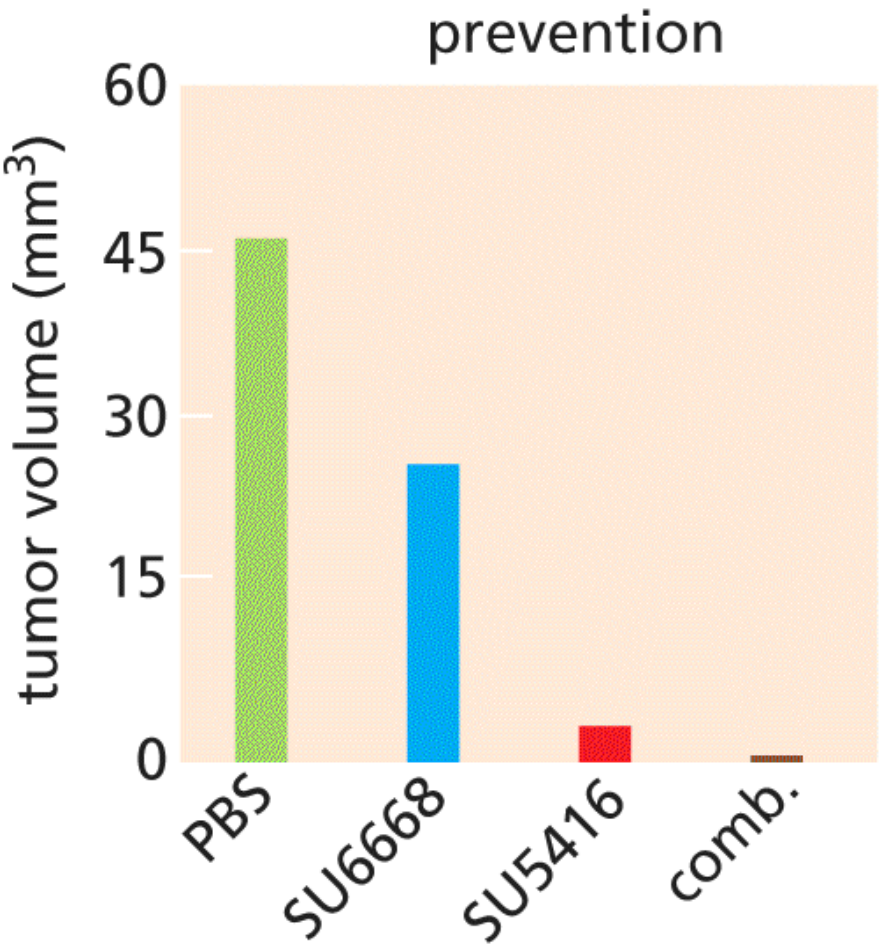
Two fluorescence microscopy images. The one on the left, labeled untreated control, contains more green patterning and red streaks than the one on the right, labeled S U 66 68 plus S U 54 16 treatment.

(A)



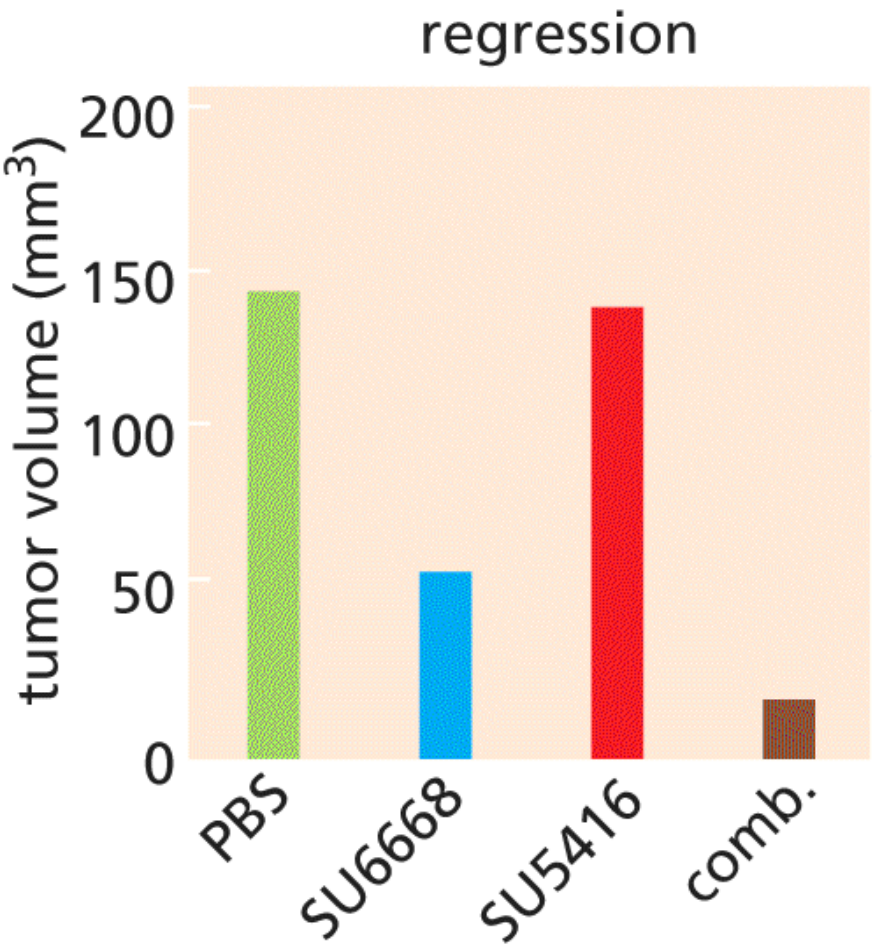
A fluorescence microscopy image showing two pericytes, which are green with blue nuclei, adhering to a row of four endothelial cells, which are red with blue nuclei.

(B)



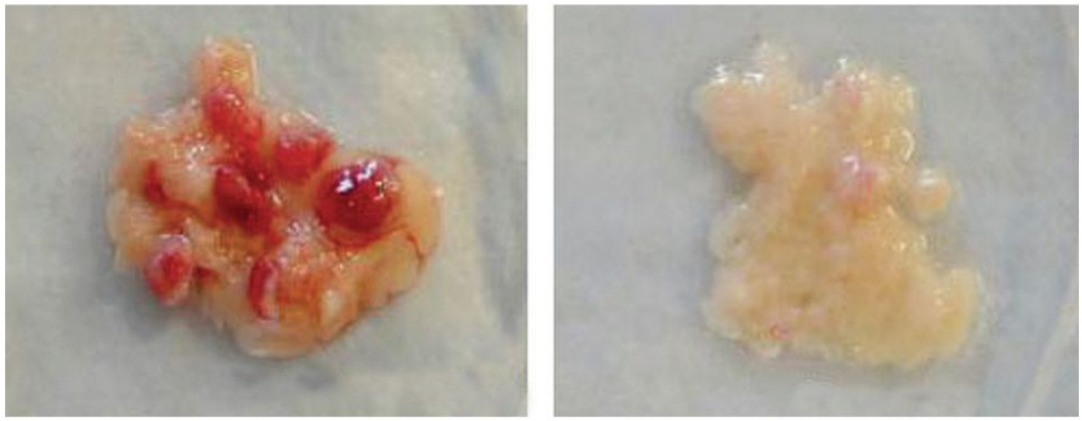
A bar graph labeled prevention that reports tumor volume under four different conditions: 46 cubic millimeters for P B S, 27 for S U 66 68, 3 for S U 54 16, and negligible size for combined.

(C)



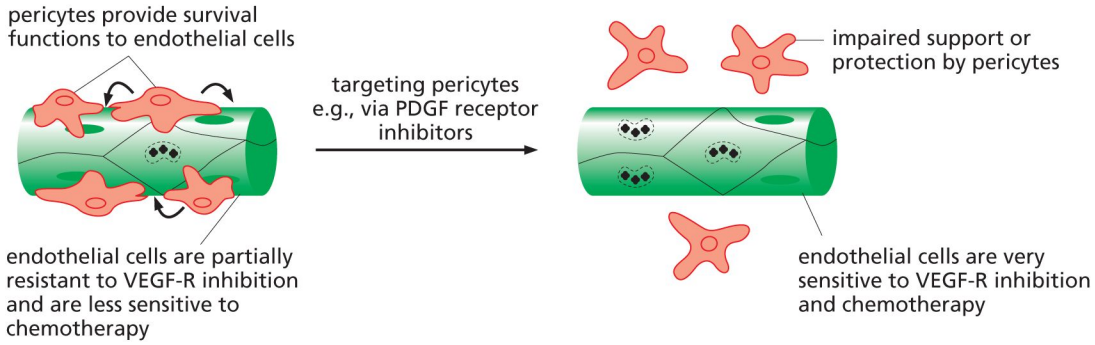
A bar graph labeled regression that reports tumor volume under four different conditions: 145 cubic millimeters for P B S, 50 for S U 66 68, 140 for S U 54 16, and 10 for combined.

(D)



Two photographs of a lab-grown tissue sample. In the first image, labeled tumors at 13.5 weeks, the sample is pink with many bright red tumors. In the second image, labeled plus 3.5 weeks treatment, the tumors have disappeared and only pale pink tissue remains.

(E)



A schematic summary of a process. Initially, pericytes are attached to endothelial cells that form the walls of a capillary. The pericytes provide survival functions to the endothelial cells, which are partially resistant to V E G F-R inhibition and are less sensitive to chemotherapy. After targeting of pericytes, for example, via P D G F receptor inhibitors, there is impaired support or protection by pericytes, which have detached from the endothelial cells. Now the endothelial cells are very sensitive to V E G F-R inhibition and chemotherapy.

(F)

Figure 13.42 Angiogenesis inhibitors as treatments of islet cell carcinogenesis
The Rip-Tag transgenic mouse model of pancreatic islet cell carcinogenesis (see

Figure 13.35) makes possible the testing of anti-angiogenic pharmacological inhibitors. (A) The treatment of mice bearing established angiogenic islet tumors (*left*) for 4 weeks with the PDGF receptor inhibitor SU6668 plus the VEGF-R inhibitor SU5416 results in regression of the vasculature (*right*). The lumina of the capillaries are labeled *light green* and the associated pericytes are labeled *red*. (B) The actions of the SU6668 PDGF-R inhibitor could be traced specifically to its effects on the pericytes, which act as support cells for the endothelial cells. In this image, an antibody reactive with the PDGF-R reveals that the only cells within the islets expressing this receptor (*green*) are the pericytes (PCs) that are closely associated with the endothelial cells (ECs, *red*). Nuclei are stained *blue*. (C) Although neither the SU6668 PDGF-R TK inhibitor (*blue bar*) nor the SU5416 VEGF receptor TK inhibitor (*red bar*) was able, on its own, to fully prevent the formation of such tumors (being applied before tumors became apparent), the two agents applied in concert (combined, *brown bar*) succeeded in doing so. PBS, phosphate-buffered saline control (*green*). (D) In an attempt to cause regression of already-formed tumors, SU5416 and SU6668 were introduced either singly or in combination into 12-week-old Rip-Tag mice and the size of tumors was measured 4 weeks later. Although the SU5416 VEGF-R antagonist on its own (*red bar*) showed only minimal reduction of tumor volume, the SU6668 PDGF-R antagonist showed greater effects (*blue bar*), and a combination of the two applied together (*brown bar*) functioned synergistically to reduce overall tumor volume by approximately 85%. This indicates, once again, that antagonists of the endothelial cells (which depend on the VEGF-R) together with antagonists of the supporting pericytes (which depend on the PDGF-R) can act synergistically in anti-angiogenic therapy. (E) When 13.5-week-old mice with substantial pancreatic islet tumors (*red growths*, *left*) are treated for another 3.5 weeks with this combination therapy, their tumors largely regress (*right*). (F) A schematic summary of these and other observations indicates that endothelial cells depend on closely apposed pericytes for various types of biological support. Inhibition of PDGF signaling causes dissociation of pericytes from endothelial cells and renders the latter sensitive to various types of subsequent therapy, including inhibition of VEGF-R function. This emphasizes that anti-angiogenesis therapy is most effective when two synergistically acting treatments are applied. (A, B, and E, from G. Bergers et al., *J. Clin. Invest.* 111:1287–1295, 2003. With permission from American Society for Clinical Investigation. C and D, courtesy of D. Hanahan. F, from K. Pietras and D. Hanahan, *J. Clin. Oncol.* 23:939–952, 2005. With permission from American Society for Clinical Oncology.)

SU5416, the anti-VEGF-R agent, was able to block 90% of the early-stage, dysplastic islets from undergoing the angiogenic switch, thereby holding them to a small size and a noninvasive state (see Figure 13.42C). However, it had no effect on late-stage, well-

established tumors, which continued to progress despite its presence in equally high concentrations. Hence, in the early stages of angiogenesis, VEGF signaling plays a critical role, whereas later on, this process seems to become increasingly independent of VEGF.

The anti-PDGF receptor agent, SU6668, had a far weaker effect on preventing dysplastic islets from undergoing the angiogenic switch, reducing by about half the islets that did so (see Figure 13.42C). But it was far more potent than the anti-VEGF-R drug in treating the late-stage, advanced tumors, reducing their size by about half and substantially reducing their vascularity (see Figure 13.42D). Importantly, the only cells expressing PDGF-R in and near these tumors were the capillary-associated pericytes and related smooth muscle cells (see Figure 13.42B), indicating that these mural cells were the targets of SU6668 action. Indeed, microscopic examination confirmed that SU6668 had prevented these mural cells from associating with and reinforcing the capillary tubes formed by endothelial cells. Together, these experiments showed that the initial steps of angiogenesis could proceed reasonably well without PDGF receptor function, but that later in tumor progression, PDGF signaling, and thus the involvement of mural cells, became increasingly important to angiogenesis and growth of the tumor masses.

Combination therapy using the two agents proved to be a highly potent way of intervening at various stages of tumor formation (see Figure 13.42C and D). Thus, simultaneous inhibition of both VEGF and PDGF receptors prevented angiogenic switching, holding virtually all (>98%) islets at a pre-angiogenic stage. This drug combination blocked the further expansion of small, already-established angiogenic tumors by 90% and caused an approximately 80% regression of large tumors, as did another PDGF-R inhibitor, the drug Gleevec (discussed in Chapter 17). In some mice, these combination drug therapies held already-formed tumors to a small size for as long as two months (see Figure 13.42E).

These observations indicate that the most effective ways of inhibiting angiogenesis and thus blocking tumor progression are likely to depend on targeting several of the cell types that construct the tumor-associated vasculature (see Figure 13.42F). Indeed, targeting only the endothelial cells yielded only a temporary regression of microvessels: when anti-VEGF therapy is halted, these vessels rapidly regenerate, often growing back in the hollow sleeves formed by the basement membranes and pericytes that are left behind after endothelial cells have succumbed to anti-VEGF therapy.

Of additional interest, neither of the agents described above—neither SU5416 nor SU6668—is currently being used clinically, having been abandoned because of limited efficacy in phase II or phase III clinical trials and showing once again the limited powers of mouse models of cancer pathogenesis to predict human clinical responses.

Still, the very real clinical benefits afforded by Avastin treatment demonstrate unequivocally that tumor growth can be constrained by treating the tumor-associated stroma rather than the neoplastic cells themselves. Since these successes, a number of other anti-angiogenic therapies have been approved (**Table 13.5**). Moreover, the actions of some of the naturally occurring angiogenesis inhibitors described in **Supplementary Sidebar 13.8** have been tested in various pre-clinical and clinical research programs, as described in **Supplementary Sidebar 13.9**. Of note, a number of the therapies listed in Table 13.5 have additional, alternative modes of action in addition to their demonstrated anti-angiogenic effects. In addition, it is worth noting that oncologists have unknowingly employed a treatment strategy—radiotherapy—whose clinical effects may have resulted from anti-angiogenic mechanisms (**Supplementary Sidebar 13.10**). As attractive as these anti-angiogenic strategies are, it is clear that tumors can develop strategies to resist these therapies and generate clinical relapses in patients whose neoplasms were initially responsive (**Sidebar 13.9**).

Table 13.5 Anti-angiogenic drugs approved for clinical use—2018[a]

Treatment	**Target/mechanism**	**Cancer type**
Avastin (Bevacizumab)	MoAb against VEGF	OvCa, CRC, RCC, BrCa, prost., NSCLC, GBM
EYLEA (Aflibercept)	VEGFR1/VEGR2 fusion	CRC, prost., NSCLC, SCLC
Erbitux (Cetuximab)	MoAb against EGFR	CRC, gastr., HNSCC
Endostar (endostatin)	endog. inhibitor	NSCLC, mel. NPC, CRC
Nexavar (Sorafenib)	inhib. of VEGFR, PDGFR, Raf	HCC, thyr., OvCa, RCC
Sunitinib/Sutent	inhib. of RTKs	RCC, NSCLC, HCC, prost.

Treatment	Target/mechanism	Cancer type
Sprycel (Dasatinib)	inhib. of Src TKs,Bcr/Abl	CML, mel., ACC
Iressa (gefitinib)	inhib. of EGFR	NSCLC, HNSCC, esoph.
Tarceva (Erlotinib)	inhib of EGFR	HCC, panc., NSCLC
Votrient (pazopanib)	inhib. of VEGFR, PDGFR, Kit	RCC, STS, OvCa, thyr.

Sidebar 13.9 Tumors may outsmart even the best anti-angiogenic therapies

Much of the allure of anti-angiogenic therapies comes from the likelihood that the cells being targeted, notably the endothelial cells, are unlikely to generate drug-resistant variants. The complexity of heterotypic signaling may, however, allow tumors to circumvent even the cleverest anti-angiogenic therapies. Imagine, for example, that we devise a strategy to block the VEGF signaling that is so critical for the formation of new vessels in a tumor and their subsequent maintenance (because VEGF is required for endothelial cell survival). A tumor treated in this way should rapidly collapse because its capillary beds will disintegrate. Indeed, just such a response has been observed in Rip-Tag mice (see Figure 13.42) that developed pancreatic islet tumors: when treated with an anti-VEGF-R2 antibody, their tumors regressed by more than 50%. However, the residual, surviving tumor cells responded by spawning variants that acquired the ability to produce elevated levels of fibroblast growth factors (FGFs), which are also potent angiogenic factors (see Table 13.3). These growth factors then supplanted VEGF as the main conveyor of signals from the islet tumor to the endothelial cells and succeeded in triggering the regeneration of vasculature and, in turn, the rebirth of vigorously growing tumors. Accordingly, truly effective anti-angiogenesis strategies will require the inhibition of multiple angiogenic pathways.

Anti-angiogenesis therapies are also attractive because of their potential selectivity for killing the proliferating endothelial cells within tumors, since many blood vessels in

these growths seem to be in a constant state of formation and collapse and are therefore susceptible to cytotoxic drugs that may leave the quiescent endothelial cells in normal tissues untouched. For example, dramatically contrasting growth states of normal and tumor-associated blood vessels can be seen in many mouse models of cancer, in which engrafted tumors expand rapidly. However, it is possible that many of the vessels in slowly growing human tumors may exist for years and therefore may have ample time to consolidate and mature into robust, well-structured vessels in which the endothelial cells turn over slowly. These tumor-associated vessels may then be as resistant to anti-angiogenic drugs as the normal blood vessels elsewhere in the body. Yet another possible source of resistance to existing anti-angiogenic therapies may derive from mechanisms that tumors have to assemble microvessels from cells other those used conventionally by tumors, as described in Sidebar 13.5. These and other mechanisms of acquired resistance to anti-angiogenesis therapies are summarized in **Table 13.4**.

Table 13.4 Alternative mechanisms of acquired resistance to anti-angiogenesis therapies

EC radioresistance: Hypoxic activation of HIF-1 renders ECs resistant to irradiation.
Vascular mimicry: A fraction of tumor vessels are lined by malignant cells and are thus unresponsive to anti-angiogenic agents. Similarly, certain types of tumor stem cells may differentiate into endothelial-like cells (see Figure 13.23).
Angiogenic switch: The outgrowth of tumor cell clones expressing elevated levels of certain angiogenic factors may be naturally favored at advanced stages of tumor progression or may emerge in response to anti-angiogenic treatment, e.g., upregulation of (1) PlGF, VEGF-C, or FGF-2 in response to VEGF inhibition; (2) VEGF after VEGF-R or EGF-R inhibition; and (3) IL-8 after HIF-1 inhibition.
Vascular independence: Mutant tumor cell clones (e.g., those lacking p53) are able to survive in hypoxic tumors.
Stromal cells: $VEGF^{-/-}$ tumors recruit pro-angiogenic stromal cells such as myofibroblasts via upregulation of PDGF-A and myeloid cells.

Mature, robust vessels: Preexisting vessels are covered by a full complement of supporting pericytes and are not readily pruned by anti-angiogenic treatments.
Bone marrow–derived cells: Tumors or ischemic tissues recruit pro-angiogenic endothelial cells and inflammatory cells independent of VEGF; the recruited cells may produce several pro-angiogenic molecules to rescue vascularization upon VEGF blockage.
RTK inhibitors: These may not synergize with chemotherapy, possibly because they do not block the actions of neuropilin-1.

Abbreviations/definitions: EC, endothelial cell; IL-8, interleukin-8, an angiogenic cytokine; neuropilin, an alternative VEGF receptor; PIGF, placental GF, an angiogenic factor related to VEGFs and a ligand of PIGF-R.

13.10 Nervous tissue contributes to tumor growth

During the second decade of the new millennium a new set of actors emerged on the tumor microenvironment stage: nervous tissue was found to contribute in significant ways to the progression of certain types of solid tumors. Until the arrival of these actors the TMEN was assumed to be formed entirely by cells of mesodermal origin, at least in carcinomas, that is, connective tissues cells of various types and derivatives of the various hematopoietic lineages spawned in the bone marrow.

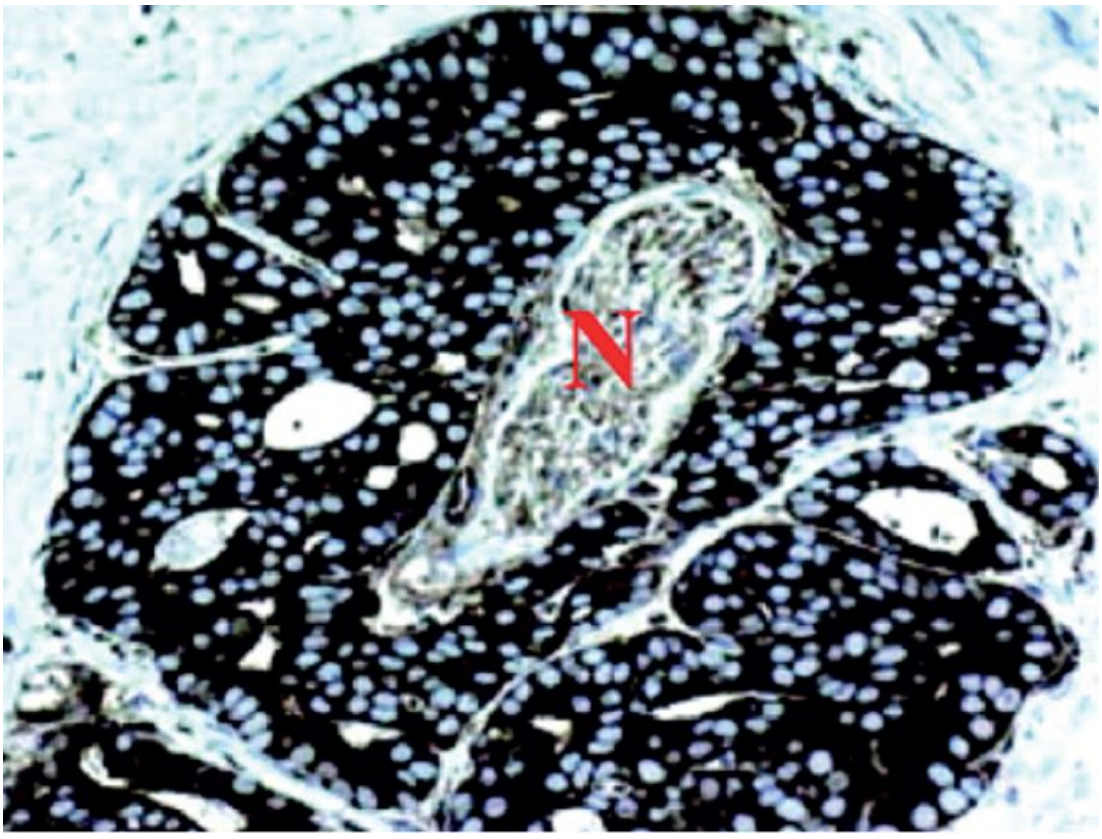
With the comfort of hindsight, it should have been clear that nervous tissue of various sorts must participate in various ways in the formation of neoplastic tissues. After all, tumors rely on the morphogenetic programs used to construct normal tissues for their own growth, and during the formation of almost all normal tissues, blood vessels and nerves grow in lockstep. Indeed, careful examination of the molecules that govern neurogenesis and angiogenesis reveal a clear common evolutionary origin and the use of homologous signaling systems to guide the growth of both types of tissue.

Thus, similar types of “tip cells” serve as the pioneers to guide both capillary growth and axon extension and use homologous proteins as guidance cues. In certain tissues, genetic disruption of genes and proteins involved in axonal guidance has also been found to disrupt the normal patterning of the vasculature morphogenesis. Hence, the deep evolutionary roots that indicate an ancient common origin of these two systems continue to influence a degree of interdependence during the morphogenesis of mammalian tissues.

Diverse observations, some quite recent, have suggested clear associations between innervation, on the one hand, and normal and neoplastic tissue development, on the other, doing so without providing detailed explanations of the underlying mechanisms. In the case of the prostate gland, as an example, this tissue does not develop normally if it is not innervated properly early in its development. Similarly, in a well-studied model of salivary gland development, mesenchymal cells in the mouse glands secrete factors such as growth nerve growth factor (NGF) together with several other neurotrophic factors, which recruit nerve axons that proceed to release acetylcholine, a key neuronal signaling molecule, which then induces branching of the developing salivary ducts. In the absence of these and other critical nerve cell-derived factors, salivary gland development fails to proceed normally. Similarly, in the developing pancreas, inability to produce NGF leads to disruption of glandular architecture.

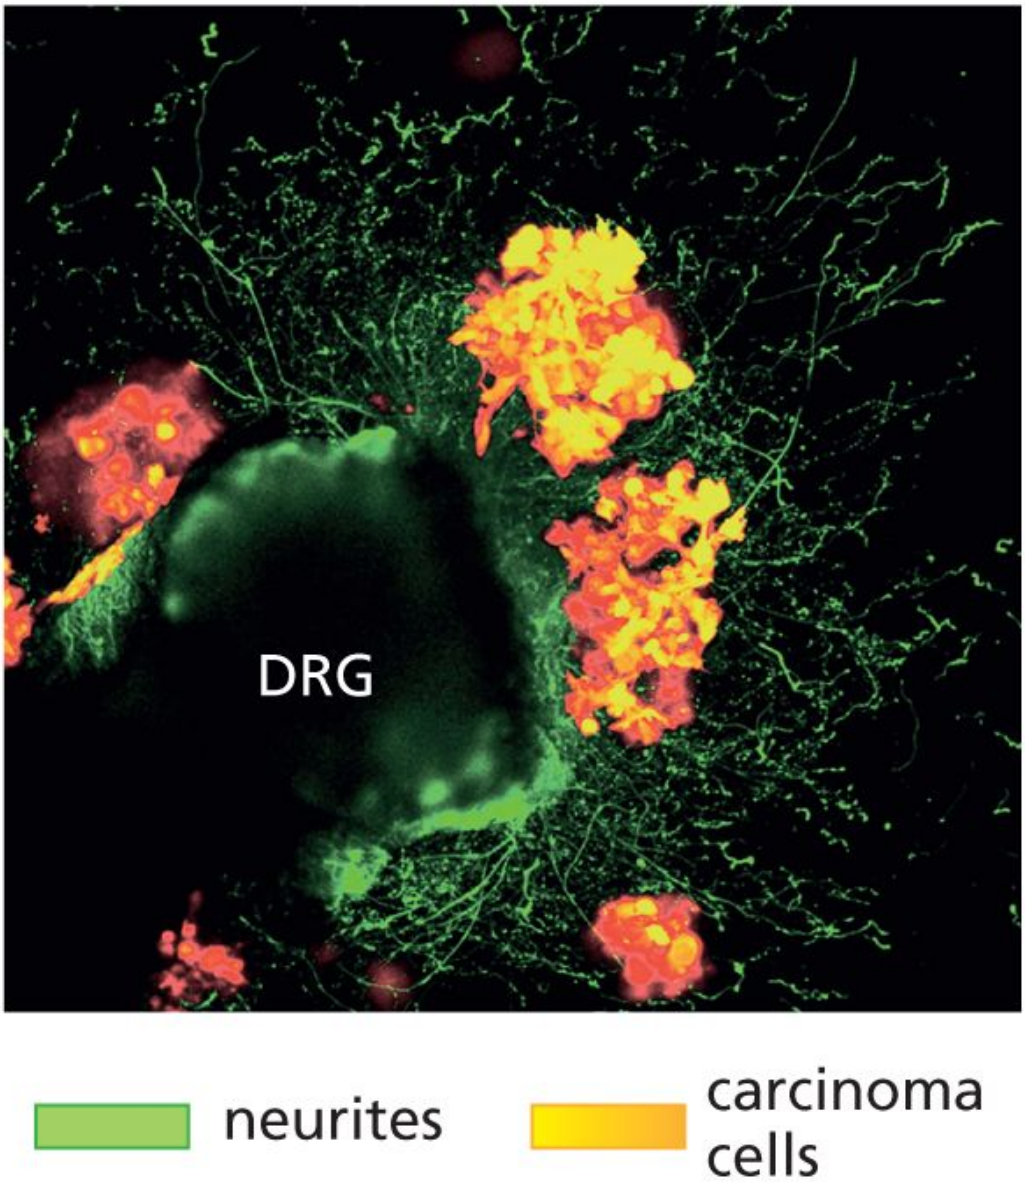
During the course of progression of certain carcinomas, the density of nervous tissue may even double in these tumors. As prostate cancer develops, carcinoma cells often invade adjacent to existing nerves, this representing the process termed perineural invasion (PNI), a process first reported by a histopathologist in 1905. Those carcinoma cells located adjacent to nerves exhibit lower rates of apoptosis and higher rates of proliferation. Moreover, surgical severing of the nerves innervating the prostate leads to regression of orthotopically implanted human prostate cancer cells in a mouse xenograft model of the disease. Reinforcing these observations are others demonstrating that severing of innervating nerves in autochthonously arising prostate carcinomas formed in a transgenic mouse model leads to inhibition of tumor outgrowth; similar observations have been made about mouse mammary and oral carcinomas. In a mouse transgenic model of pancreatic carcinoma, the efficacy of chemotherapy was enhanced when ganglia that generate the nerves innervating the pancreas were surgically removed.

In vitro assays have demonstrated that cancer cells release substances that stimulate neurite outgrowth, that is, the initial provisional protrusion of a neuron that has the potential to be stabilized and mature into a fully functional axon. In a number of tumor types, the density of nerves increases as progression proceeds, indicating that the ultimate drivers of such progression, specifically the carcinoma cells, release morphogenetic signals that incite neurite and axon outgrowth (**Figure 13.43**).



A round cluster of dark cells with pale nuclei growing around an elongated cluster of cells labeled N.

(A)



Neurites, shown in green, encircle a dark region labeled D R G and fan outward. Clumps of bright yellow-orange carcinoma cells adhere to the fan.

(B)

Figure 13.43 Interaction of neuronal tissue with carcinoma cells (A) This section of a human prostate carcinoma has been immunostained with an antibody

against NF-κB, which confers survival signals on carcinoma cells. The carcinoma cells (*black*) are seen growing around a cluster of neuronal tissue (*red* N). Cells in closer proximity to nerves show higher levels of NF-κB, higher rates of proliferation, and lower levels of apoptosis (*not shown*). (B) In this *in vitro* cell culture model, a portion of a mouse dorsal root ganglion (DRG), which represents a cluster of neuronal cell bodies that are associated with the spinal cord and relay inputs from sensory receptors (DRG, *black, lower left*) have been cultured together with cells of DU145 prostate carcinoma cell line (*red orange*) that had been transfected with the red fluorescent protein reporter gene. As is apparent, the presence of clusters of prostate cancer cells (*middle*) induces the DRG to extend numerous neurites (*green*), which are immature axon-like extensions of neurons. The prostate carcinoma cells respond reciprocally by growing toward the DRG, and in the presence of co-cultured stromal cells (*not shown*), initiate a model of perineural invasion. In human prostate carcinomas, the carcinoma cells stimulate the formation of new axons. (A, from G.E. Ayala, H. Dai, M. Ittmann et al. *Cancer Res.* 64:6082–6090, 2004. Reprinted by permission from the American Association for Cancer Research. B, Courtesy of Gustavo Ayala, M.D.)

When taken together, these various phenomena indicate clearly that in many types of tumors, nervous tissue qualifies as a functionally important component of the stroma that interacts in a bidirectional manner with nearby neoplastic cells. These interactions extend as well to those operating in metastatic colonies. For example, the outgrowth of carcinoma metastases to the brain can be fostered by glutamate released by a subset of neurons that impinge on specific types of glutamate receptors expressed by the carcinoma cells. This research on cancer:neuronal signaling is still in its infancy. Nonetheless, results reported to date already provide clear indications of critical heterotypic interactions appear to represent attractive targets for the development of various types of novel anti-cancer therapeutics.

OceanofPDF.com

Glossary

neurotrophic
: Referring to secreted factors that support the growth, survival, and differentiation of nervous tissue.

perineural invasion
: Invasion of cancer cells along tracts established by neurons and axons.

neurite
: A thin provisional protrusion from the cell body of a neuron that has the potential to develop into a fully formed, functional axon. *See also* **axon**, **neuron**.

axon
: Long slender protrusion from the cell body of a neuron through which nerve signals are transmitted, often to other neurons.

ganglion
: (pl., **ganglia**) Cluster of neuron cell bodies formed in various parts of the peripheral nervous system and, to a smaller extent, in the central nervous system.

13.11 Synopsis and prospects

Metazoan tissues are organized as condominiums of various cell types that are continuously communicating with one another. To the developmental biologist, the need for this organizational plan is self-evident: only through such interactions can the proper numbers and locations of each of these cell types be ensured. These heterotypic interactions continue to operate after embryogenesis has been completed in order to support the maintenance and repair of already-formed tissues.

As we have learned in this chapter, this organizational plan confers another, quite distinct benefit on the organism. By making its cells so interdependent, none is easily able to extricate itself from its complex web of interactions and go off on its own. Interdependence imposes the regimentation that wards off the chaos of neoplasia.

Earlier, we viewed multi-step cancer progression as the hurdling of successive barriers placed in the path of developing cancer cells (see Chapter 11). Each successfully completed step, whether achieved by genetic or epigenetic changes operating within incipient cancer cells, removes one of these obstacles and places the developing pre-neoplastic cell incrementally closer to full-fledged malignancy. Now we can revisit these barriers by confronting *non-cell-autonomous* mechanisms: as premalignant cells evolve toward malignancy, they progressively sever some of their ties with their neighbors and their dependence on support by nearby cells, often those residing within the tumor-associated stroma (see however **Sidebar 13.10**).

Sidebar 13.10 How truly autonomous are highly progressed cancer cells?

Work reported in 2012 has revealed how dependent the behavior of highly aggressive carcinoma cells is on their surrounding microenvironment. This research involved the admixture of small numbers of malignant human breast carcinoma cells with larger numbers of normal mouse mammary epithelial cells (MECs). When implanted on their own in mouse mammary stromal fat pads, the mouse MECs are able to generate entire functionally normal mammary glands within two months; the breast cancer cells, when implanted in multiple anatomical sites on their own (in immunocompromised mouse hosts), yield

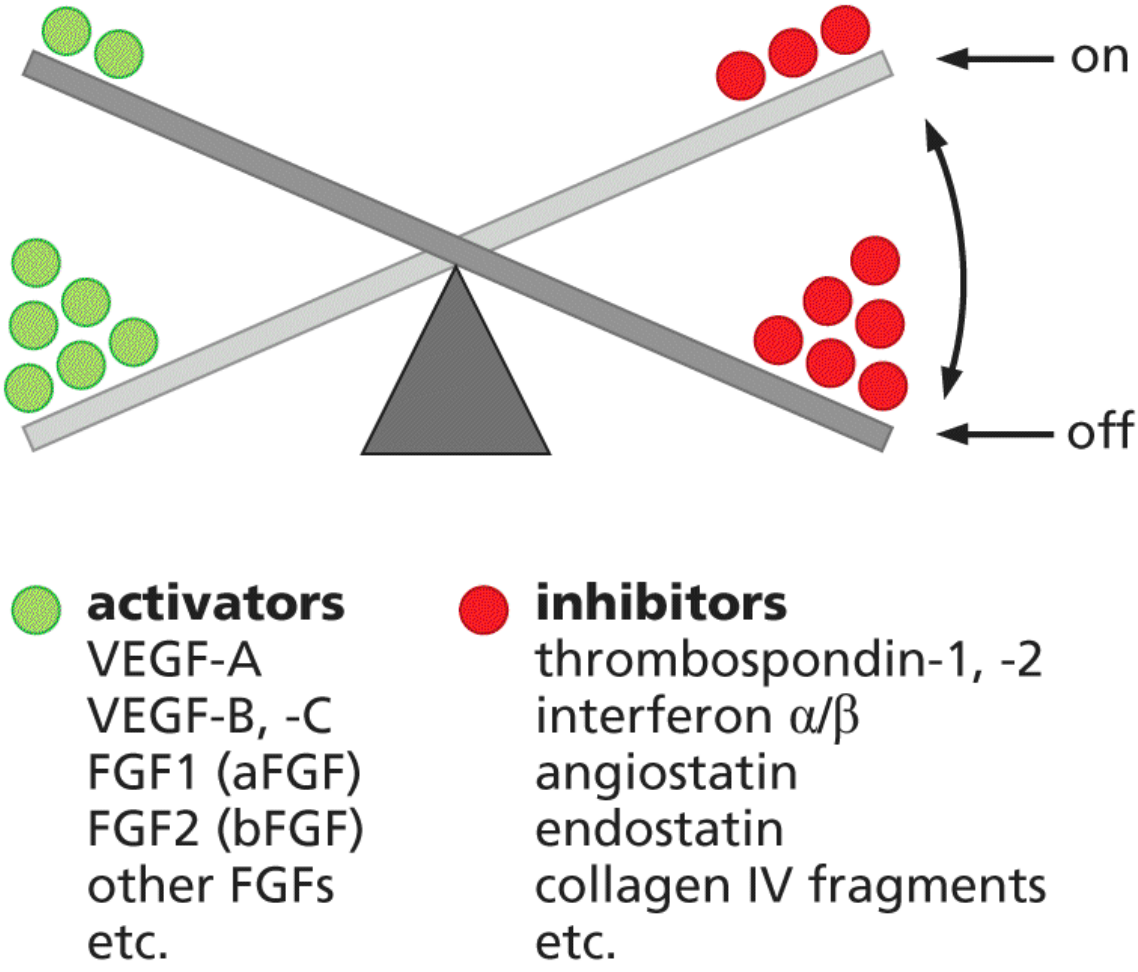
rapidly growing metastatic tumors. However, admixture of the small numbers of the human carcinoma cells with majority populations of mouse MECs prior to implantation in the stromal fat pads caused the human cells to integrate into the ducts being formed in the resulting developing mouse mammary glands, participating in normal duct formation and doing so without any evidence of tumor formation. Hence, the high degree of autonomy that we have ascribed to high-grade, multiply-mutated carcinoma cells is a mirage, in light of this demonstration of the profound influence of nearby epithelial and mesenchymal cells on cancer cell behavior.

Perhaps the biggest surprise is how dependent most cancer cells remain on stromal support despite having completed multiple steps of tumor progression. The epithelial cells residing in many carcinomas continue to rely on many of the physiological signals that sustained their precursors in normal tissues; equally elaborate heterotypic signaling may operate in other types of tumors as well. This conservatism is also suggested by microscopic examination of tumors. Thus, a well-trained pathologist can recognize the origins of perhaps 95% of the tumor samples viewed under the microscope, because most of the heterotypic interactions that govern normal morphology appear to be operative in the great majority of cancers.

The remaining approximately 5% of tumors present a challenge, because they are anaplastic and therefore often have minimal losses of the histologic traits that make identification of their tissue of origin possible. The cells in these anaplastic tumors have shed most forms of dependence that tied their precursors to normal neighboring cells. However, most anaplastic tumor cells have not progressed all the way to total independence because they still assemble to form solid tumors. The ultimate independence is achieved only by the cells in those cancers that have advanced so far that they can grow as pleural effusions or ascites (see **Supplementary Sidebar 13.3**) and therefore have minimal or no contact with supporting cells and, apparently, with an extracellular matrix (ECM).

Even without detailed knowledge of heterotypic interactions, the dependence of most carcinoma cells on at least one form of stromal support could have been predicted from the known physiology of mammalian tissues: virtually all of them depend on a functional blood supply. Less predictable was the mechanism by which most tumors acquire their vasculature. Rather than invading normal tissue and expropriating existing capillary beds, most tumors actively recruit endothelial cells that proceed to construct capillaries and larger vessels within the tumors, usually by extending the vasculature of nearby normal tissues. They succeed in

this endeavor by orchestrating the expression of a complex array of signaling molecules that together ensure the formation of the tumor-associated neovasculature (**Figure 13.44**).



The angiogenic switch, visualized as a seesaw. Activators are listed on the left: V E G Effs A, B and C; F G F1 (a F G F); F G F 2 (b F G F); other F G Effs, etcetera. Inhibitors are listed on the right: thrombospondin 1 and 2, interferon alpha and beta, angiostatin, endostatin, collagen IV fragments, etcetera. When activators outweigh inhibitors, the switch is on. When inhibitors outweigh activators, the switch is off.

Figure 13.44 Balancing the angiogenic switch This diagram presents the major physiological regulators that work to promote or inhibit angiogenesis within tissues and indicates that it is the balance between these two countervailing groups of regulators that determines whether or not angiogenesis proceeds. Although the angiogenic switch has been described

here as an essentially on–off binary decision, in fact diagrams like this one suggest that the rate of neovasculature formation may change continuously within a tumor mass after the switch has been activated and often increases progressively, seemingly governed by a rheostat rather than a binary switch. (From D. Hanahan and J. Folkman, *Cell* 86:353–364, 1996. With permission from Elsevier.)

The sources of these endothelial cells could also not be deduced from first principles. The proliferation of endothelial cells originating in neighboring tissues seems to be the main mechanism for acquiring neovasculature soon after the angiogenic switch has been tripped (see Figure 13.44). However, in some tumors, the initially formed vessels may be constructed largely by endothelial precursor cells (EPCs) that originate in the bone marrow and then differentiate in the tumor stroma into functional endothelial cells. In fact, the relative contributions of EPCs are still unclear in most types of tumors.

Major aspects of angiogenesis are still poorly understood, even paradoxical. For example, it seems apparent that once tumors become angiogenic, they can launch into a prolonged phase of growth and expansion, and that tumors that are more angiogenic can grow even more rapidly than those that are less able to attract new vasculature. Indeed, as we have read, measurements of microvessel density—the number of capillaries per microscope field—correlate quite well with the likelihood that a primary tumor, such as a breast cancer, will progress to a highly malignant endpoint.

The paradox comes from the frequent observations that patients bearing highly hypoxic tumors also confront a poor prognosis. Indeed, hypoxic tumors, including those exposed to anti-angiogenesis therapies, are often more aggressive than their normoxic counterparts. This makes no sense, given that hypoxia should starve tumor cells and lead to their death through apoptosis and, on a larger scale, to extensive necrotic regions within tumors (see Figure 13.29). The paradox may one day be resolved by invoking the actions of the HIF-1 transcription factor, which becomes activated in hypoxic cells and induces production of a large number of other proteins besides VEGF. Indeed, a high level of HIF-1 expression is also an indicator of poor clinical prognosis. Included among the genes activated by HIF-1 are those specifying PDGF, TGF-α, TGF-β, and several matrix metalloproteinases (MMPs), the latter being responsible for remodeling the extracellular matrix (ECM). As we have learned, several of these secreted

proteins act as potent mitogens that drive the proliferation of both epithelial cells and their stromal neighbors.

An additional HIF-1–induced gene encodes the Met protein, which functions as the receptor for the hepatocyte growth factor (HGF) ligand, also known as scatter factor (SF). HGF, for its part, seems to be widely available in many human tumors of both epithelial and mesenchymal origin. Consequently, HIF-1–mediated increases in expression of the Met RTK can sensitize tumor cells to HGF molecules that are present in their surroundings, having been released by nearby stromal cells. Once the Met receptor is activated by binding its HGF ligand, it activates a diverse set of responses within epithelial cells, including the epithelial–mesenchymal transition (EMT), a cell-biological program that imparts increased motility and invasiveness (see Section 13.3 and Chapter 14). At the molecular level, the concentrations of two potent EMT-inducing transcription factors—Twist and Snail—are significantly increased in hypoxic cells; as we will see in the next chapter, carcinoma cells that have undergone an EMT acquire many of the phenotypes of the cells forming high-grade malignancies. These diverse products of HIF-1 action and tissue hypoxia help explain the poor prognosis attached to hypoxic tumors, which thrive despite great adversity and actually turn out to be more aggressive than their well-oxygenated counterparts (see also **Supplementary Sidebar 13.6**).

These paradoxical, indeed counterproductive responses to anti-angiogenesis therapies, together with the evasive maneuvers that tumors may take to circumvent these therapies (see Table 13.4), may explain the modest successes that most of these therapies have achieved in the oncology clinic. Thus, most clinical outcomes have fallen far short of anticipated outcomes. Still, some combinations of anti-angiogenesis therapy and chemotherapy have shown clear utility in terms of increasing progression-free survival (PFS) and even overall survival of cancer patients and thus are finding their way into standard clinical practice. In the longer term, more efficacious anti-angiogenesis therapies may derive from dosing schedules that serve to normalize the tumor-associated microvasculature, enabling more efficient drug delivery, while avoiding the complete vascular collapse that triggers tumor hypoxia and the induction of increased tumor aggressiveness.

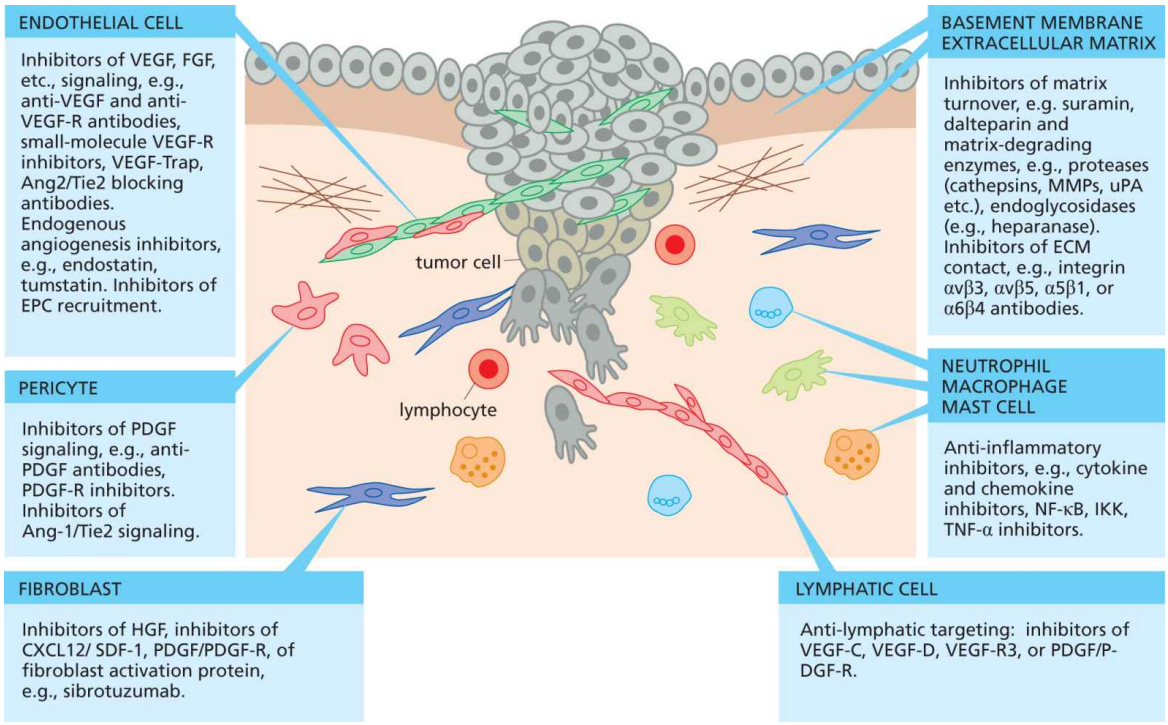
Certain recently discovered dynamic interactions between tumors and the bone marrow have been a surprise to most cancer researchers. In the absence of metastasis, most tumors have traditionally been considered to be localized diseases confined to one or another corner of the body. But the more we learn

about the cells of the stromal compartment, the more we come to realize that even localized tumors extend their reach far and wide throughout the body in order to recruit the cells that they need in order to support their own survival and proliferation programs. Besides the endothelial precursor cells (EPCs) cited above, carcinomas recruit mast cells and monocytes from the marrow, the latter differentiating on-site into various types of macrophages. Mesenchymal stem cells (MSCs and fibrocytes) of bone marrow origin are also recruited in large numbers to the stroma of many carcinomas; once present within these tumors, they may differentiate into fibroblasts and myofibroblasts, which then release signals favoring the survival and malignant progression of nearby cancer cells.

Throughout most of this chapter, we have focused on epithelial–stromal interactions within tumors and the heterotypic signals that they exchange via *paracrine* signaling channels. The presence of a variety of bone marrow–derived cells in the tumor stroma creates an additional dimension of complexity. Recognizing their existence and their potential contributions to tumor physiology, we now need to include interactions of cancer cells with the faraway bone marrow. Thus, tumors may communicate with the marrow to elicit the production and mobilization into the circulation of certain cell types that can then be recruited from the circulation into the tumor stroma. Such systemic interactions depend, by definition, on information conveyed by *endocrine* signals rather than the paracrine signals that have been a central focus of our discussions here.

Even if we confine our attention to the bidirectional exchanges of paracrine signals between the epithelial and stromal compartments operating within tumors, we confront extraordinary complexity. The tumor stroma is composed of almost a dozen distinct cell types (fibroblasts, myofibroblasts, MSCs, endothelial cells, pericytes, smooth muscle cells, mast cells, monocytes, macrophages, lymphocytes, nerve cells, and, in some tissues, adipocytes), each of which signals to the neoplastic epithelial cells as well as to other cellular components of the stroma. Physicists have struggled, so far unsuccessfully, with general solutions to the three-body problem. Here, we confront a world of a far larger number of distinct cell types, each of which is sending a complex mixture of signals to other types of cells. Examinations of only a single cell type—fibroblasts—reveal the heterogeneity of these cells and their ability to change dynamically in response to the contextual signals that they encounter within the tumor stroma (**Supplementary Sidebar 13.11**). We have only begun to scratch the surface of the complex epithelial–stromal interactions operating in neoplastic tissues and in their normal counterparts.

For more than half a century, the mindset of oncologists has been focused on eradicating the bulk of the cancer cells within solid tumors, with the hope of achieving the seemingly impossible—cures of common carcinomas that have traditionally been incurable. As we learned, first in Chapter 11 and now in this one, this focus needs to be radically redirected. First, the targets of anti-cancer therapies can no longer be confined to the bulk of neoplastic cells in a tumor, because these cells have limited self-renewal capacity; instead, we are likely to find that truly durable cures can come only from eradicating as well the still-elusive cancer stem cells (CSCs) that hide out, here and there, throughout tumor masses and represent their engines of self-renewal. Second, many of the useful anti-cancer therapies to be developed in the future will not come from targeting the cancer cells themselves. Instead, it may often be far more profitable to attack the cells that provide them with vital physiological support; by undermining the elaborate stromal support network on which most cancer cells depend, truly dramatic regressions of solid tumors may one day be achieved (**Figure 13.45**).



A graphic summarizing Heterotypic interactions as targets for therapeutic intervention. At the center is a clump of abnormal tissue, penetrating downward through basement membrane into the extracellular matrix. Tumor cells at the bottom of the clump are well on the way to becoming cancerous. Different cell and tissue types are labeled with a list of proteins and other substances. The label for basement membrane and extracellular matrix reads:

Inhibitors of matrix turnover, e.g. suramin, dalteparin and matrix-degrading enzymes, e.g., proteases (cathepsins, M M Pees, u P A, etcetera), endoglycosidases (e.g., heparanase). Inhibitors of E C M contact, e.g., integrin alpha v beta 3, alpha v beta 5, alpha 5 beta 1, or alpha 6 beta 4 antibodies. The label for NEUTROPHIL, MACROPHAGE, MAST CELL reads: Anti-inflammatory inhibitors, e.g., cytokine and chemokine inhibitors, N F-kappa B, I K K, T N F-alpha inhibitors. The label for LYMPHATIC CELL reads: Anti-lymphatic targeting: inhibitors of V E G F-C, V E G F-D, V E G F-R3, or P D G F slash P D G F-R. The label for FIBROBLAST reads: Inhibitors of H G F, inhibitors of C X C L 12 slash S D F-1, P D G F slash P D G F-R, of fibroblast activation protein, e.g., sibrotuzumab. The label for PERICYTE reads: Inhibitors of P D G F signaling, e.g., anti-P D G F antibodies, P D G F-R inhibitors. Inhibitors of Ang-1 slash Tie 2 signaling. The label for ENDOTHELIAL CELL reads, Inhibitors of V E G F, F G F, etcetera, signaling, e.g., anti-V E G F and anti-V E G F-R antibodies, small-molecule V E G F-R inhibitors, V E G F-Trap, Ang-2 slash Tie-2 blocking antibodies. Endogenous angiogenesis inhibitors, e.g., endostatin, tumstatin. Inhibitors of E P C recruitment.

Figure 13.45 Heterotypic interactions as targets for therapeutic intervention As described in this chapter, cancer cells depend on the nearby stromal microenvironment for a variety of cell-physiological supports. This dependence on heterotypic interactions has inspired development of new types of cancer therapy, some of which have been featured in this chapter. Instead of focusing on the intracellular signaling defects within cancer cells, this new class of therapies is directed toward interrupting heterotypic signaling, thereby depriving cancer cells of essential stromal support. This scheme indicates some of the anti-tumor therapies that are being developed or under consideration (*light blue boxes*). (From J.A. Joyce, *Cancer Cell* 7:513–520, 2005. With permission from Elsevier.)

The insight that tumors are “wounds that do not heal” extends and echoes our earlier discussions (see Sections 11.13 and 11.14), in which the critical role of chronic inflammation in promoting tumor formation was described in great depth. Inflammation and wound healing are intertwined processes, and the mechanisms of inflammation-driven tumor promotion, which lead to the initial formation of cancers, are extended and elaborated by the chronic wound healing that seems to best characterize the biology of the stroma of well-established tumors.

Here, too, there has been another surprise. Inflammatory cells, notably macrophages, have traditionally been depicted as the front-line soldiers of the immune response that deal effectively with infectious agents, such as bacteria, by consuming them and help guide the long-term immune response through antigen presentation, as we will see later in Chapter 15. Now we learn that macrophages can also function as key sources of tumor promotion by producing mitogenic growth factors, liberating angiogenic factors, and remodeling the extracellular matrix (ECM); the latter process is also critical for tumor invasion and metastasis, as we will see in Chapter 14.

So, the traditional job description assignments of various stromal cell types are being extended and blurred. Cells of the immune system, which are purportedly dispatched to protect us from infection and even cancer, are often active collaborators in tumor development. And the deletion of one or another cell type from the immune system, achieved in mice through germ-line re-engineering, often creates a host organism that is, paradoxically, less able to support tumorigenesis.

Normal, multifaceted morphogenetic programs that depend on epithelial–stromal interactions, such as wound healing and the EMT, are likely to explain how carcinoma cells are clever enough to acquire the complex cell phenotypes that they need in order to execute the later stages of malignant progression. In retrospect, this notion is not so surprising, because the more we learn about cancer cells, the more we realize how opportunistic they are in co-opting and exploiting normal biological processes in order to further their own ends. This insight leaves us with the last question of this chapter: Have we begun to truly understand the mechanistic complexity of heterotypic interactions, or is there an entire universe of undiscovered signaling pathways and behavioral programs lurking within tumors waiting, like intergalactic dark matter, to surprise us once again?

OceanofPDF.com

Glossary

pleural effusion
: Accumulation of cancer cells and fluid in the space between the lungs and the surrounding pleural membrane.

ascites
: (adj., - **itic**) Fluid that accumulates in the peritoneal cavity of some cancer patients, often containing malignant cells.

OceanofPDF.com

Key concepts

- Tumors are complex tissues that depend on intercommunication between various cell types. Indeed, most tumors are as complex histologically as the normal tissues in which they arise.
- In carcinomas, these cell types can be separated into the neoplastic epithelial cells and recruited stromal cells, which include fibroblasts, myofibroblasts, and macrophages, other types of inflammatory cells, nervous tissue, as well as the various cell types that participate in the construction of the tumor-associated vasculature, specifically endothelial cells, pericytes, and smooth muscle cells.
- Most carcinomas depend absolutely on recruited stromal cells for various types of physiological support. This dependence is lost only in the small subset of tumors that progress to an extremely malignant state, notably some of the tumor cells growing in the ascites and pleural fluids of patients suffering advanced cancer.
- At the biochemical level, this interdependence is manifested by the exchange of various types of mitogenic and trophic factors. For example, carcinoma cells may release PDGF to recruit and activate stromal cells, whereas the latter respond by releasing IGFs that sustain the survival of the carcinoma cells.
- The formation of tumor-associated vasculature, formed by the process of neoangiogenesis, is a critical, rate-limiting determinant of the growth of all tumors larger in size than approximately 0.2 mm.
- In the case of carcinomas, the acquisition of tumor-associated stroma closely resembles the process of healing in wounded epithelial tissues. The genesis of stroma therefore relies on the same gene expression programs that are activated during wound healing.
- As tumor progression proceeds, the fibroblast-rich stroma is increasingly replaced by myofibroblasts, which eventually may generate collagen-rich, desmoplastic stroma.
- The recruitment of the cells that participate directly in the construction of the neovasculature of tumors involves the release of factors, such as VEGF, by both the tumor cells and inflammatory cells, notably macrophages.

- Neoangiogenesis represents an attractive target for the development of novel anti-cancer agents, in that the targeted cells are the various normal, genetically stable stromal cell types participating in angiogenesis rather than the ever-changing cancer cells.
- Anti-angiogenic therapies often provoke paradoxical responses in carcinomas, including progression to higher grade malignancy, tempering the enthusiasm for introducing some of these therapies into clinical practice.

OceanofPDF.com

Thought questions

1. What diverse lines of evidence prove directly that most carcinoma cells depend on stromal cell types for various types of physiological support?
2. How might anti-angiogenesis therapies improve (in some cases) or neutralize (in other cases) the efficacy of conventional chemotherapeutic agents?
3. How might macrophages facilitate or antagonize tumorigenesis?
4. Which lines of evidence persuade you that the generation of tumor-associated stroma depends on the same biological programs that are activated during wound healing?
5. Which biological forces cause the tumor-associated vasculature to be defective in so many respects?
6. Which types of anti-cancer therapeutic agents would you deploy in order to encourage the collapse of an established tumor by depriving it of vasculature support?
7. What biochemical strategies can tumor cells use to lessen their dependence on stromal support?
8. How might you determine what proportion of endothelial cells in the vasculature of a tumor derive from the expansion of adjacent vasculature and what proportion of these cells arise from circulating endothelial precursor cells?

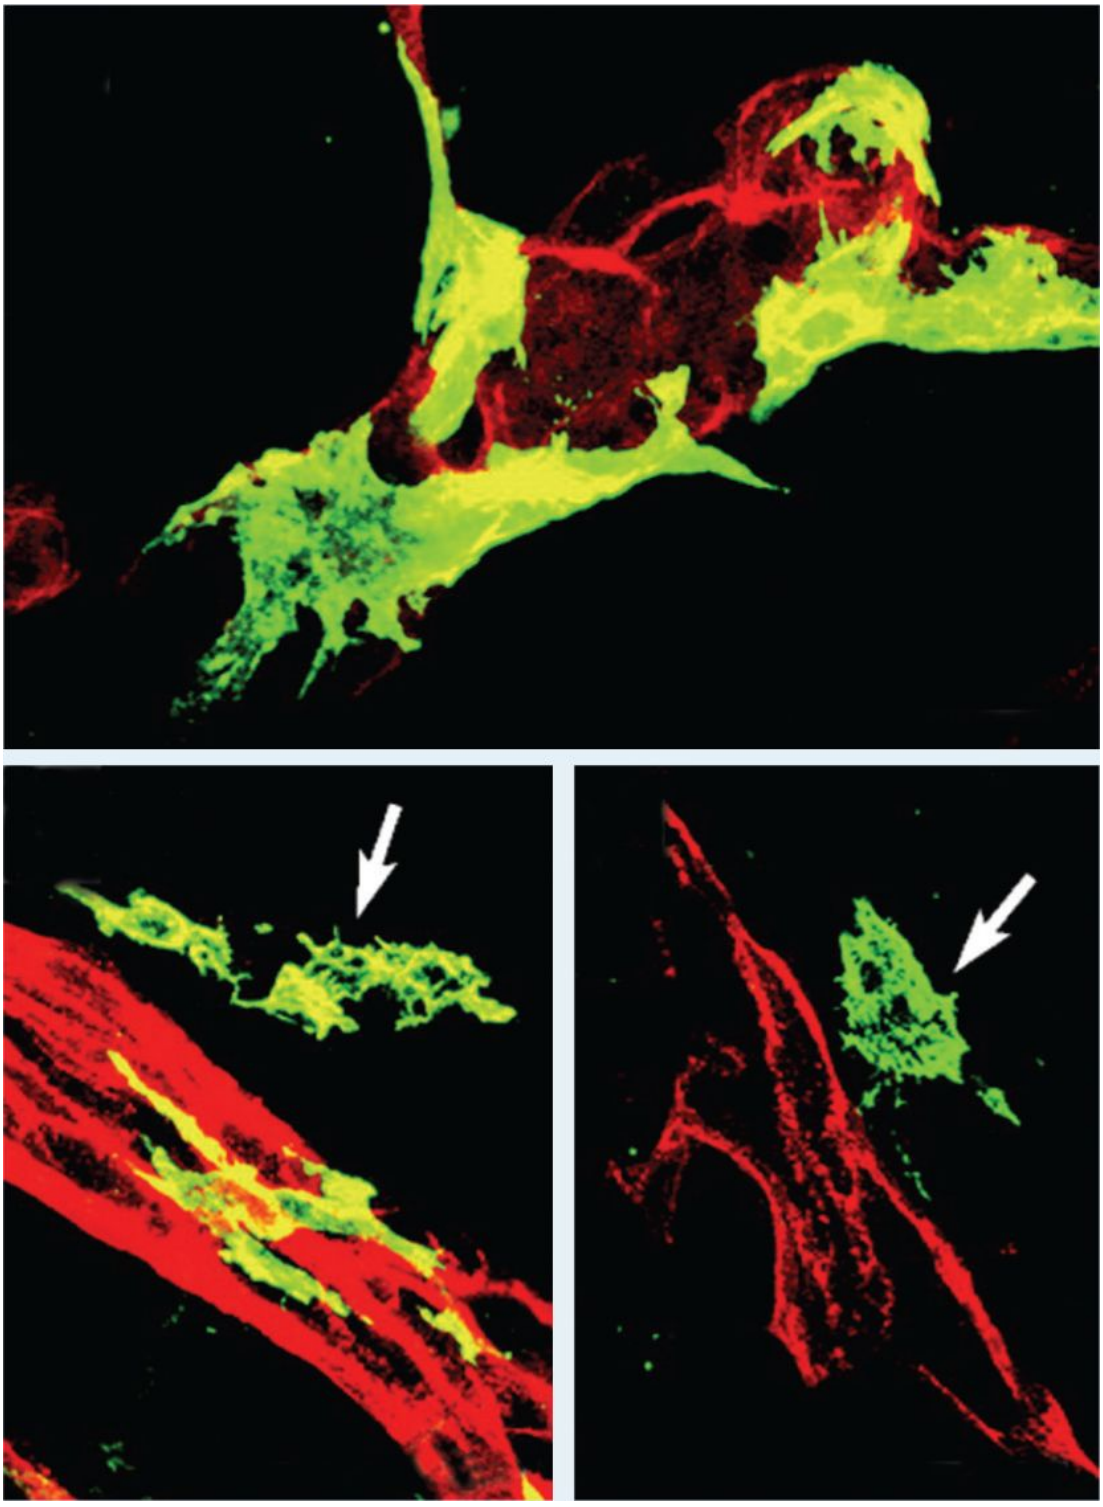
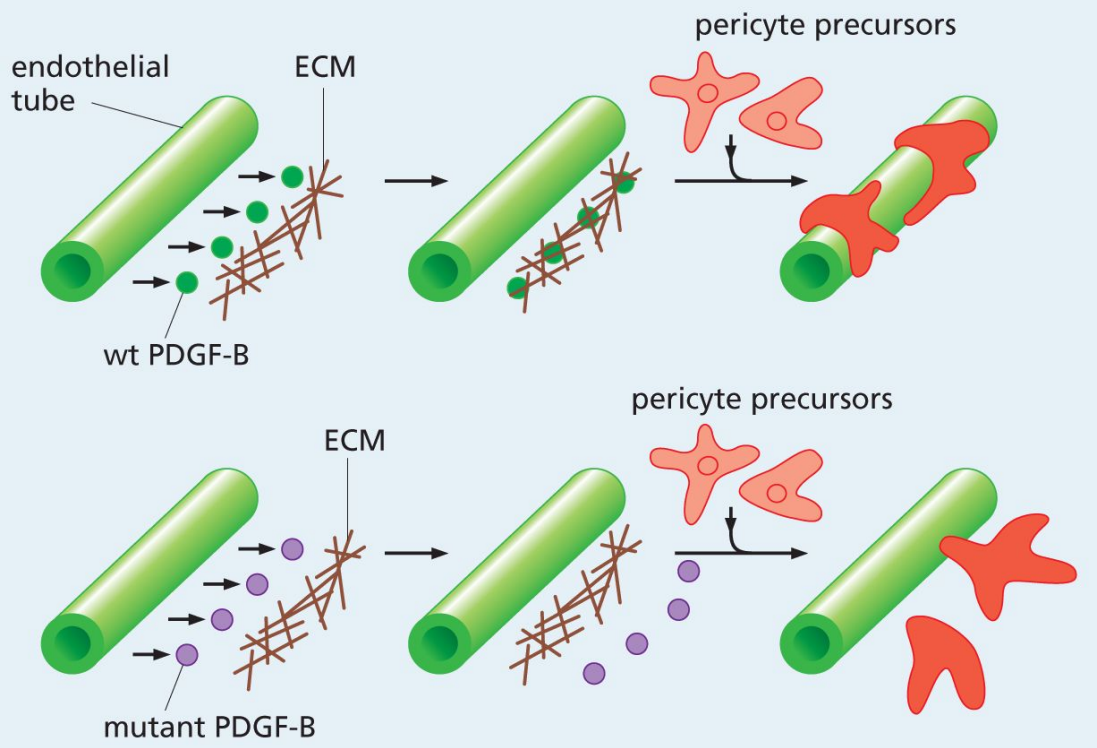
Supplementary Sidebars

Supplementary Sidebar 13.1 Localization of growth factors is important for proper heterotypic interactions

Paracrine signaling operates over short distances between nearby cells, rather than over long distances via the circulation, the latter being termed *endocrine* signaling. (Some paracrine signaling is termed *juxtacrine* to indicate signaling between immediately adjacent cells.) In the case of microvessel formation, highly localized concentrations of PDGF are needed to ensure that the pericytes recruited to the outer layers of capillaries become directly *apposed* to the endothelial cells rather than dispersed randomly some distance away (**Figure S13.1**). Like many other growth factors, the PDGF-B molecule—the specific form of PDGF that operates here—contains a "retention motif," which ensures its binding to proteoglycans in the extracellular matrix (ECM). Consequently, soon after PDGF-B molecules are secreted by endothelial cells into the space around capillaries, these molecules are trapped in the nearby ECM and therefore accumulate in high concentrations immediately next to the endothelial cells. Once liberated from this tethering by proteases, the resulting high local concentrations of activated PDGF-B molecules ensure the recruitment of pericytes to locations directly adjacent to the endothelial cells. However, in mice expressing a mutant PDGF-B that lacks this retention motif, the secreted PDGF-B molecules diffuse away from endothelial cells, causing the recruitment of pericytes to the general area of the endothelial cells but not directly apposed to them. These endothelial cells therefore lack the structural support afforded by the pericytes, as well as the VEGF supplied by the pericytes that is required for long-term endothelial cell survival.



(A)

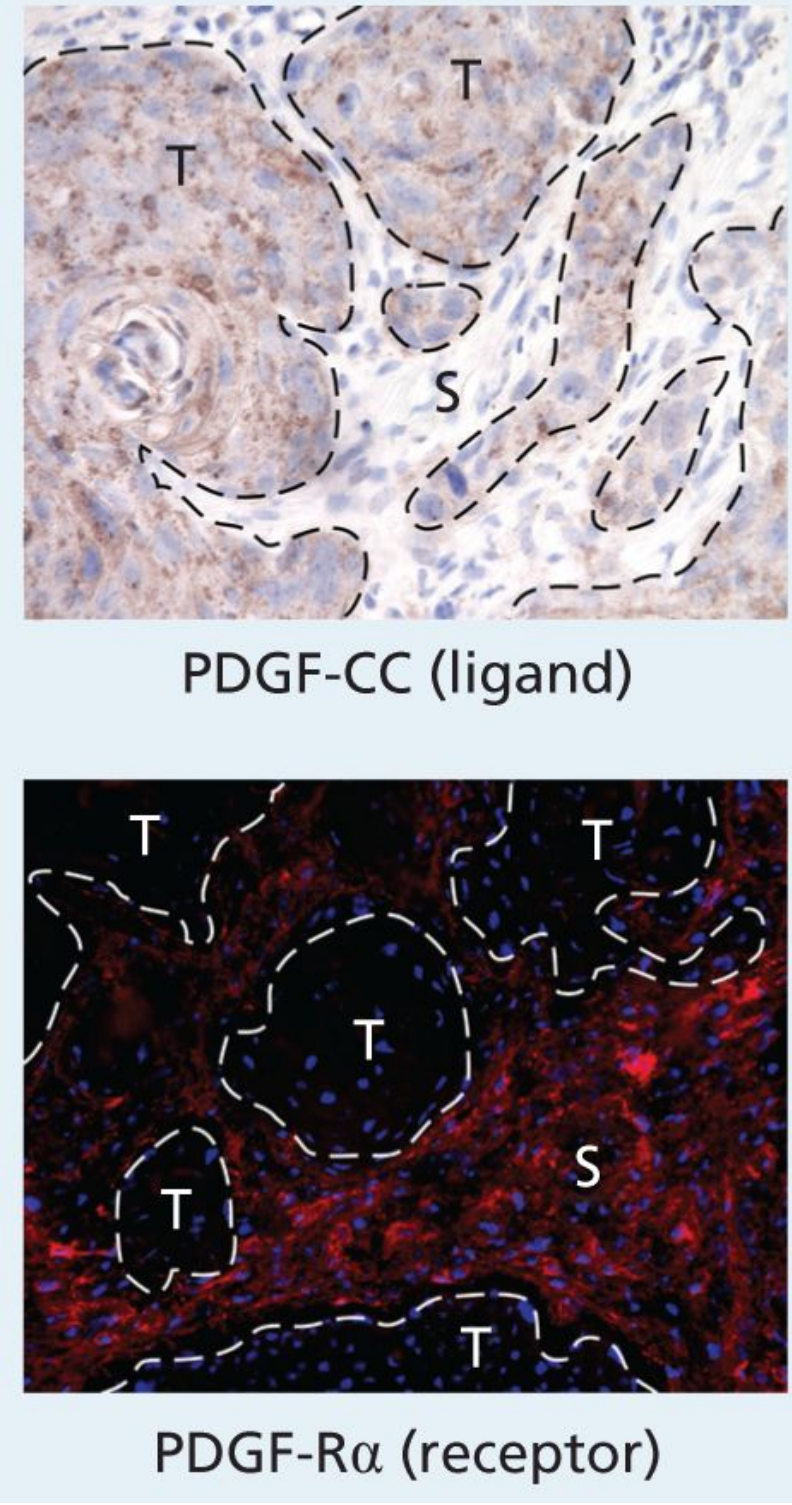


(B)

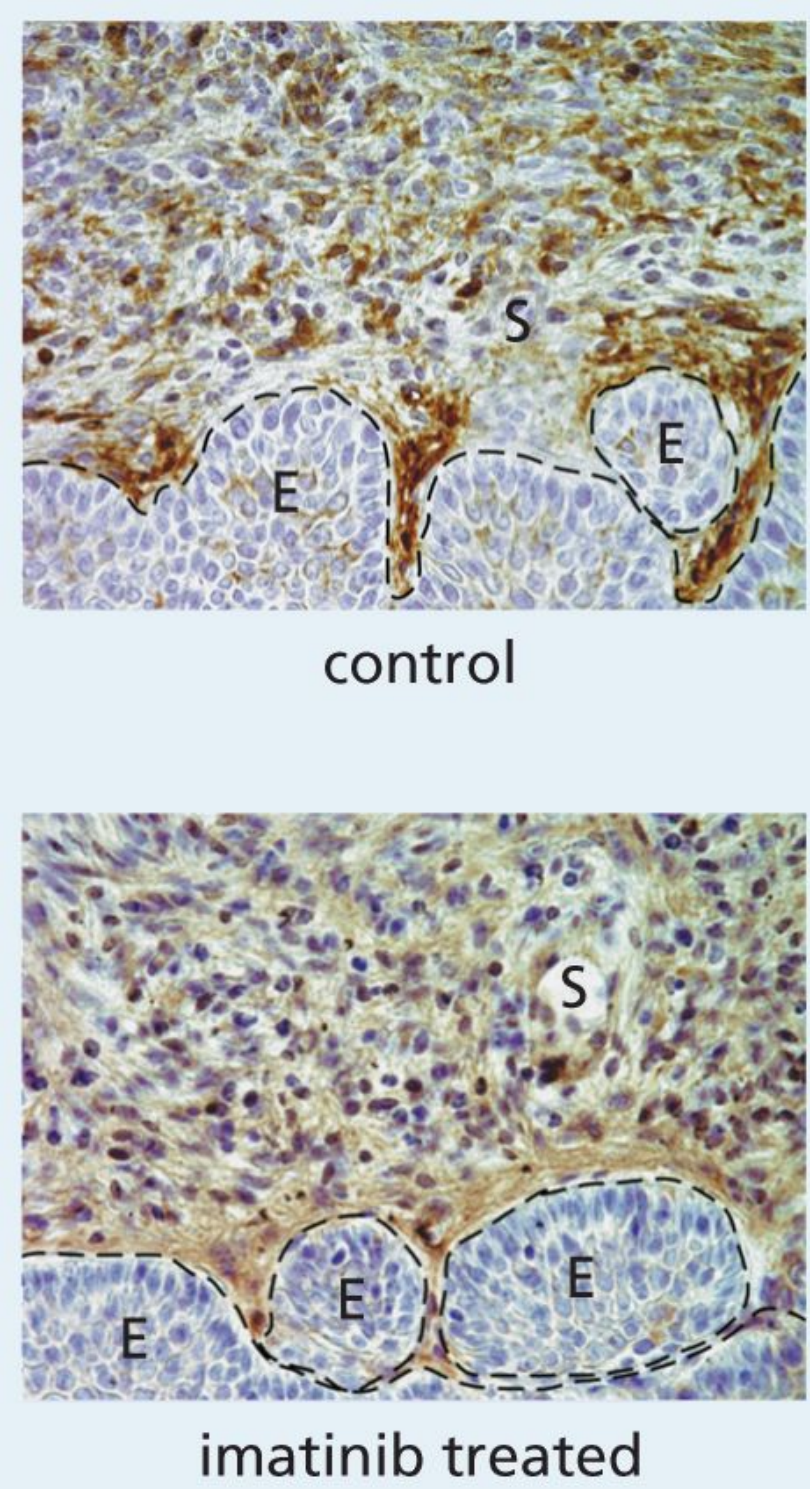
Figure S13.1 Role of PDGF in the recruitment of pericytes to capillaries (A) Normally, the pericytes (*yellow, green*) are tightly attached to capillaries (*red, upper panel*). However, in one strain of mice, the gene encoding PDGF-B has been altered to encode mutant PDGF-B molecules that cannot attach to the extracellular matrix and therefore diffuse away from the endothelial cells producing this growth factor. As a consequence, the pericytes are no longer attracted to the endothelial cells and lack intimate contact with the capillary tubes (*arrows, lower panels*). (B) This close juxtaposition of pericytes with the capillaries depends on the localization of PDGF-B, which is secreted by endothelial cells (*lighter green tubes*). Normally (*above*), this wild-type (wt) PDGF-B (*dark green*) is trapped immediately adjacent to the endothelial cells in the extracellular matrix (ECM, *brown*), where it serves to attract pericyte precursors (*pink*) that attach themselves (*red*) tightly to the capillary tubes formed by the endothelial cells. However (*below*), if PDGF-B is deprived of the amino acid sequences that normally tether it to the ECM (*purple*), as described in panel A, it diffuses away from the capillary tubes, and any pericytes that are recruited are found scattered at some distance from the capillaries. (A, from A. Abramsson, P. Lindblom and C. Betsholtz, *J. Clin. Invest.* 112:1142–1151, 2003. With permission from American Society for Clinical Investigation.)

Supplementary Sidebar 13.2 Heterotypic signaling in carcinomas is an ongoing process

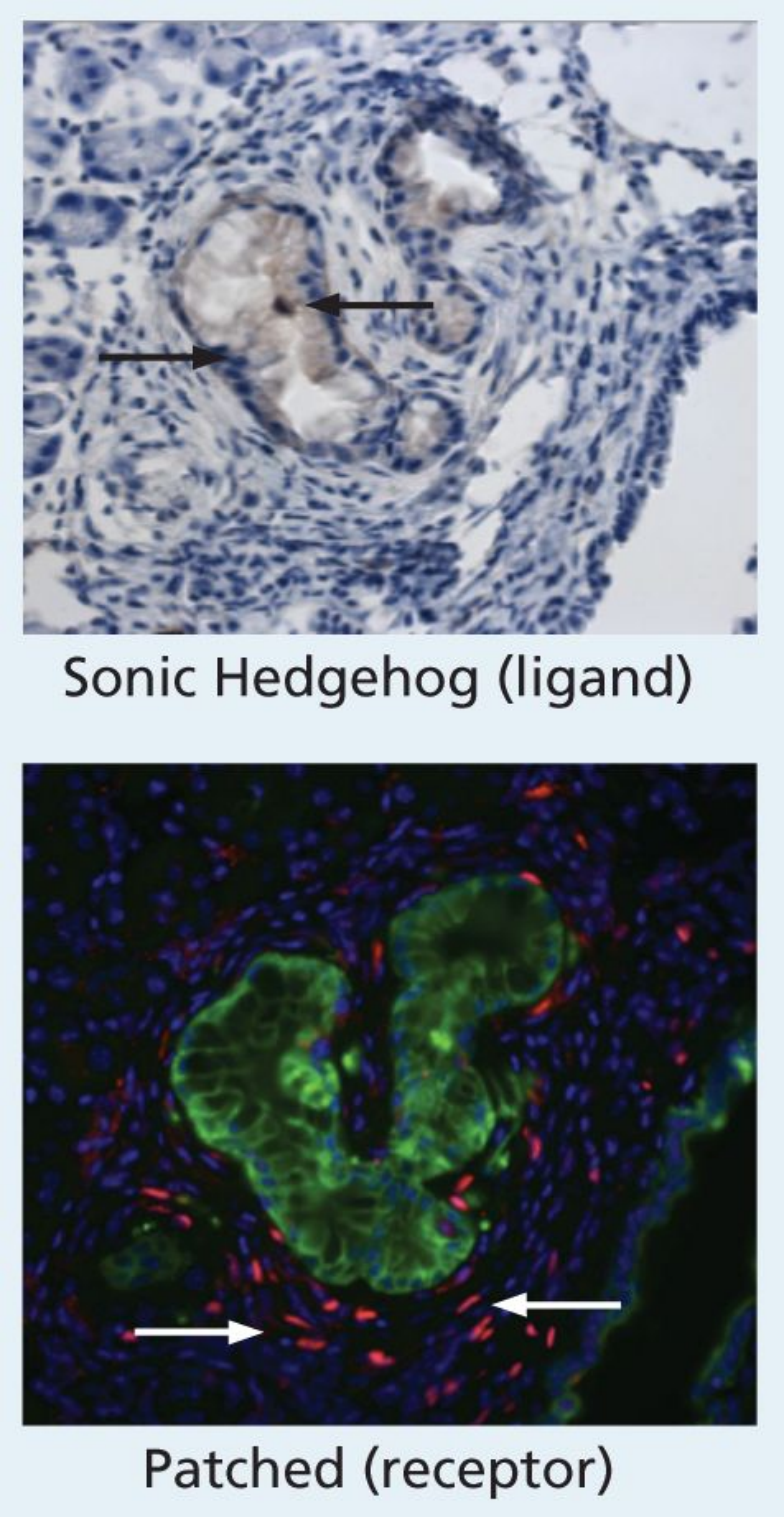
A variety of heterotypic signaling channels have been described in carcinomas involving signaling from the neoplastic epithelial cells to various cellular components of the stroma and in the reverse direction from stroma to the epithelial cells. Three examples are given in **Figure S13.2**.



(A)



(B)



(C)

Figure S13.2 Heterotypic signaling between epithelium and stroma in carcinomas A variety of heterotypic signaling axes have been documented in

carcinomas in which the cells in one cell layer release a signaling ligand, while the cells in an adjacent cell layer display the cognate receptor, allowing them to respond to the released ligand. (A) In a mouse model of cervical carcinoma pathogenesis, the PDGF-CC ligand (*light brown*) is made by islands of carcinoma cells (T) and is absent from the surrounding stroma (S) (*upper panel*). Conversely, the cognate receptor—PDGF-Rα (*red*)—is displayed by the stromal cells (*lower panel*). (B) Binding of PDGF-CC by the stromal PDGF-Rα enables the stromal cells (S) to respond to PDGF *(not shown)* released by nearby carcinoma cells (E), doing so by secreting FGF-2 (*upper panel*, *brown*); the latter then signals back to and stimulates the epithelial carcinoma cells. When PDGF-R signaling is blocked in the stromal cells by treatment with imatinib/Gleevec (*lower panel*), production of FGF2 by the stromal fibroblasts is significantly attenuated. (C) In a mouse model of pancreatic carcinoma development, the Shh Hedgehog ligand (*upper panel*) is made by the pancreatic epithelial cells surrounding the ducts within the tumor (*light brown, arrows*), while cells in the stroma (*lower panel*) express the cognate Patched receptor (*red, arrows*). The ductal epithelial cells express a cytokeratin (*green*). (A and B, from K. Pietras et al., *PLoS Med.* 5:e19, 2008. © 2008 Pietras et al. Supplementary Sidebar 13.3 Certain highly advanced tumors provide exceptions to the generally observed dependence of carcinoma cells on stroma

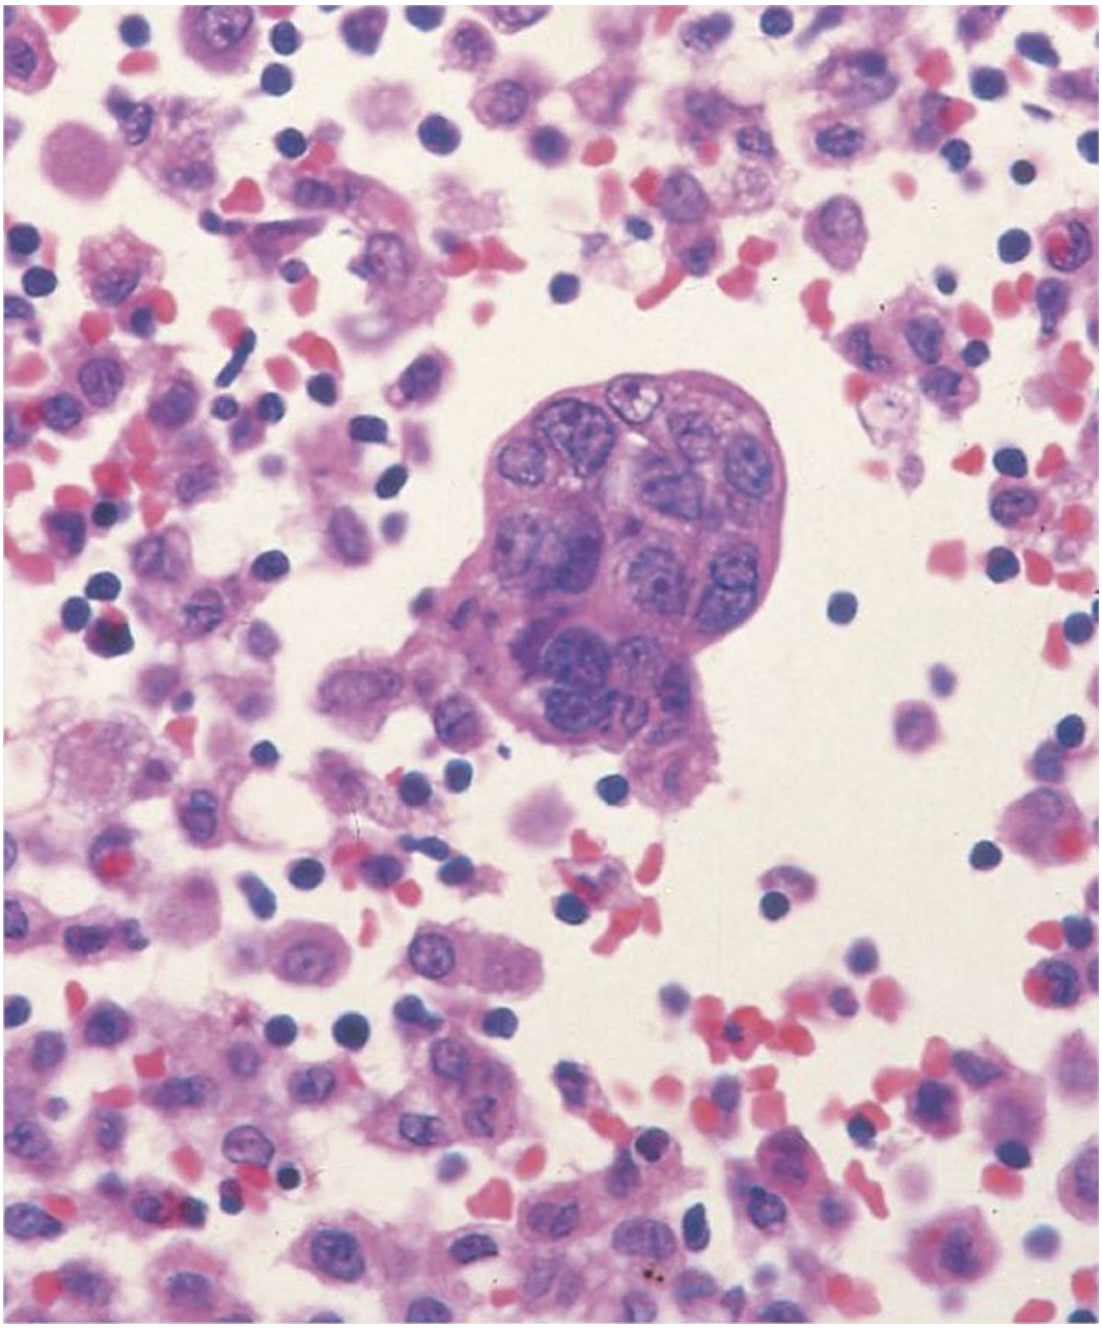
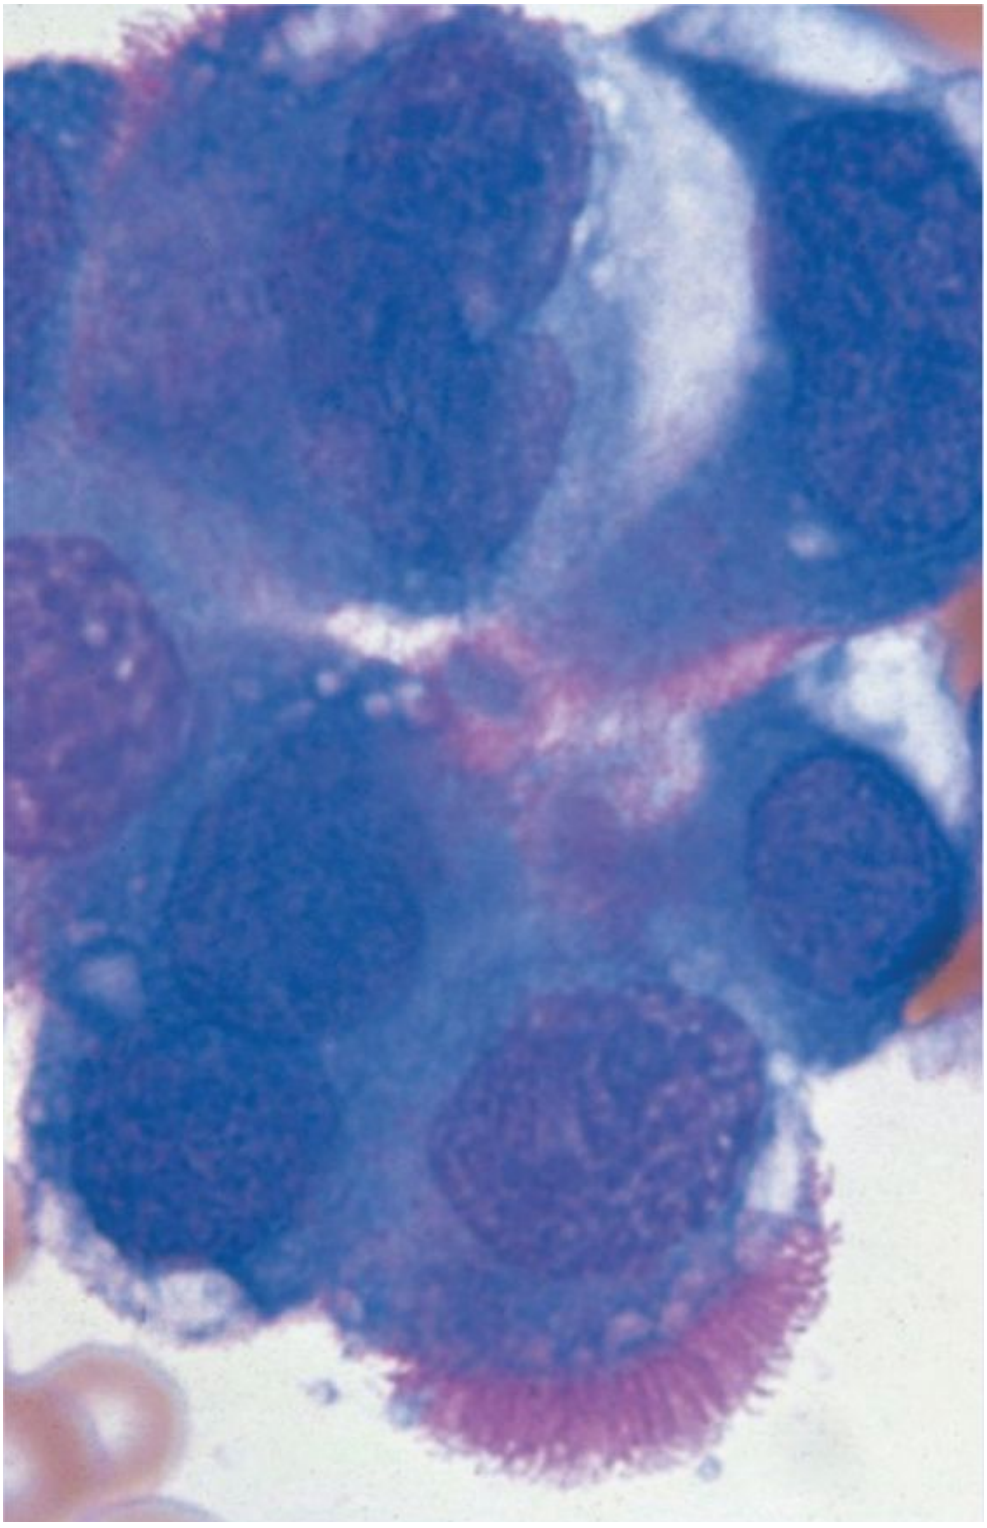
The cells in a small subset of carcinomas have evolved so far *in vivo* that they no longer require stromal support. Examples are provided by pleural and peritoneal effusions, that is, cancer cells that have left the primary solid tumor mass and acquired the ability to grow, essentially in suspension, in pleural fluid around the lung (**Figure S13.3A**) or in ascitic fluid in the abdominal cavity; the formation and accumulation of these fluids is driven in both cases by the cancer cells (Figure S13.3B). In these cases, there is no question that the cancer cells have become completely independent of direct support by other nearby cell types and instead seem to require only nutrients (and possibly soluble growth factors) for their support. Not unexpectedly, such highly progressed tumor cells adapt far more readily to tissue culture and have become the progenitors of many of the cancer cell lines used in laboratories. A prominent example here is provided by HeLa cells (see Section 10.2), which have proven to be a boon for the study of the molecular biology of human cells. These cells were readily adapted to tissue culture in 1951 because they derived from an unusually aggressive adenocarcinoma of the cervix that grew in suspension in ascites and has been propagated in culture since that time. Some evidence indicates that such highly

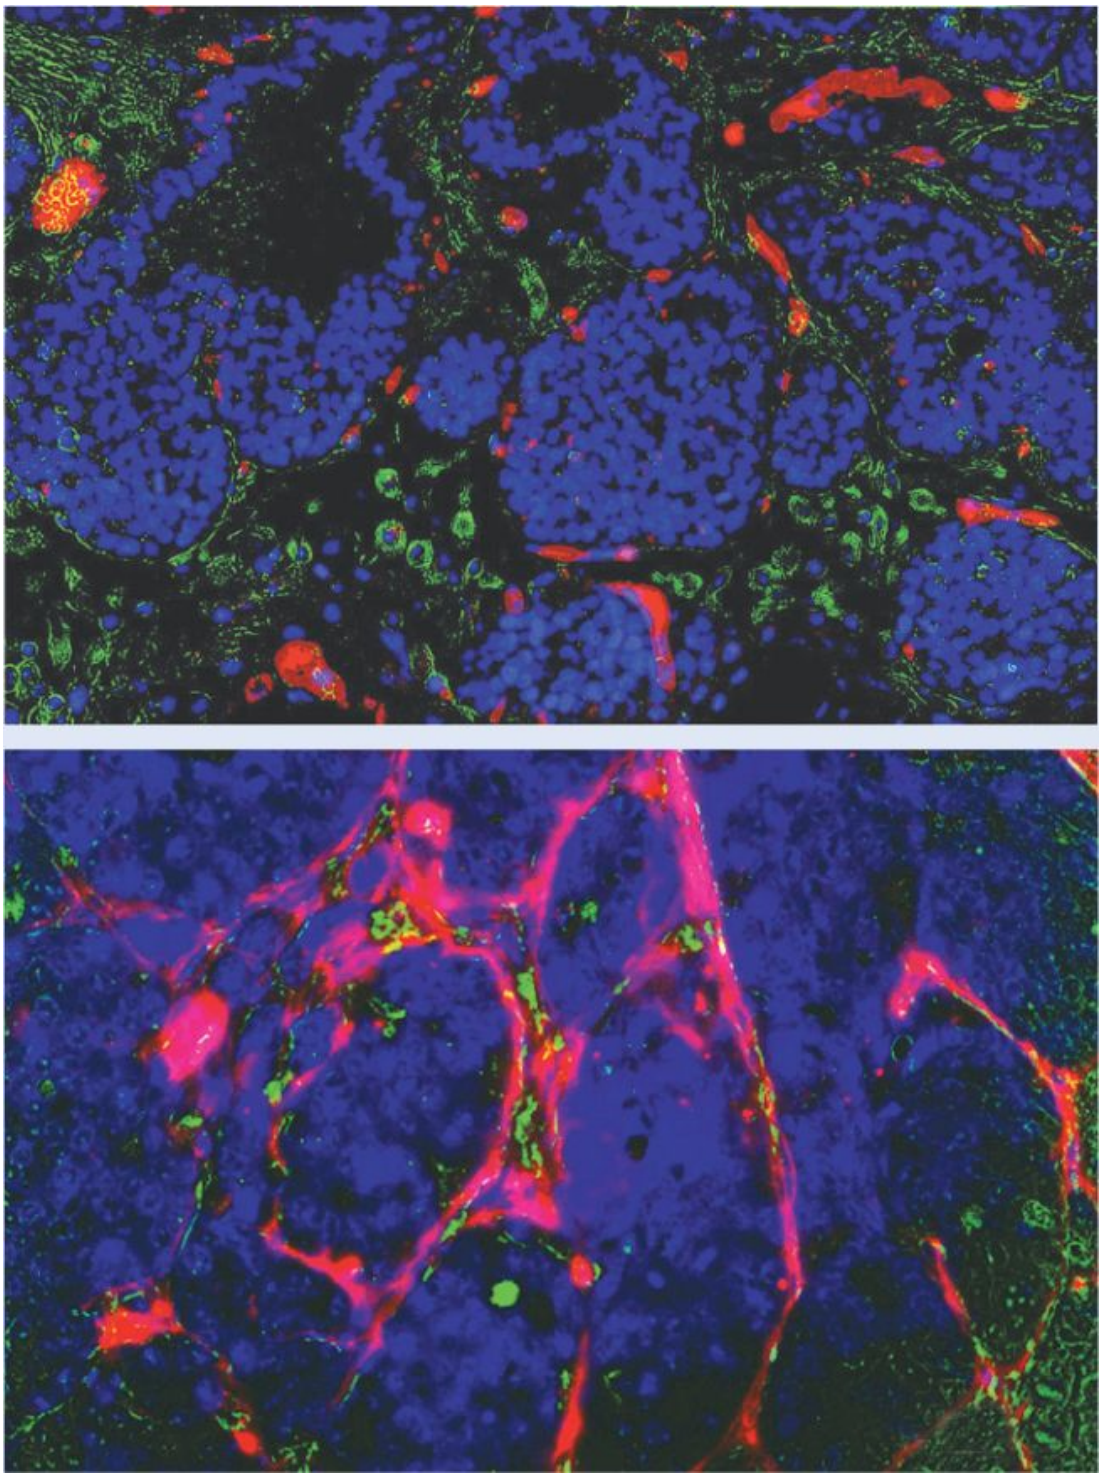
autonomous human tumor cells produce a variety of growth factors to which they can also respond; this enables them to stimulate their own proliferation and survival through autocrine signaling loops. Similarly, in the middle of a carcinoma that has become highly malignant, one can often observe cancer cells that appear to be almost as independent, in that they have virtually no stroma near them, with the exception of the tumor-associated vasculature (see Figure S13.3C).



(A)



(B)



(C)

Figure S13.3 Independence of cancer cells from stromal support (A) These cancer cells, found in the pleural fluid of a breast cancer patient, are growing essentially in suspension without any apparent contact with a supporting tumor

stroma. Such pleural effusions, or their abdominal counterparts, called ascites, are indications of the most advanced, aggressive stages of many types of solid tumors. A small clump of breast cancer cells is seen in the middle. (B) Ascites are often seen in patients with advanced tumors of abdominal organs, including carcinomas of ovary (*seen here*), pancreas, and colon. The tumor cells are often found growing as single cells or in small clumps in the ascitic fluid and can be best studied by concentrating them by centrifugation prior to examining them under the microscope, as was done here. Like many kinds of highly malignant cancer cells, these have unusually large nuclei. (C) In some solid tumors, such as these mouse mammary carcinomas, one can see sectors toward the periphery (*upper panel*) in which groups of carcinoma cells (*blue nuclei*) are layered between stromal cells, including macrophages (*green*) and those forming the neovasculature (*red*). In the same tumors, however, there are sectors (*lower panel*) where hardly any stroma is apparent besides the cells forming the neovasculature, indicating that the cells in the center have become independent of stromal support except that provided by this neovasculature. (A, courtesy of A. Lukacher. B, from A.T. Skarin, Atlas of Diagnostic Oncology, 4th ed. Philadelphia: Elsevier Science Ltd., 2010. With permission from Elsevier. C, courtesy of E.Y. Lin and J.W. Pollard.)

Supplementary Sidebar 13.4 Heterotypic signals provoke an EMT

The descriptions of the signals that induce activation of an EMT program in epithelial cells, as described in Figure 13.15, only begin to reveal the complexity of the heterotypic signals that converge on epithelial cells in various physiological situations. A more thorough accounting is provided by the diagram of **Figure S13.4**. This diagram indicates that a variety of signals released by various cell types participating in wound healing and, by extension, in the progression of carcinomas, converge on an epithelial cell and conspire with one another in various combinations to induce an EMT.

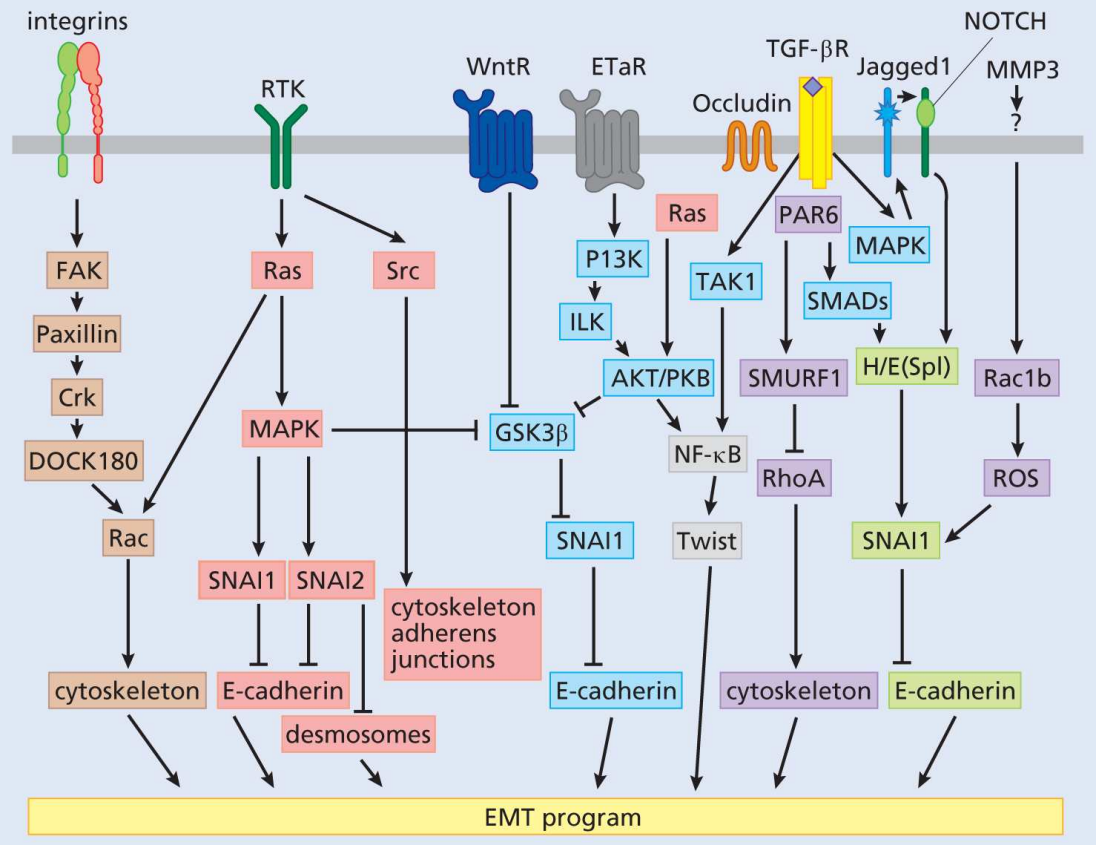


Figure S13.4 Cellular circuitry operating to trigger an EMT A diverse array of heterotypic signals converge on individual epithelial cells to induce an EMT in the latter. At present it is unclear which of these heterotypic signals and in which combinations are required in various biological situations and locations to induce expression of an EMT program. (From J.P. Thiery and J.P. Sleeman, *Nat. Rev. Mol. Cell Biol.* 7, 131–142, 2006. With permission from Nature.)

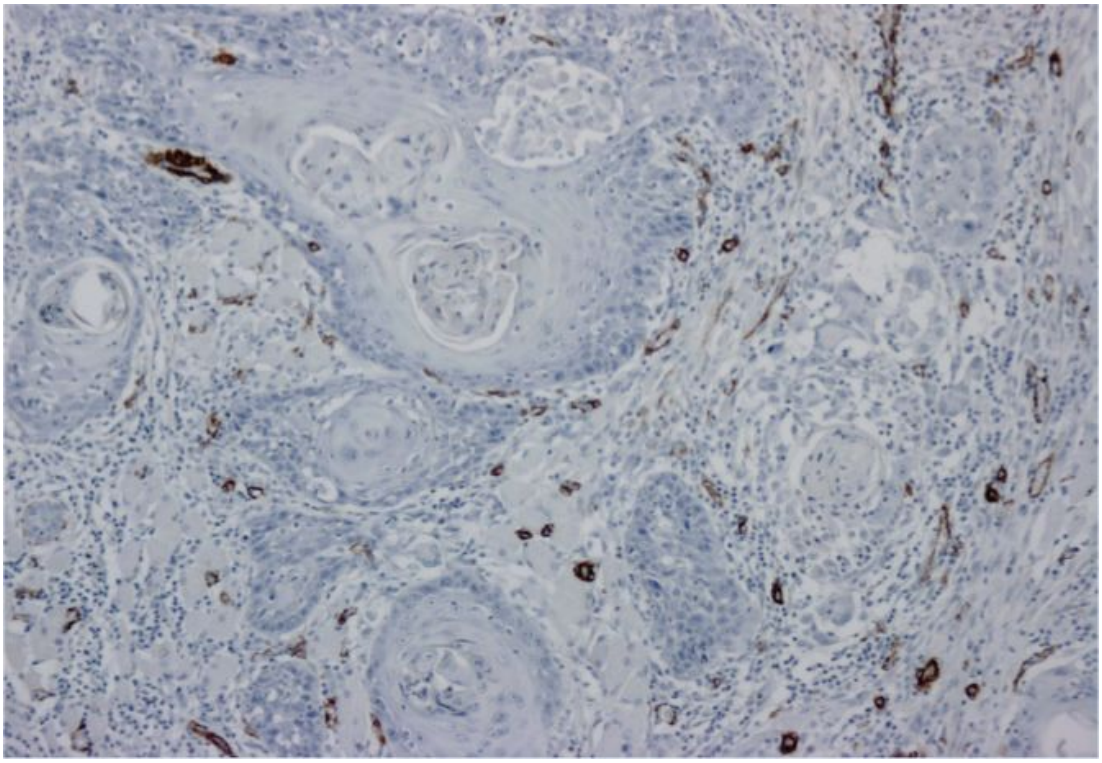
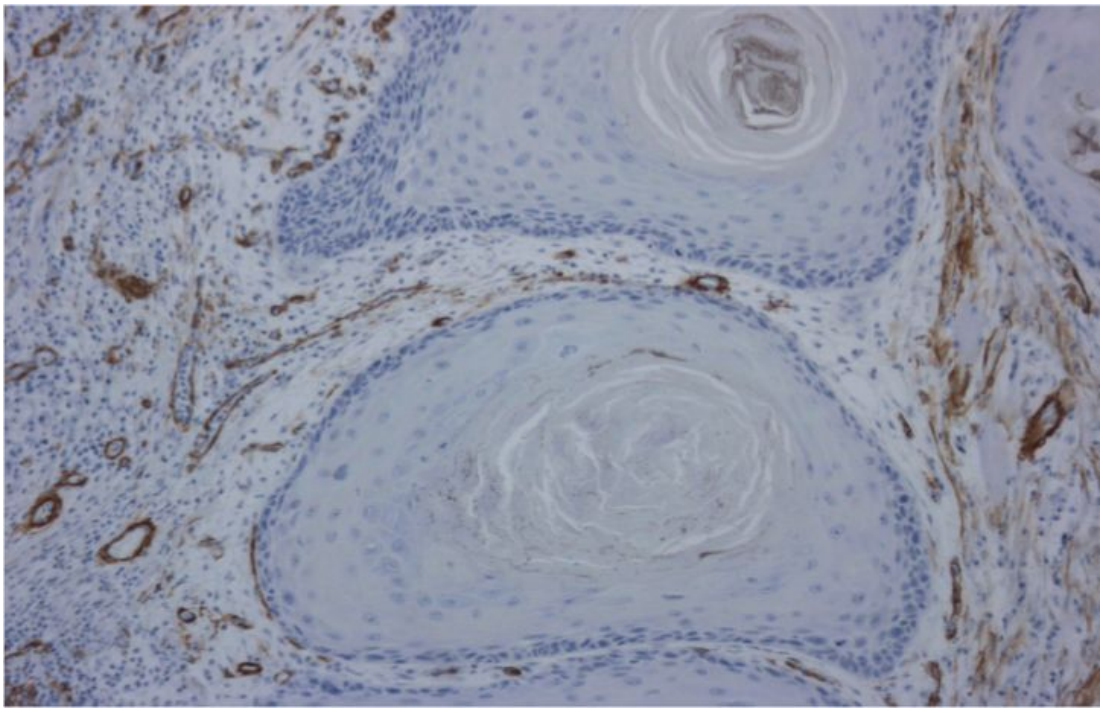
Supplementary Sidebar 13.5 Myofibroblasts predict clinical progression of cancer

A strong correlation can be observed between the predicted survival of a cancer patient and the content of myofibroblasts in the patient's tumor. As seen in this example of patients bearing squamous cell carcinomas of the mobile portion of the tongue (**Figure S13.5**), an increasing content of myofibroblasts in the stroma correlates with an increase in the rapidity with which these carcinomas progress to a fatal endpoint. Another study of oral carcinomas, published in the same year, reported that the most powerful prognostic marker for rapid progression to fatal disease could be found not in the islands of carcinoma cells but in the tumor-associated stroma, specifically in the quantity of α-smooth muscle actin (α-SMA)–positive myofibroblasts; their presence in high numbers generated a greater than threefold increased risk of death, independent

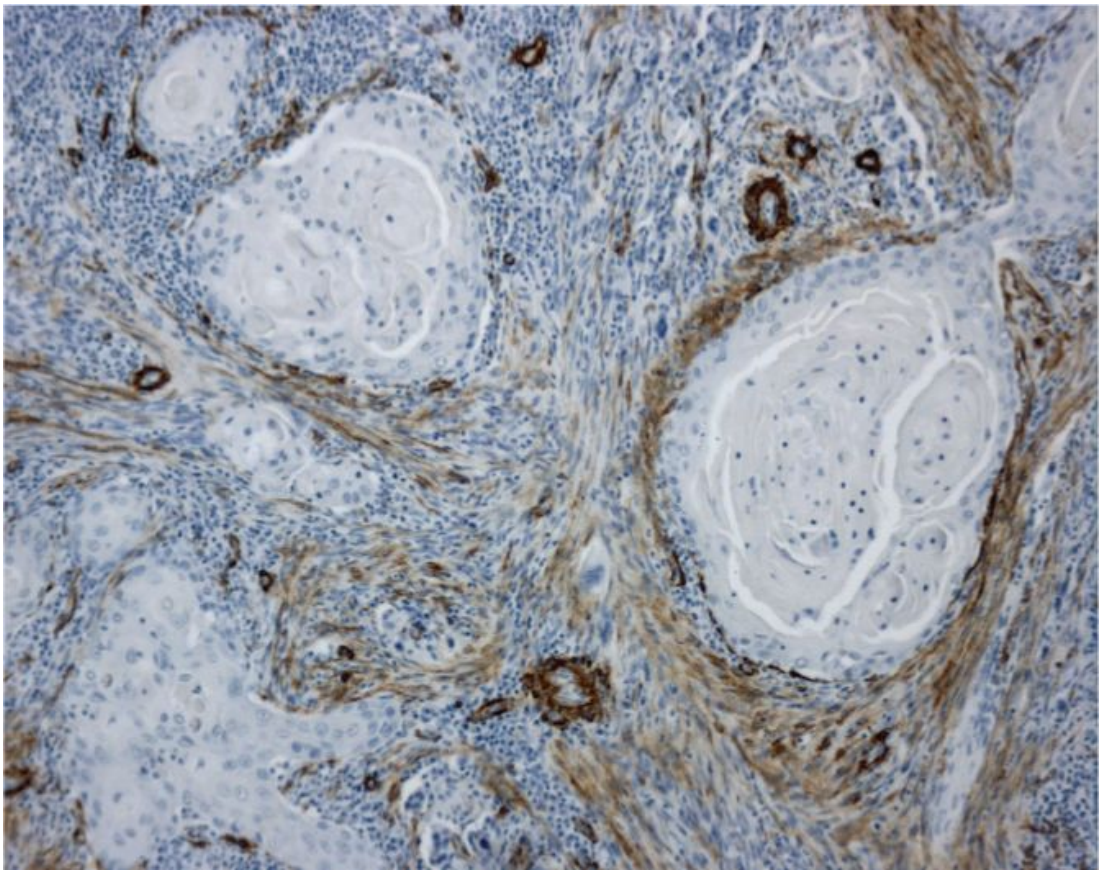
of other histopathological criteria. Importantly, the data from both studies represent correlations and thus do not on their own prove that myofibroblasts actually serve as causal forces driving tumor progression forward.



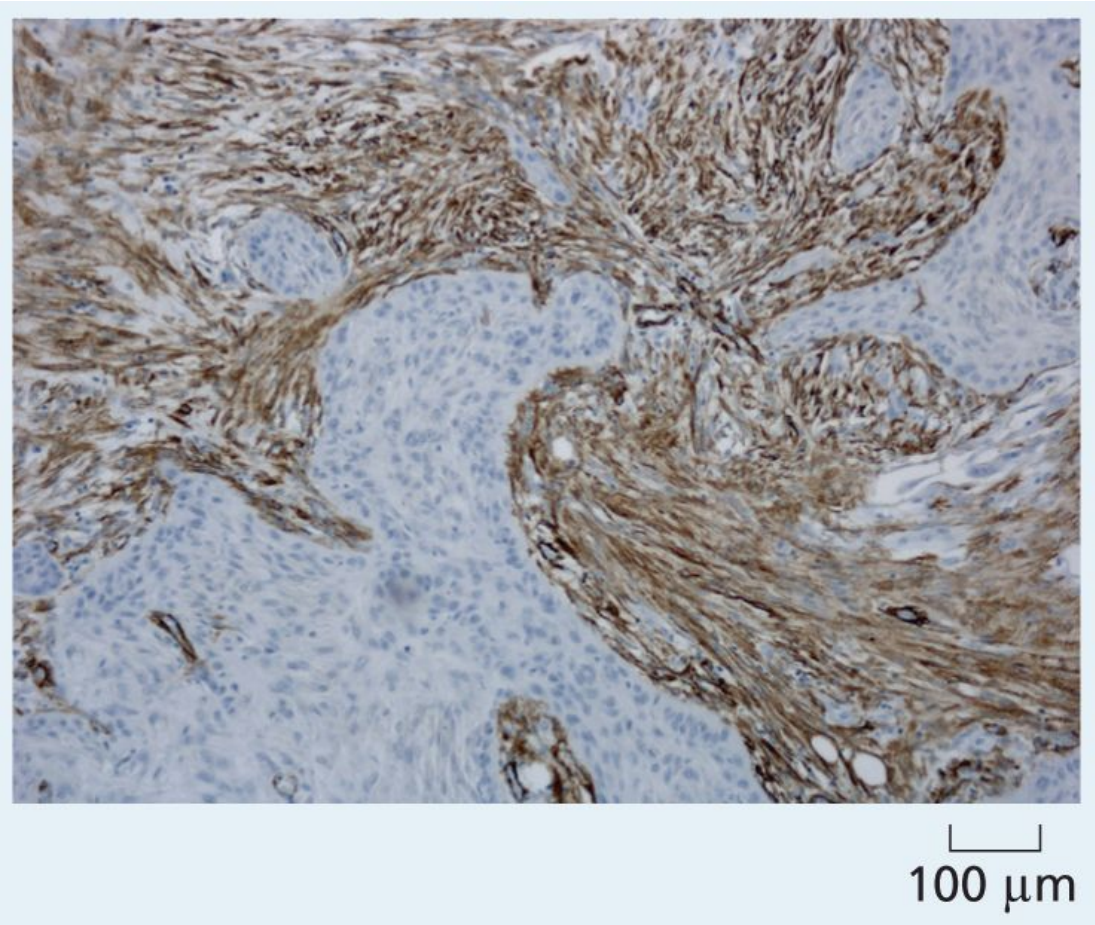
(A)



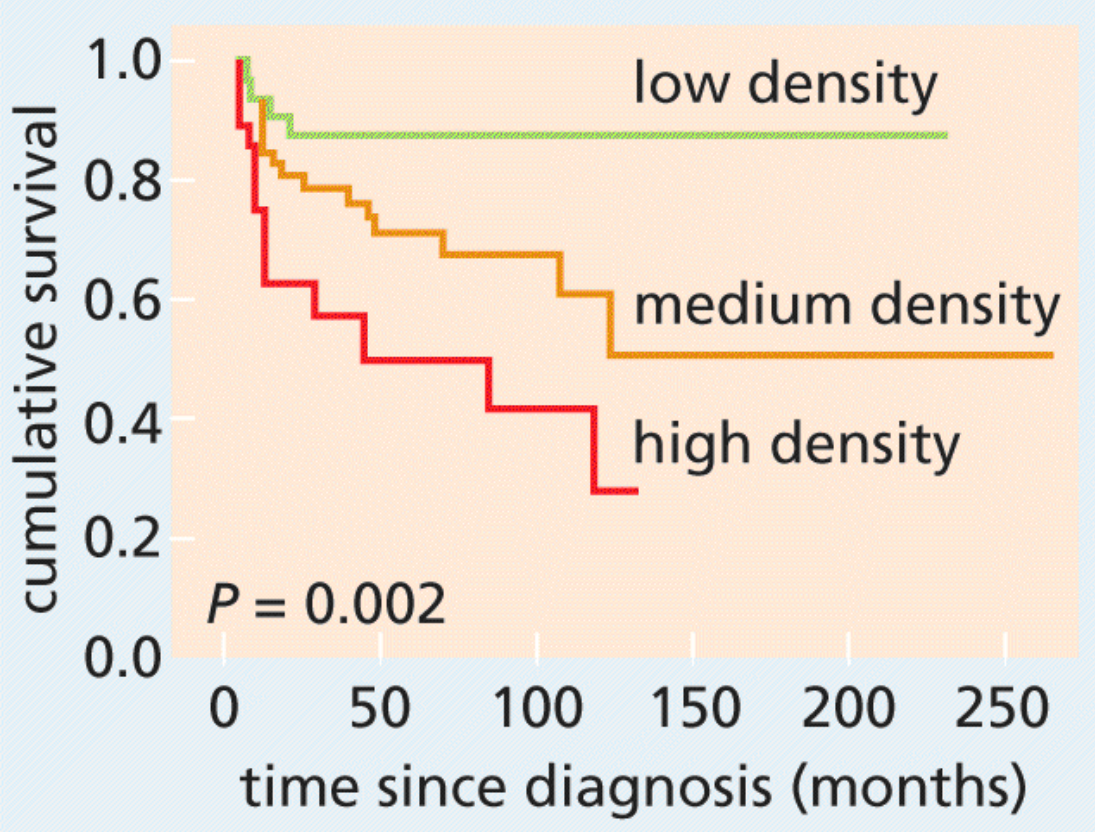
(B)



(C)



(D)



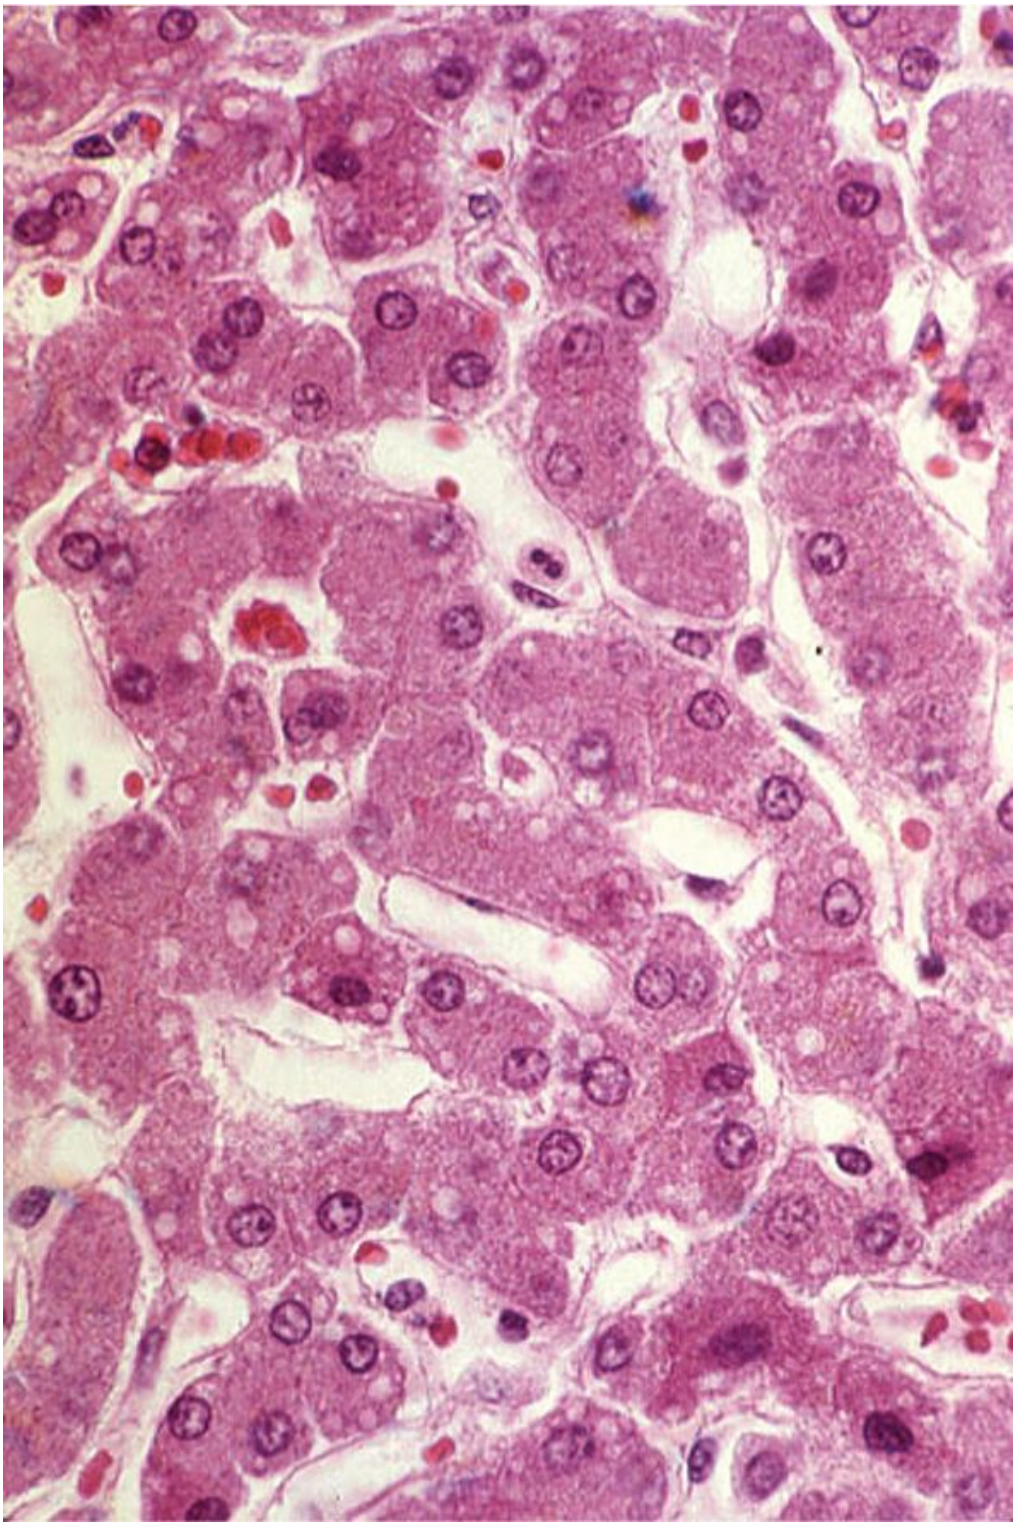
(E)

Figure S13.5 Content of myofibroblasts and clinical prognosis One strategy for determining prognosis—in this case long-term survival of a cancer patient—comes from measuring the content of α-smooth muscle actin (α-SMA)–containing myofibroblasts in the tumor-associated stroma. This measurement provides striking correlations between the content of these cells in the stroma and the rapidity of tumor progression. In these squamous cell carcinomas of the mobile portion of the tongue, different densities of α-SMA–containing myofibroblasts can be observed: (A) low, (B and C) medium, and (D) high densities. (E) The densities of stromal myofibroblasts have been correlated with the proportion of patients surviving for various times after initial diagnosis. These data provide compelling evidence of the inverse relationship between stromal myofibroblast density and survival time of patients. (A–D, from I.O. Bello et al., *Oral Oncol.* 47:33–38, 2011. With permission from Elsevier.)

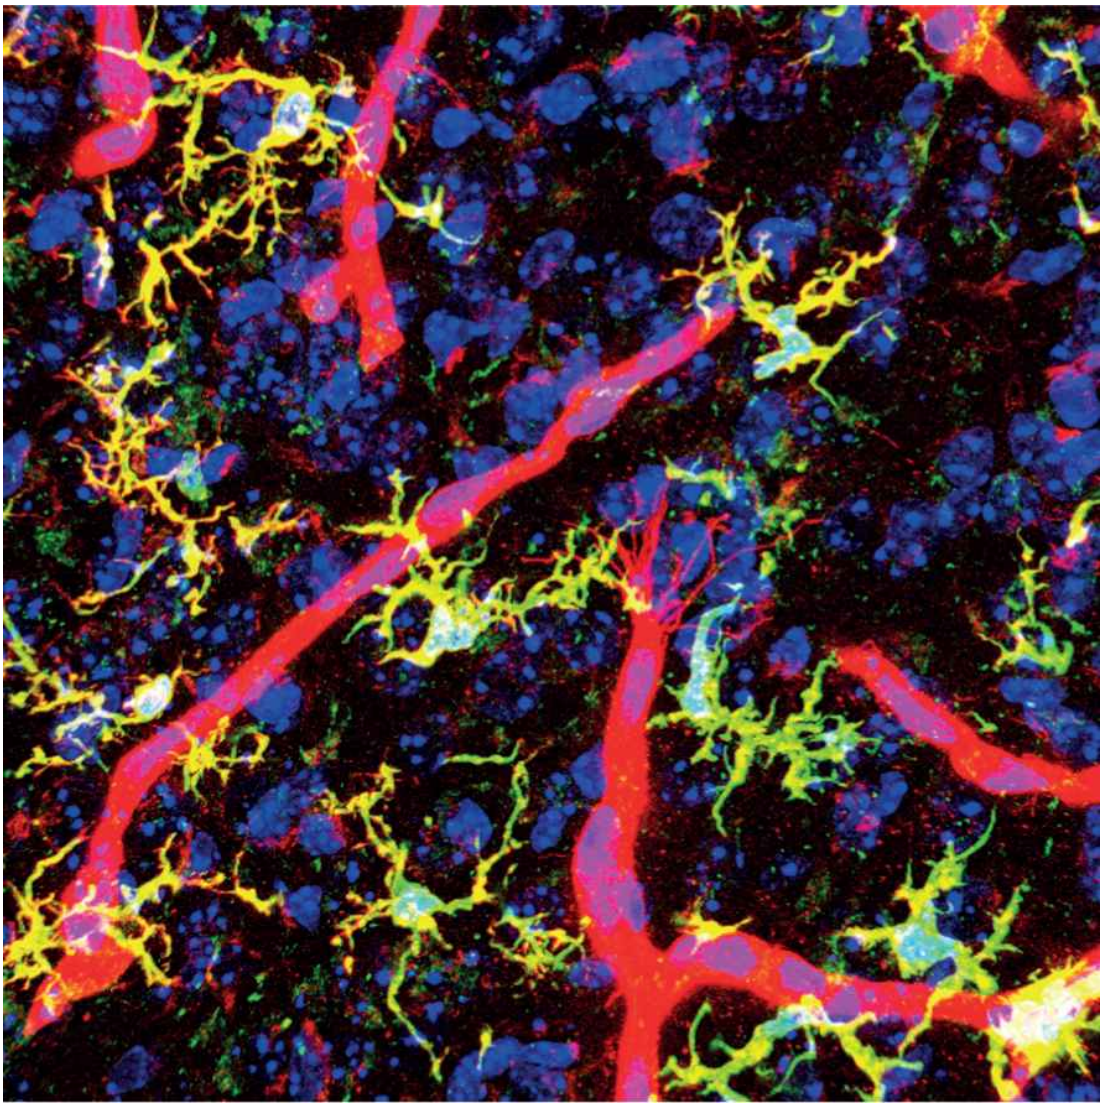
Supplementary Sidebar 13.6 Alternative mechanisms incite neoangiogenesis

Hypoxia is only one price that cells lacking close proximity to the circulatory system pay. Cells also require effective interactions with the vasculature in order to acquire

nutrients and to shed metabolic waste products and carbon dioxide. The capillary networks threading their way through many normal tissues are arrayed so densely that virtually all cells in a tissue are no more than several cell diameters away from the nearest capillary (**Figure S13.6**). In some normal tissues with an especially high metabolic activity, most cells enjoy direct contact with at least one capillary. This intimate association ensures that their access to oxygen and critical nutrients does not depend on the diffusion of these molecules over longer distances and through densely packed cell layers.



(A)



(B)

Figure S13.6 Dense microvasculature in normal liver and muscle Because of high metabolic rates, certain tissues develop an extremely high density of capillaries, ensuring almost every cell direct contact with endothelial cells and the capillaries that they form. (A) Virtually every hepatocyte in the liver is adjacent to a space, termed a *sinusoid*, that is lined with endothelial cells and serves as a capillary. (B) In the developing mouse brain, microglia (*yellow*) are seen to be closely juxtaposed with mature and growing capillaries (*pink*). Yet other nearby cell types are indicated by their DAPI-stained nuclei (*blue*). (A, courtesy of Loyola University Medical Education Network. B, from Wälchli, T., Mateos, J., Weinman, O. *et al*. Quantitative assessment of angiogenesis, perfused blood vessels and endothelial tip cells in the postnatal mouse brain. *Nat Protoc* 10, 53-74 (2015). With permission from Nature.)

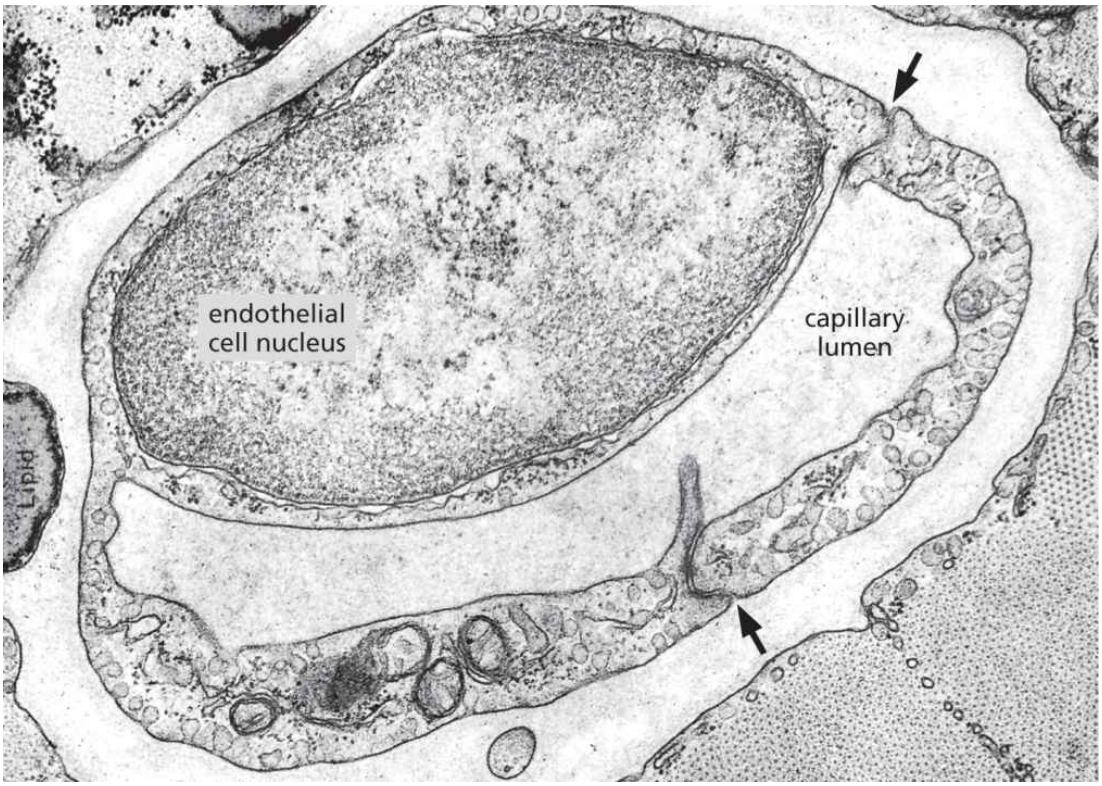
These observations illustrate the central importance of the vasculature to the growth and survival of all types of tissue, normal and neoplastic. The process of developing this vasculature through angiogenesis (the outgrowth via sprouting of new blood vessels from existing ones) can be observed during embryonic development, implantation of the placenta, wound healing, and certain pathological conditions such as diabetic retinopathy, psoriasis, rheumatoid arthritis, and, of course, tumorigenesis.

During embryonic development, the overall size and architecture of an organ or tissue is genetically programmed, but the precise locations of its individual component cells are not. This organization applies as well to the vasculature: the genome determines the overall layout of the major vessels and delegates to the individual cells within a tissue the task of designing and assembling local capillary networks and slightly larger vessels. Heterotypic interactions operating over short distances determine the routing of individual capillaries constituting the microvasculature. More specifically, capillaries appear to form wherever they are needed by the nonvascular (that is, parenchymal) cells in a tissue.

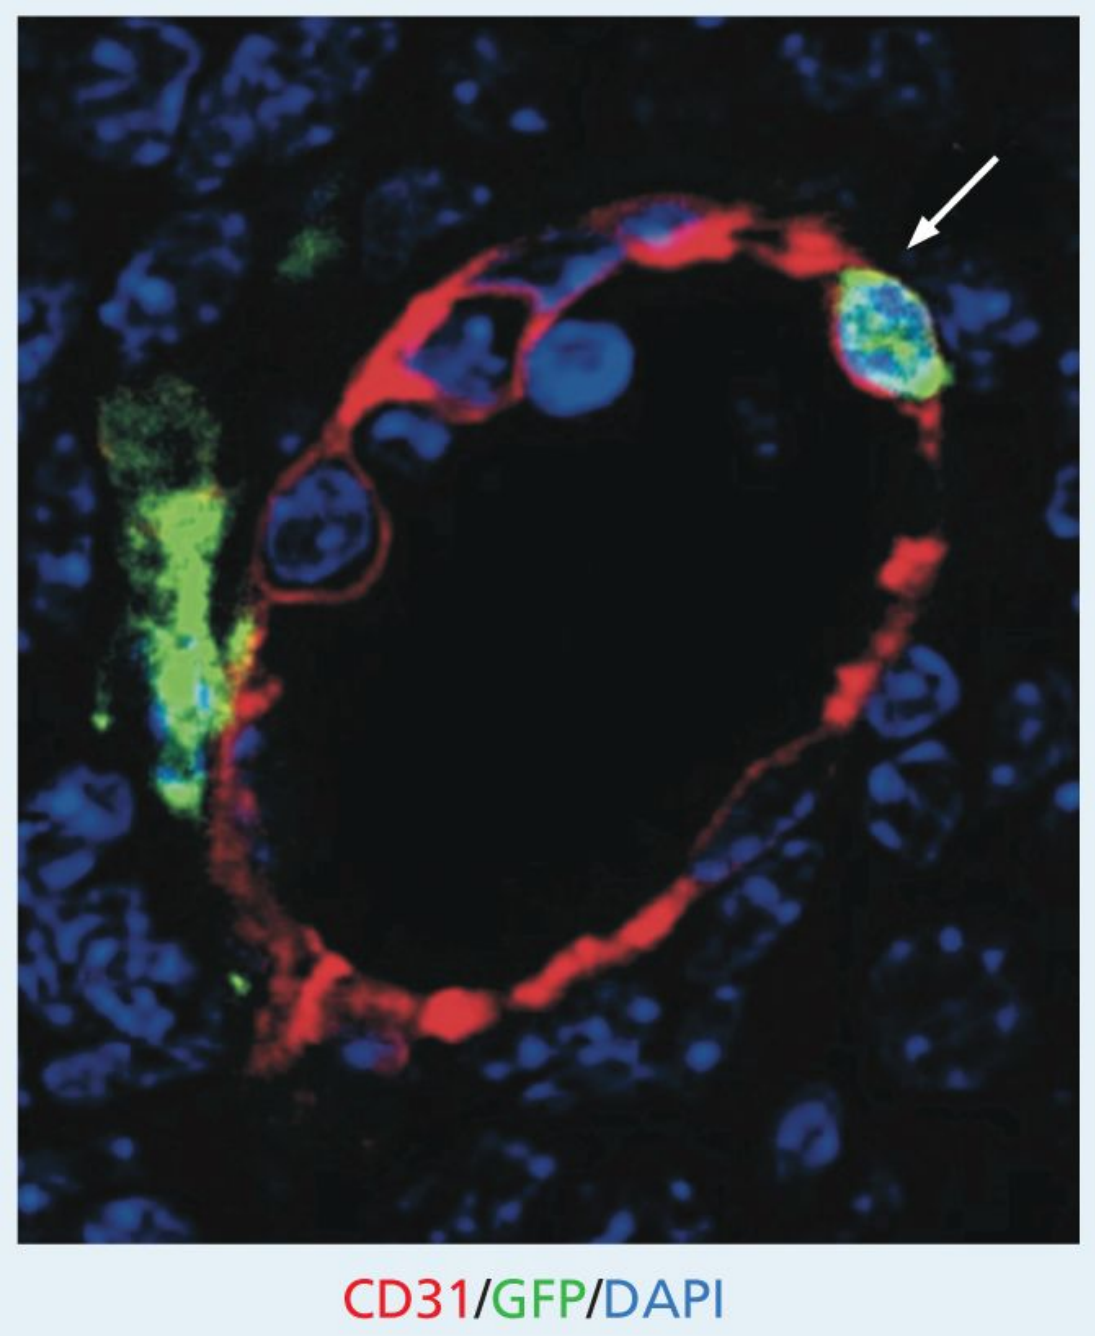
A variant of this plan operates during tumorigenesis. The overall architecture of individual tumors cannot be determined by the genome of an organism, because each tumor that arises is a novel invention whose design is not anticipated by the genome. This fact has implications for tumor angiogenesis as well: tumors cannot rely on some genetic blueprint to aid them in configuring their blood supply and must, instead, design the layout of their own vasculature, doing so step by step as they grow. In particular, when assembling their own blood supply, tumors depend completely on the localized heterotypic interactions between the cells of the vasculature (including endothelial cells, pericytes, and smooth muscle cells) and the individual nonvascular cells in tumors (including the neoplastic cells and the other cell types of the supporting stroma).

Many types of cells continuously take stock of their own intracellular oxygen tension through the actions of the VHL tumor suppressor protein and its partners. Under conditions of hypoxia, this complex of proteins permits functional HIF-1α and -1β transcription factors to accumulate, which in turn drives the expression of a number of genes whose products encourage angiogenesis. (In addition, low pH and signaling by the RTK–PI3K–Akt/PKB pathway can activate HIF-1–dependent signals, doing so in a fashion that is independent of oxygen tension.) Prominent among the HIF-1–induced gene products is VEGF. Synthesis of this key angiogenic factor has been associated with tumor cells, macrophages, and myofibroblasts, depending on the tumor type and its stage of progression. (In fact, there are two structurally related, functionally similar proteins termed VEGF-A and VEGF-B, with VEGF-A being the dominant angiogenic factor in most settings. We use the generic term VEGF to refer to both factors.)

Like many other growth factors, VEGF functions as a ligand of tyrosine kinase receptors—in this case, VEGF receptor-1 (also termed Flt-1) and VEGF receptor-2 (known also as Flk-1/KDR). Both are displayed on the surfaces of endothelial cells. Similarly, basic fibroblast growth factor (bFGF), another important angiogenic factor, binds to its own cognate receptors displayed by endothelial cells. Once stimulated by these angiogenic factors, the endothelial cells proliferate and contort their cytoplasms to construct the cylindrical walls of capillaries (**Figure S13.7**). These capillaries also penetrate existing cell layers, moving toward the highest localized concentration of angiogenic factors.



(A)



(B)

Figure S13.7 Endothelial cells and the formation of capillaries (A) This transmission electron micrograph reveals the cross section through a capillary in the midst of cardiac muscle and shows how the cytoplasms of two endothelial cells have become joined (*arrows*) to form the lumen of a capillary. The tight sealing of the plasma membranes of adjacent endothelial cells to one another results in capillary tubes whose walls are continuous and without gaps. The

nucleus of one of the endothelial cells is also seen here. (A pericyte coating the outside surface of a capillary can be seen in Figure 13.8A.) (B) Early in the formation of many tumors, the bulk of the endothelial cells derive from endothelial progenitor cells (EPCs) that are acquired via the circulation from the bone marrow and differentiate within the tumor stroma. In the experiment illustrated here, a mouse was lethally irradiated and then rescued by engrafting GFP^+ hematopoietic stem cells, resulting in an almost-complete replacement of its bone marrow cells by donor green fluorescent protein (GFP)-labeled cells. Seen here is a capillary growing within a Lewis lung carcinoma (LLC) that was subsequently implanted in this mouse. The endothelial cells are indicated by the CD31 endothelial-specific marker (*red*). This capillary also contains a GFP^+ cell (*green*, *arrow*), demonstrating the bone marrow origin of this particular endothelial cell. Nuclei are stained with DAPI (*blue*). As the tumor grows, an increasing proportion of the endothelial cells derive via the proliferation of local endothelial cells rather than from EPCs originating in the bone marrow. (A, from D.W. Fawcett, *J. Histochem. Cytochem.* 13:75–91, 1965. With permission from SAGE. B, from D.J. Nolan et al., *Genes Dev.* 21:1546–1558, 2007. With permission from Cold Spring Harbor Laboratory Press.)

Interestingly, early in the formation of certain experimental tumors, many of the endothelial cells forming the capillaries in the tumor-associated stroma derive from the circulating endothelial progenitor cells (EPCs) cited earlier, which originate in the bone marrow and are then induced to settle in the tumor stroma and differentiate (see Figure 13.23). However, as tumor growth continues, an increasing proportion of the capillaries are assembled from endothelial cells that are already residing locally within the tumor stroma. These EPCs are only one of several distinct hematopoietic cell types that are recruited from bone marrow and contribute to various aspects of tumor angiogenesis in the tumor stroma.

In addition, similar mechanisms appear to operate during the formation of lymphatic vessels. As we will see later in this chapter, lymph ducts are important regulators of fluid balance in the tumor stroma. In Chapter 14, they assume great importance, because they provide avenues for cancer cells to escape primary tumors and disseminate to distant sites in the body.

Supplementary Sidebar 13.7 Microvessel leakiness dooms many forms of anti-cancer therapy: optimizing anti-angiogenic VEGF-neutralizing treatment was discovered as a factor that promoted blood vessel permeability and initially was termed vascular permeability factor (VPF)

When an antibody that neutralizes VEGF is introduced into the circulation of a tumor-bearing mouse, the permeability of the tumor-associated capillaries is substantially reduced, demonstrating that the deregulated production of VEGF within tumors is responsible for much of the pathological leaking of plasma-derived water into the tumor parenchyma. This leaking causes much of the elevated hydrostatic pressure within the *interstitial* fluids of a tumor parenchyma, that is, the fluids lying between the nonvascular cells in the tumor parenchyma.

In normal tissues, the fluid pressure in the interstitial spaces is 0.4 mmHg or less, but in tumors, this pressure may reach 20 mmHg and occasionally far more. This means that the steep pressure gradient that normally operates between the lumen of a blood vessel (20 to 25 mmHg) and the surrounding parenchyma (0.4 mmHg) is absent in most solid tumors. Consequently, the introduction of low–molecular-weight drugs into tumor masses via the circulation becomes very difficult, because these molecules remain in the circulation rather than riding with surrounding water molecules down pressure gradients into the extravascular spaces. This likely explains at least some of the difficulties that have bedeviled almost all attempts to develop effective drug therapies for solid tumors; these therapies are usually stymied by the great difficulty of delivering drugs in significant concentrations to the cancer cells within the parenchyma of solid tumors.

These difficulties have inspired a new form of anti-tumor therapy in which anti-angiogenic agents are given to *normalize* the tumor-associated vasculature. Shutdown of VEGF production by tumor cells, using antisense RNA directed against the VEGF mRNA, results in a dramatic decrease in capillary permeability (**Figure S13.8A**). In addition, when an anti-VEGF monoclonal antibody is introduced into a tumor-bearing mouse, the poorly constructed blood vessels in the tumor vasculature are pruned back, returning the vasculature trees to a more normal configuration (Figure S13.8B). This shift also results in a reduction in the interstitial hypertension of the tumor parenchyma and therefore permits far more effective delivery, via the circulation, of therapeutic drugs to the tumor cells. Importantly, an even more intensive (or longer-term) anti-angiogenic therapy is more than likely to be *counterproductive*, because it results in the regression of most of the residual vasculature in a tumor, thereby making drug delivery to the tumor extremely difficult once again (see Figure S13.8B). Moreover, as discussed in Sections 13.5 and 13.11, the local areas of hypoxia that may result from excessive reduction of the tumor microvasculature can induce an increased invasiveness in cancer cells and, quite possibly, metastatic dissemination of cancer cells. Hence, doses and dosing schedules of anti-angiogenic agents must be optimized in order for these agents to serve as effective complements to more conventional chemotherapy.

Figure S13.8 Normalization of the tumor-associated vasculature (A) The permeability of tumor vessels was gauged here through the ability of a *light blue* dye, introduced into the circulation 2 minutes before sacrifice of a tumor-bearing mouse, to permeate into and throughout the tumor parenchyma from the circulation (*left panel*). Human endometrial carcinoma cells were constructed that released two angiogenic factors—FGF-2 and VEGF. When FGF-2 expression was shut down, the number of tumor-associated vessels decreased greatly, but those that remained were still highly permeable (*not shown*). However, when VEGF production was shut down (*right panel*), once again the number of tumor-associated vessels (*red*) decreased greatly and, in addition, the permeability of the surviving vessels was strongly reduced, as indicated by the virtual absence of *light blue* staining. *Arrows* indicate two vessels that are no longer connected with the circulation. (B) Intra-vital microscopy can be used to visualize, through an implanted glass window, the vasculature of a subcutaneously implanted tumor. Especially high resolution was obtained here by using a multiphoton laser scanning microscope. The vasculature of the same region of a subcutaneously implanted murine mammary adenocarcinoma was monitored following the introduction of anti-VEGF-R monoclonal antibody. The vasculature was highlighted through the intravenous injection of a contrast agent. In comparison with normal vasculature (*far left*), the vasculature of the tumor (*second image*)

initially appears contorted with many large-diameter vessels. After 2 days of treatment, the vasculature has normalized substantially. However, after 5 days, the vasculature in the tumor has regressed so far that it is barely visible (*far right*). (C) Thirty patients suffering from glioblastoma multiforme were treated daily with cediranib (AZD2171), a drug that inhibits the tyrosine kinase domains of all three VEGF receptors. Patients in whom the intra-tumoral blood flow increased during treatment, ostensibly because of normalization of the tumor-associated microvasculature, survived longer than patients in whom the blood flow was constant or decreased. (D) Anti-angiogenic treatments may elicit several alternative responses from the aberrant tumor-associated microvasculature that develops during primary tumor formation. The microvasculature may become normalized, which may facilitate drug delivery and avoid hypoxia and associated increases in tumor cell invasiveness. The microvasculature may remain unaltered, in which case continued capillary leakiness may lead to high interstitial hydrostatic pressure in the tumor parenchyma, complicating delivery of drugs from the vessel lumina to the tumor cells. Finally, the microvasculature may be almost eradicated, which may result in widespread hypoxia, tumor necrosis, or the emergence of tumor cells that respond to hypoxia by becoming more invasive. (A, from R. Giavazzi et al., *Am. J. Pathol.* 162:1913–1926, 2003. With permission from American Society for Investigative Pathology. B, from R.K. Jain, *Nat. Med.* 9:685–693, 2003. With permission from Nature. C, from A.G. Sorensen et al., *Cancer Res.*72:402–407, 2012. With permission from American Association for Cancer Research. D, from R. Jain, *Nat. Med.* 7, 987–989, 2001. With permission from Nature.)

These various arguments suggest that causing the *normalization* of the intra-tumoral vasculature rather than the *regression* of the vasculature may actually prove to be more productive therapeutically, and, indeed, certain clinical observations appear to support this notion. For example, intra-tumoral blood flow was measured in 30 patients suffering from glioblastoma by using noninvasive magnetic resonance imaging (MRI) technology. These patients were treated with an agent that inhibited the tyrosine kinase functions of all three VEGF receptor subtypes, and their tumors responded in one of three ways to the treatment: decreased blood flow (11 patients), constant blood flow (12 patients), and increased blood flow (7 patients). As is apparent from Figure S13.8C, those patients whose blood flow increased in the tumor enjoyed longer survival before they succumbed to this invariably fatal disease. This indicates that normalization of blood flow (see Figure S13.8D) may actually benefit a cancer patient.

Supplementary Sidebar 13.8 Angiogenesis is normally suppressed by physiological inhibitors

The actions of the actively pro-angiogenic factors described in Sections 13.7 and 13.8 are counterbalanced by a number of anti-angiogenic proteins and protein fragments that exist in normal tissues, largely as components of the ECM or as soluble proteins in the interstitial fluid. In addition, several of the components of the extracellular matrix are used by tissues to actively block excessive angiogenesis (**Table S13.1**). The best characterized of these is the thrombospondin-1 (Tsp-1) protein that is secreted by many cell types into the surrounding extracellular space, where it forms homotrimers and carries out several distinct functions. Most important for our discussion, Tsp-1 associates with a receptor (termed CD36) that is displayed on the surfaces of endothelial cells and halts their proliferation. In addition, research indicates that Tsp-1 treatment of endothelial cells causes them to release Fas ligand (FasL), the pro-apoptotic signaling protein that acts by binding to the Fas death receptor (**Figure S13.9**). Recall that the latter, once it has bound its ligand, activates an intracellular caspase cascade that triggers apoptosis (see Section 9.14). Therefore, once Tsp-1 causes endothelial cells to release FasL, the latter may act in an autocrine fashion to trigger the death of these cells in the event that they also display the Fas receptor.

Table S13.1 Endogenous inhibitors of angiogenesis

Inhibitor	**Description**
A. Derived from extracellular matrix	
anastellin	fragment of fibronectin
arresten	fragment of type IV collagen α_1 chain of vascular basement membrane
canstatin	fragment of type IV collagen α_2 chain of vascular basement membrane
chondromodulin-I	component of cartilage ECM
EFC-XV	fragment of type XV collagen

Inhibitor	**Description**
endorepellin	fragment of perlecan
endostatin	fragment of collagen type XVIII
fibulin	fragment of basement membrane protein
thrombospondin-1 and -2	ECM glycoproteins
troponin I	component of cartilage ECM
tumstatin	fragment of type IV collagen α_3 chain
B. Non-ECM–derived growth factors and cytokines	
interferon-α (IFN-α)	cytokine
interleukins (IL-1β, -12, -18)	cytokines
pigment epithelium-derived factor (PEDF)	growth factor
platelet factor-4	released by platelets during degranulation
Other types	
angiostatin	fragment of plasminogen

Inhibitor	Description
antithrombin III	fragment of antithrombin III
2-methoxyestradiol	endogenous metabolite of estrogen
PEX	fragment of MMP-2
plasminogen kringle 5	fragment of angiostatin
prolactin fragments	specific cleavage fragment
prothrombin kringle 2	fragment of prothrombin
sFlt-1	soluble form of VEGF-R1 (= Flt-1)
TIMP-2	inhibitor of metalloproteinase-2
TrpRS	fragment of tryptophanyl-tRNA synthetase
vasostatin	fragment of calreticulin

Figure S13.9 Thrombospondin, endothelial cell survival, and tumorigenesis (A) The stimulation of resting endothelial cells with angiogenic agents, such as VEGF or bFGF, creates activated, growing endothelial cells (*left branch*), which soon express the Fas death receptor (*light brown*) on their surface. Subsequent treatment of mature and recently formed endothelial cells with thrombospondin-1 (Tsp-1; *light blue*) causes both groups of cells to secrete FasL (*green*), the ligand of Fas. However, because only the activated endothelial cell displays the Fas receptor, it is preferentially induced to enter apoptosis by Tsp-1, whereas the FasL secreted by the mature, resting endothelial cell cannot be induced to enter apoptosis because it cannot bind and respond to secreted FasL. This behavior seems to explain why Tsp-1 can block new angiogenesis but has relatively minimal effects on already-constructed vasculature, whose endothelial cells are only rarely involved in active proliferation. (B) The loss of *ras* oncogene expression can lead to a rapid increase in Tsp-1 expression. This may explain why, in this transgenic mouse model of melanoma development, shutdown of *ras* oncogene expression in already-formed *ras*-induced tumors leads to rapid collapse

of the tumor-associated vasculature and tumor regression. Here, the TUNEL assay (see Figures 9.19 and S9.3) for apoptosis reveals apoptotic endothelial cells within a capillary (*arrow*) of a regressing melanoma. (A, adapted from O.V. Volpert et al., *Nat. Med.* 8:349–357, 2002. B, from L. Chin et al., *Nature* 400:468–472, 1999. With permission from Nature.)

Interestingly, the Fas receptor is displayed on endothelial cells that are actively proliferating or have recently ceased proliferation, but its display is suppressed once these cells have successfully formed mature capillaries and retreated into quiescence (see Figure S13.9). This seems to explain a most intriguing aspect of Tsp-1 behavior: it selectively inhibits and causes regression of newly formed and still-growing capillaries but has little if any effect on already-formed, mature capillaries. In fact, several other natural anti-angiogenic factors also exhibit such selectivity and, like Tsp-1, seem to depend upon activation of the pro-apoptotic caspase cascade in endothelial cells, because compounds that inhibit the caspase enzymes also protect endothelial cells from the anti-angiogenic effects of Tsp-1 and the other natural blockers of angiogenesis.

Transcription of the *TSP1* gene is strongly induced by p53, ostensibly as part of the p53-mediated emergency response that leads to a generalized shutdown of cell proliferation and tissue growth. Conversely, the loss of p53 function, which is seen in almost all human tumors (see Chapter 9), leads to a substantial decrease in Tsp-1 levels. This permits angiogenesis to be induced by cells that normally would have been prevented from doing so by the high Tsp-1 concentrations in the surrounding extracellular matrix.

The Ras oncoprotein, acting through a complex signaling cascade, acts in the opposite fashion, because it causes shutdown of *TSP1* gene expression. The resulting absence of significant levels of Tsp-1 can also contribute substantially to the elevated angiogenic powers of *ras*-transformed cells compared with their normal neighbors. In one study of melanomas arising in transgenic mice, expression of the H-*ras* oncogene, which had been used to initiate these tumors, was shut down after they had grown to a considerable size. These tumors collapsed rapidly thereafter, and this collapse was directly traceable to their loss of functional vasculature, most of which was recently synthesized and began to disintegrate within six hours after the loss of Ras function. The observed rapid entrance into apoptosis of endothelial cells forming the tumor vasculature preceded any decline in the levels of VEGF (which provides survival signals for endothelial cells). Although not demonstrated directly in these experiments, it seems likely that this apoptosis derived from the rapid re-expression of Tsp-1 that follows close on the heels of Ras shutdown.

Tsp-1 is surely a major governor of angiogenesis, but as hinted above, it is only one of a large cohort of natural inhibitors of angiogenesis that are found in the spaces between cells (see Table S13.1). Observations of the behavior of certain primary tumors and their derived metastases first suggested the existence of several other anti-angiogenic molecules. In some mouse models of tumorigenesis, metastases were found to remain small in size as long as the primary tumor that spawned them continued to grow. However, the moment the primary tumor was surgically removed, the metastases began to grow vigorously. This behavior is echoed by anecdotal reports of cancer surgeons, who have observed that after the successful surgical removal of a primary tumor, substantial numbers of metastases may suddenly sprout and flourish, doing so within several months' time.

Such observations suggested that some type of inhibitory substance released by the primary tumor acted, via the circulation, to suppress the proliferation of distant nests of metastatic cells. More specifically, these inhibitory factors, whatever their nature, seemed to block angiogenesis in these secondary growths, which failed to expand to a diameter of more than several tenths of a millimeter. Once the primary tumors were excised, the hypothetical inhibitory factors disappeared from the circulation, removing some constraints on the growth of already-seeded metastases.

The subsequent isolation of these circulating factors, initially from the urine of tumor-bearing animals, yielded the intensively studied angiostatin and endostatin molecules. Determination of the amino acid sequences of these two protein species indicated that they arise as cleavage products of familiar proteins of the extracellular matrix (ECM) or plasma. With the passage of time, yet other anti-angiogenic substances have been isolated (see Table S13.1), many of which are also formed by the proteolysis of extracellular proteins. Taken together, these discoveries suggest that as angiogenesis proceeds in normal tissues during development and wound healing, this process is eventually curtailed by the accumulation of anti-angiogenic protein fragments in the extracellular space. These naturally occurring anti-angiogenic substances can therefore be depicted as important components of negative-feedback loops operating to ensure that excessive vascularization of a tissue does not occur.

Other natural anti-angiogenic proteins function as antagonists of the matrix metalloproteinases (MMPs). VEGF stimulates the localized production of MMPs 1 to 4, which enable elongating capillaries to invade the extracellular matrix between cells. A class of secreted proteins, termed tissue inhibitors of metalloproteinases (TIMPs), can prevent this elongation by blocking the actions of these and other MMPs. For example, by forcing the ectopic expression of TIMP-2 in tumor cells, researchers have blocked the angiogenic and thus tumorigenic powers of these cells. However, the precise mechanisms by which TIMPs block angiogenesis are still not clearly resolved.

When integrated, these disparate observations about the physiological regulators of angiogenesis reinforce the idea, cited earlier, that angiogenesis is not a binary state—either on or off. Instead, different types of tumor cells acquire greater or lesser angiogenic powers, and even within a given tumor, the tumor cells are likely to show differing abilities to attract vasculature. Such behavior can be explained by a scheme (see Figure 13.44) in which the balance between pro- and anti-angiogenic factors determines whether neoangiogenesis will proceed, and if so, how intensively regions within tumors will become vascularized.

Supplementary Sidebar 13.9 Natural angiogenesis inhibitors may be employed in various forms of anti-angiogenic therapy

Arguably the most effective agents to deploy in anti-angiogenesis are molecules that are normally present in the body and used by various physiological mechanisms to constrain neoangiogenesis, that is to serve as counterweights to the pro-angiogenic factors that operate in various tissues (see **Supplementary Sidebar 13.8**). The existence of such anti-angiogenic molecules was first suggested by observations of the behavior of certain primary tumors and their derived metastases, as described in **Supplementary Sidebar 13.8**. Because these agents, such as angiostatin and endostatin, are native to the body, they have the advantage of being reasonably well tolerated without toxic side effects. They have virtually no effect on the *in vitro* proliferation of a variety of cells and, instead, are biologically active only on endothelial cells that are actively participating in neoangiogenesis *in vivo*. Moreover, these proteins can persist for some time in the circulation, thereby increasing the exposure of tumor vasculature to their anti-angiogenic effects. On the negative side, their manufacture in large quantities, like that of all proteins, is costly and challenging, and their precise mechanisms of action have been elusive.

Both angiostatin and endostatin had only modest effects in blocking the angiogenic switch in the pancreas of Rip-Tag mice (see Section 13.8). But when applied to already-vascularized small tumors, endostatin reduced by more than 80% their subsequent growth, and angiostatin reduced it by 50%. When large, well-established tumors were treated with either of these agents, relatively little effect was seen, but the two introduced together caused a 75% reduction in the mass of such tumors. Long-term endostatin treatment of mice bearing tumors formed from a lung carcinoma cell line led to regression of the tumors. This success might suggest that endostatin may be a highly effective therapeutic in the oncology clinic, but good responses in mice are rarely predictive of similar efficacy in the oncology clinic.

In fact, the development of angiostatin and endostatin as clinically useful anti-cancer agents has been abandoned in the West because clinical responses were, at best, equivocal. However, large-scale clinical trials in China have demonstrated significant

clinical benefit from adding a recombinant form of endostatin to standard chemotherapeutic agents when treating a variety of cancers. In these multiple clinical trials, the recombinant endostatin was found to act synergistically with the standard chemotherapeutics to prolong disease progression and patient survival significantly.

Yet another class of natural angiogenesis antagonists (see Table S13.1) are the interferons, which are usually studied in the context of their ability to modulate the activities of various cell types operating in the immune system. Interferon-α and -β have proven to be potent suppressors of the synthesis of basic fibroblast growth factor (bFGF) and of interleukin-8 (IL-8), both of which are strong angiogenic agents. And administration of interferon-α has proven to be useful in causing the regression of some hemangiomas (endothelial cell tumors) as well as Kaposi's sarcomas, which are also of endothelial cell origin (likely the endothelial cells forming lymph ducts). In both cases, the tumor regressions have been attributed to the anti-angiogenic effects of the interferon.

Supplementary Sidebar 13.10 Do the effects of radiotherapy depend on damaging tumor-associated microvessels?

Anti-angiogenic therapy may have been in use for many years: unbeknownst to clinical oncologists, much of the efficacy of some traditional anti-tumor therapies may derive from their effects on tumor-associated microvasculature. One striking example of this, which sheds light on how radiation therapy succeeds in destroying certain tumors, has come from studies of genetically altered mice that lack the genes encoding either the Bax protein or the acid sphingomyelinase (asmase) enzyme. Both these proteins are important pro-apoptotic regulators in a variety of cell types including, importantly, endothelial cells. Consequently, the endothelial cells from these genetically altered mice are far more resistant to toxic agents, including X-rays, than their wild-type counterparts.

In the experiments shown here, mouse tumor cells from a fibrosarcoma cell line were introduced into both wild-type and *asmase*$^{-/-}$ mice. After tumors had grown to a substantial size, these animals were exposed to a dose of 15 grays (Gy) of X-rays (**Figure S13.10**). This dose of radiation usually causes a significant reduction in tumor burden, and indeed it succeeded in doing so in the wild-type mice. However, the identically sized tumors grown in the *asmase*$^{-/-}$ host mice responded quite differently, in that their growth continued unabated. When, as a further experiment, the bone marrow of *asmase*$^{+/+}$ mice was replaced with transplanted mutant (*asmase*$^{-/-}$) bone marrow cells, the tumors became highly resistant to X-ray–induced killing.

(B)

Figure S13.10 Survival of wild-type and asmase-negative tumor-bearing mice
The responses of tumors to radiotherapy may often be determined by the

radiosensitivity of the endothelial cells that form their vasculature. Mice were bred to be either wild type or homozygous null for the gene encoding the pro-apoptotic enzyme acid sphingomyelinase (asmase). When mouse fibrosarcoma cells were implanted in the mice, the tumors grew twice as fast in the *asmase*$^{-/-}$ mice as in the wild-type mice, suggesting that a host factor, such as recruited endothelial cells, was governing the rate of tumor growth. (A) When exposed to a therapeutic dose (15 Gy) of radiation (*arrow*), the tumors in wild-type mice regressed (*red circles*) and, after a while, began to grow again. In contrast, the tumors in the *asmase*$^{-/-}$ hosts (*blue circles*) continued to grow unabated. (B) When these tumors were examined microscopically following irradiation, the endothelial cells (identified by a cell-specific immunostain) in tumors carried by wild-type mice (*below*) were apoptotic, as indicated by the TUNEL staining (*brown spots*; see Figure 9.19), whereas the endothelial cells in tumors borne by the *asmase*$^{-/-}$ hosts showed no signs of apoptosis (*above*). (C) When the bone marrow of wild-type hosts was replaced through transplantation of either wild-type or *asmase*$^{-/-}$ donor marrow cells, the tumors implanted in mouse hosts with engrafted mutant marrow (*blue curve*) continued to grow following 15 Gy of radiation (*arrow*), whereas tumors implanted in mouse hosts engrafted with wild-type marrow were stopped by the radiation (*red curve*). This procedure demonstrated that the radiosensitivity of the tumor was determined by cells of host bone marrow origin, not by the tumor cells themselves. The numbers in parentheses indicate that number of tumor-bearing mice in each experimental group. (From M. Garcia-Barros et al., *Science* 300:1155–1159, 2003. With permission from AAAS.)

These experiments demonstrate that the radiosensitivity of these tumors was not intrinsic to the tumor cells themselves. Instead, it was governed by host cells, specifically by cells recruited into engrafted tumors from the host bone marrow. These recruited host cells were indeed endothelial cells, as evidenced by the observations that (1) the apoptosis of the endothelial cells in tumor fragments irradiated *in vitro* directly paralleled and predicted the *in vivo* behavior of the tumors, and (2) the only cells that showed significant apoptosis in the tumors shortly after irradiation were associated with capillaries.

Observations like these indicate that anti-angiogenesis therapy has played a far greater role in a conventional anti-tumor radiotherapy than anyone dared to imagine; similarly, clinical responses to certain types of conventional chemotherapy may also be strongly influenced by the sensitivity of the tumor-associated microvasculature to these agents. This realization suggests that in the future, treatments with many anti-cancer chemotherapeutics may be optimized by gauging their effects on the tumor-associated microvessels rather than on the tumor cells themselves.

Supplementary Sidebar 13.11 Fibroblasts are heterogeneous and can change dynamically in response to signals

Many of the mesenchymal cell types that are recruited into the tumor stroma, either from afar (that is, from the bone marrow) or from adjacent tissues, actually represent distinct subtypes of a single well-studied cell type rather than a single, well-defined histopathological entity. Fibroblasts represent one such cell type, which under certain conditions may be induced to transdifferentiate into myofibroblasts. Fibroblasts and their derivatives exhibit great heterogeneity, depending on their tissue of origin and their association with neoplastic cells within tumors. The observations presented in **Figure S13.11** reveal how internally complex this class of cells actually is. Indeed, two dimensions of heterogeneity are indicated here: the fibroblasts prepared from various normal tissues show quite distinct gene expression patterns (Figure S13.11A), and the gene expression pattern of the stromal cells (essentially fibroblasts) from a single organ often changes as the tissue progresses increasingly toward high-grade neoplasia (Figure S13.11B). These differences in gene expression reflect underlying functional differences in fibroblast populations (Figure S13.11C).

Figure S13.11 Fibroblasts represent a heterogeneous collection of cells rather than a single distinct cell type (A) Fibroblasts were prepared from normal tissues in 43 locations throughout the human body, including both skin (samples 1–35) and internal organs, specifically the lungs, liver, aorta, skeletal muscle, and prostate gland (samples 36–43) (*left*). The results of gene expression analyses that were performed on each of these are presented in the *heat map* (*right*), in which probes reactive with a large series of genes are arrayed along the ordinate (vertical axis) and samples of fibroblasts from different tissues are arrayed along the abscissa (horizontal axis). The samples whose gene expression patterns are more closely related to one another are grouped together as indicated by the hierarchical clustering above the heat map. The degree of relative expression is given by the color bar below the heat map, where the numbers above the bar represent intensity of expression on a $\log_2$ scale. This heat map reveals several dozen distinct gene expression patterns, indicating that normal fibroblasts may reside in at least this many distinct states of differentiation. (B) The stroma from three distinct stages of esophageal cancer progression was isolated by microdissection, and the expression of stroma-specific genes was analyzed by microarrays. The expression patterns of the three distinct stages of progression—metaplasia (Barrett's esophagus), dysplasia, and frank carcinoma—were compared pairwise (labels to *left* of heat maps). These analyses reveal quite different gene expression patterns, largely of the fibroblasts within the stroma. Gene probes are arrayed *left to right*, and tissue samples are arrayed *vertically*. High expression is indicated by *red/maroon*; low expression, by *green/aquamarine*. (C) Normal human esophageal epithelial cells were experimentally transformed through the introduction of three genes (as described in Figure 11.28A). *Organotypic* cultures were prepared in which three distinct types of fibroblasts were embedded in extracellular matrix components in order to mimic *in vitro* the stroma present in the three tissues. The experimentally transformed epithelial cells were then layered above the fibroblast/ECM layer and propagated for 10 days in a series of media. The resulting cultures were sectioned and stained with hematoxylin/eosin (H&E). The fetal skin fibroblasts permitted limited invasion of the transformed keratinocytes

downward into the fibroblast/ECM layer, whereas fetal esophageal fibroblasts induced extensive, highly aggressive invasion by the epithelial cells. Adult esophageal fibroblasts permitted almost no invasion in the fibroblast/ECM layer. These images present a dramatic demonstration of the functional differences among different types of normal fibroblasts. (A, from J.L. Rinn et al., *PloS Genet.* 2:e119, 2006. © 2006 Rinn et al. This is an open-access article distributed under the terms of the Creative Commons Attribution License. B, from A. Saadi et al., *Proc. Natl. Acad. Sci. USA* 107:2177–2182, 2010. With permission from National Academy of Sciences, U.S.A. C, from T. Okawa et al., *Genes Dev.* 21:2788–2803, 2007. With permission from Cold Spring Harbor Laboratory Press.)

Initial surveys of macrophages prepared from tissues and involved in different physiological responses suggest comparable complexity. Similar analyses of other stromal cell types have not yet been produced. These analyses, when taken together, indicate an array of distinct stromal cell types that vastly exceeds the ten or so that are usually invoked to explain the complexity of stromal biology.

OceanofPDF.com

Glossary

pleural
: Referring to the spaces between the membrane covering the lungs and the wall of the chest and the underlying tissues covered by this membrane.

peritoneal
: Referring to the cavity in the abdomen that is limited by an enclosing membrane and includes the lower gastrointestinal tract and associated organs, including pancreas and liver.

angiogenesis
: Process by which new blood vessels are formed by sprouting from existing vessels; *also called* **neoangiogenesis** in certain circumstances. *Compare* **vasculogenesis**.

ascites
: (adj., **-itic**) Fluid that accumulates in the peritoneal cavity of some cancer patients, often containing malignant cells.

parenchyma
: The portion of a tissue that lies outside the circulatory system and often is responsible for carrying out the specialized functions of the tissue.

radiotherapy
: Treatment of a disease, notably cancer, through irradiation, usually in the form of X-rays that, in the case of cancer treatment, are focused on a targeted tumor or tumor-bearing tissue.

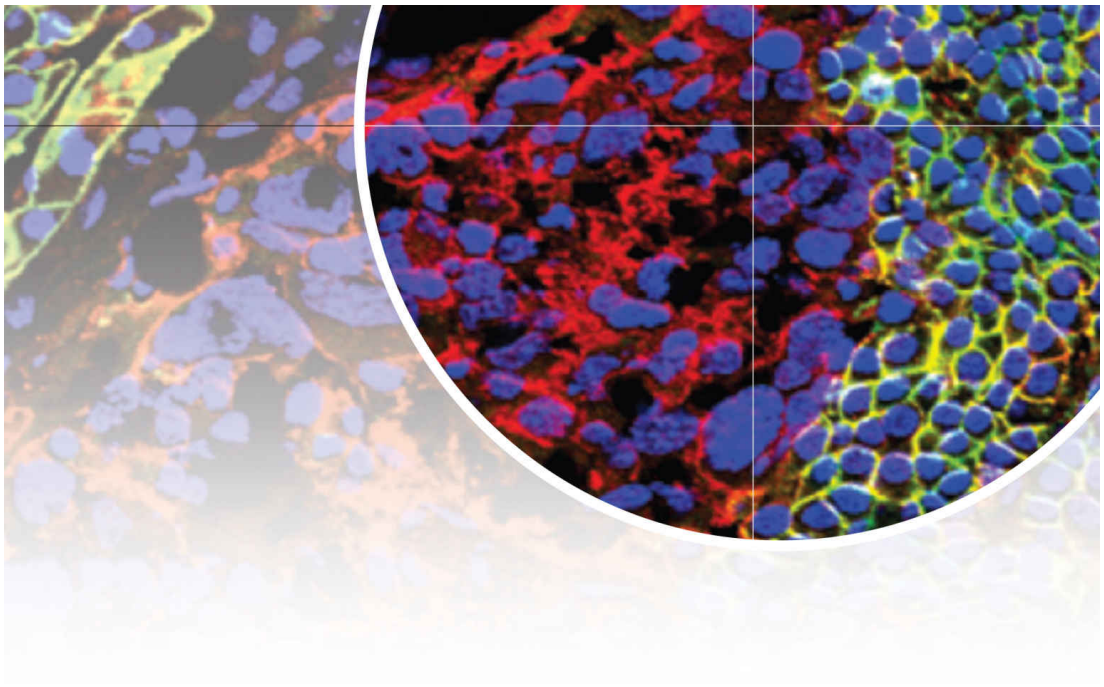
Chapter 14
Moving Out: Invasion and Metastasis



A fluorescence microscopy image of epithelial and mesenchymal pancreatic cancer cells.

The fact of cells identical with those of the cancer itself being seen in the blood may tend to throw some light upon the mode of origin of multiple tumors existing in the same person.

T.R. Ashworth, physician, 1869

What is it that decides what organs shall suffer in a case of disseminated cancer?

Stephen Paget, surgeon, 1889

It is not birth, marriage, or death, but gastrulation, which is truly the most important time in your life.

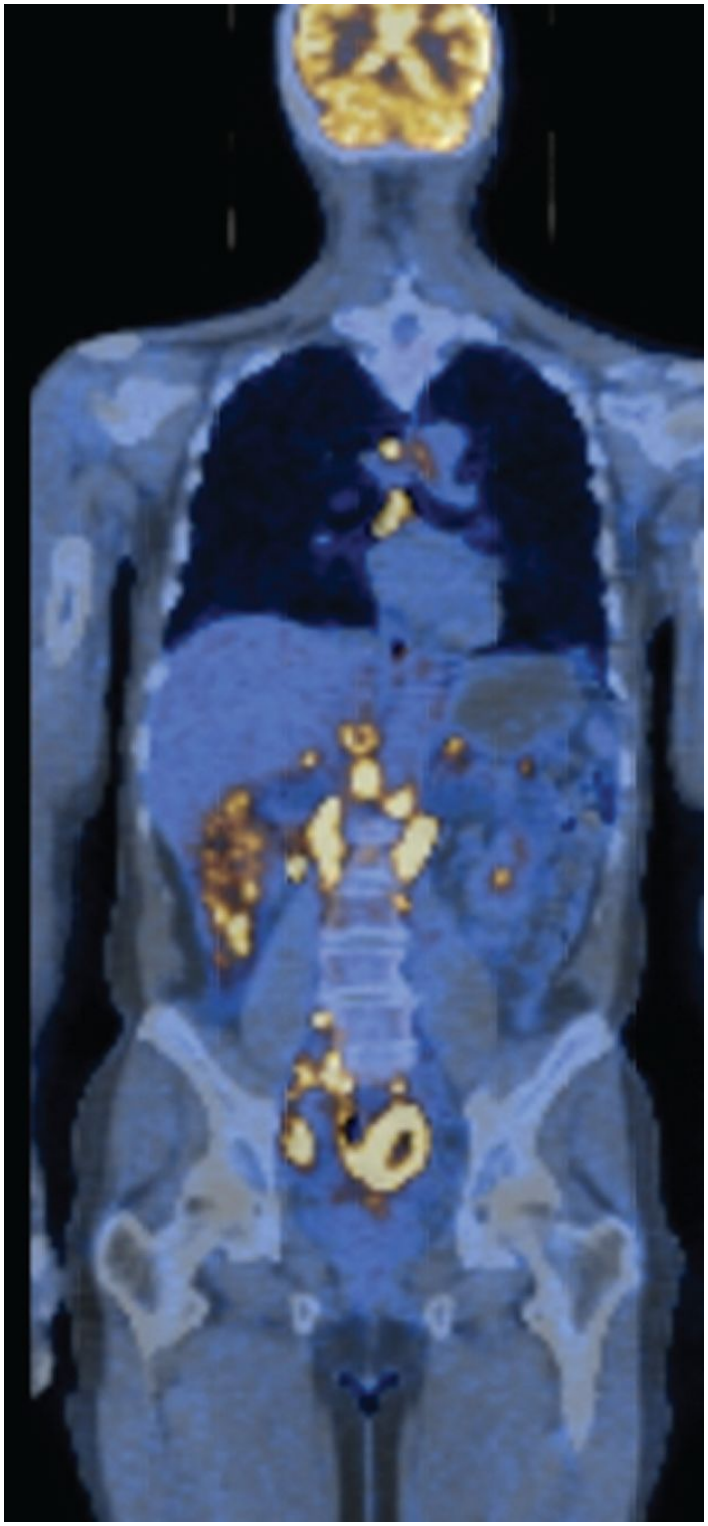
Lewis Wolpert, embryologist, 1986

In the early phases of multi-step tumor progression, cancer cells multiply near the site where their ancestors first began uncontrolled proliferation. The result, usually apparent only after many years' time, is a primary tumor mass. Given that a cubic centimeter of tissue may contain as many as 10^9 cells, we can easily imagine that tumors may often reach a size of 10^{10} or 10^{11} cells before they become apparent to the individual carrying them or to the clinician in search of them.

Primary tumors in some organ sites—specifically those arising within the peritoneal or pleural space—may well expand without causing any discomfort to the patient, simply because these cavities are expansible and their contents are quite plastic; in other sites, such as the brain, the presence of a tumor is often apparent when it is still relatively small. Sooner or later, however, in all sites throughout the body, tumors of substantial size compromise the functioning of the organs in which they have arisen and begin to evoke symptoms.

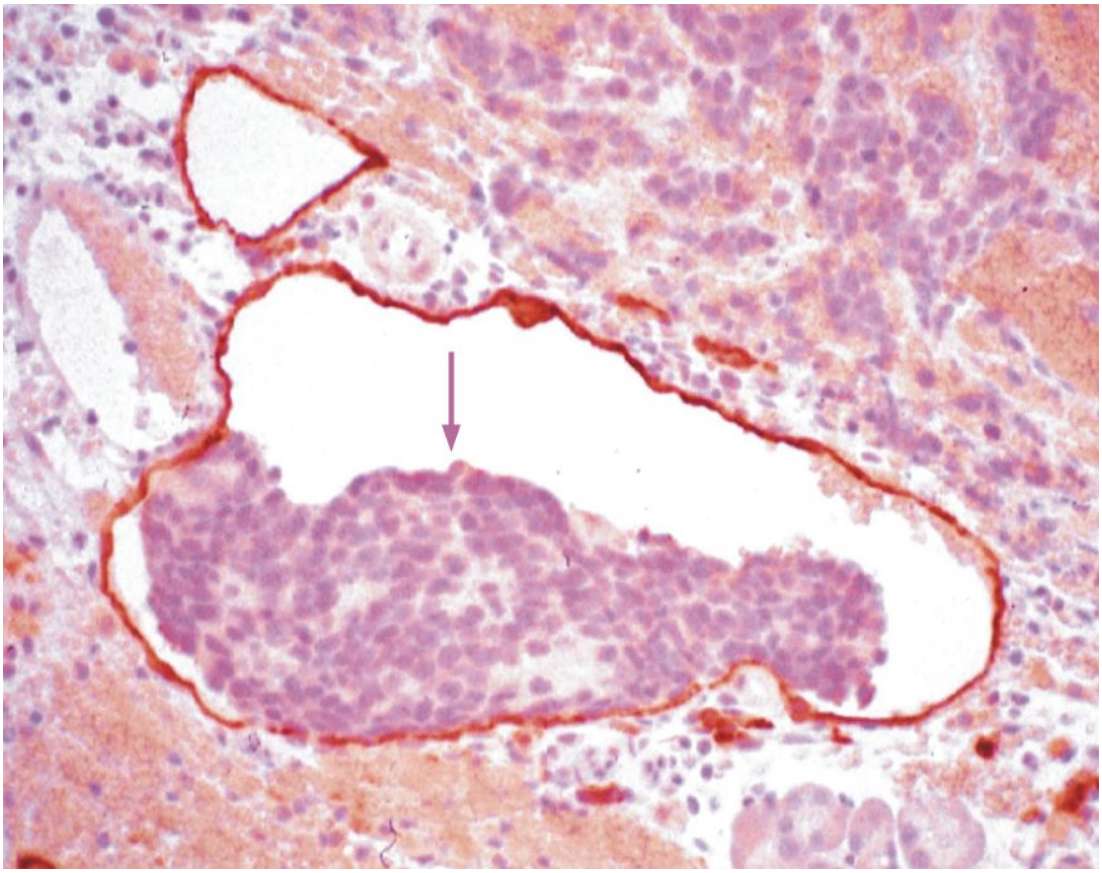
In many cases, the effects on normal tissue function come from the physical pressure exerted by the expanding tumor masses. In others, cells from the primary tumor mass invade adjacent normal tissues and, in so doing, begin to compromise vital functions. Large tumors in the colon may obstruct passage of digestion products through the lumen, and in tissues such as the liver and pancreas, cancer cells may obstruct the flow of bile through critical ducts. In the lungs, airways may be compromised.

As insidious and corrosive as these primary tumors are, they ultimately are responsible for only about 10% of deaths from cancer. The remaining 90% of patients are struck down by cancerous growths that are discovered at sites often far removed from the locations where their primary tumors first arose (**Figure 14.1**; see also Figure 2.2). These metastases are formed by cancer cells that have left the primary tumor mass and traveled by the body's highways—blood and lymphatic vessels—to seek out new sites throughout the body where they may found new colonies (**Figure 14.2**). Breast cancers often spawn metastatic colonies promiscuously in many tissues throughout the body, including the brain, liver, bones, and lungs. Prostate tumors are most often seeded to the bones, whereas colon carcinomas preferentially form new colonies in the liver.



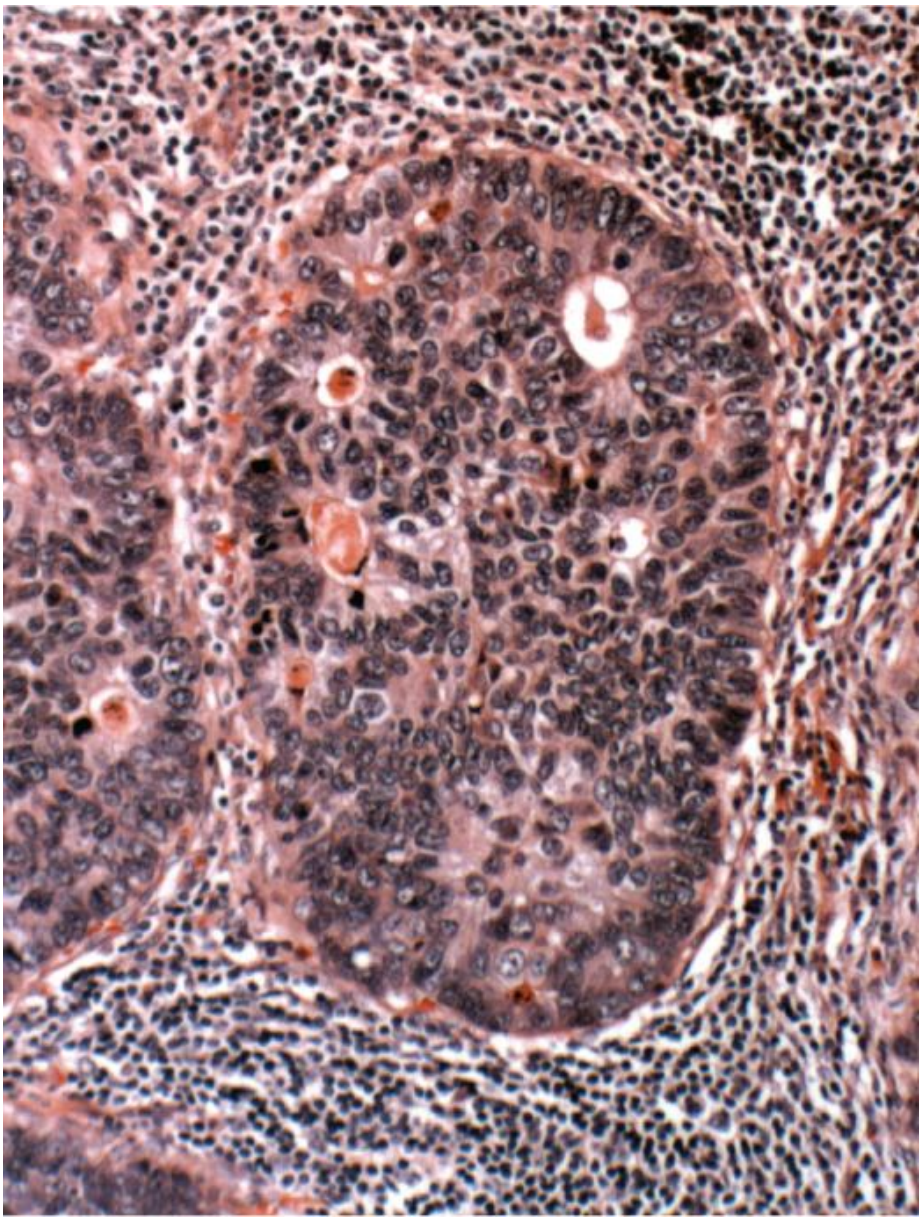
A radiographic image of a cancer patient’s body. Normal tissue appears blue or gray. The brain appears yellow, which is normal, but there are abnormal yellow regions in the pelvis, the upper abdomen below the liver and stomach, and the upper chambers of the heart.

Figure 14.1 Disseminated tumors The diagnosis of metastatic disease often represents a death sentence for a cancer patient, yet the mechanisms by which cancer cells metastasize from a primary tumor to distant sites in the body remain poorly understood. Seen here is a whole-body scan of a patient with metastatic non-Hodgkin's lymphoma (NHL). This is a fusion image of a CT (computed X-ray tomography) scan of the body's tissues (*gray, blue*) and a PET (positron-emission tomography) scan in which the uptake of radioactively labeled fluorodeoxyglucose (FDG) in various tissues (*yellow*) has been detected. FDG uptake indicates regions of high glucose uptake associated with aerobic glycolysis (see Section 11.15). The activity associated with the brain is normal. However, the yellow spots in the abdominal regions indicate multiple NHL metastases. (Courtesy of S.S. Gambhir.)



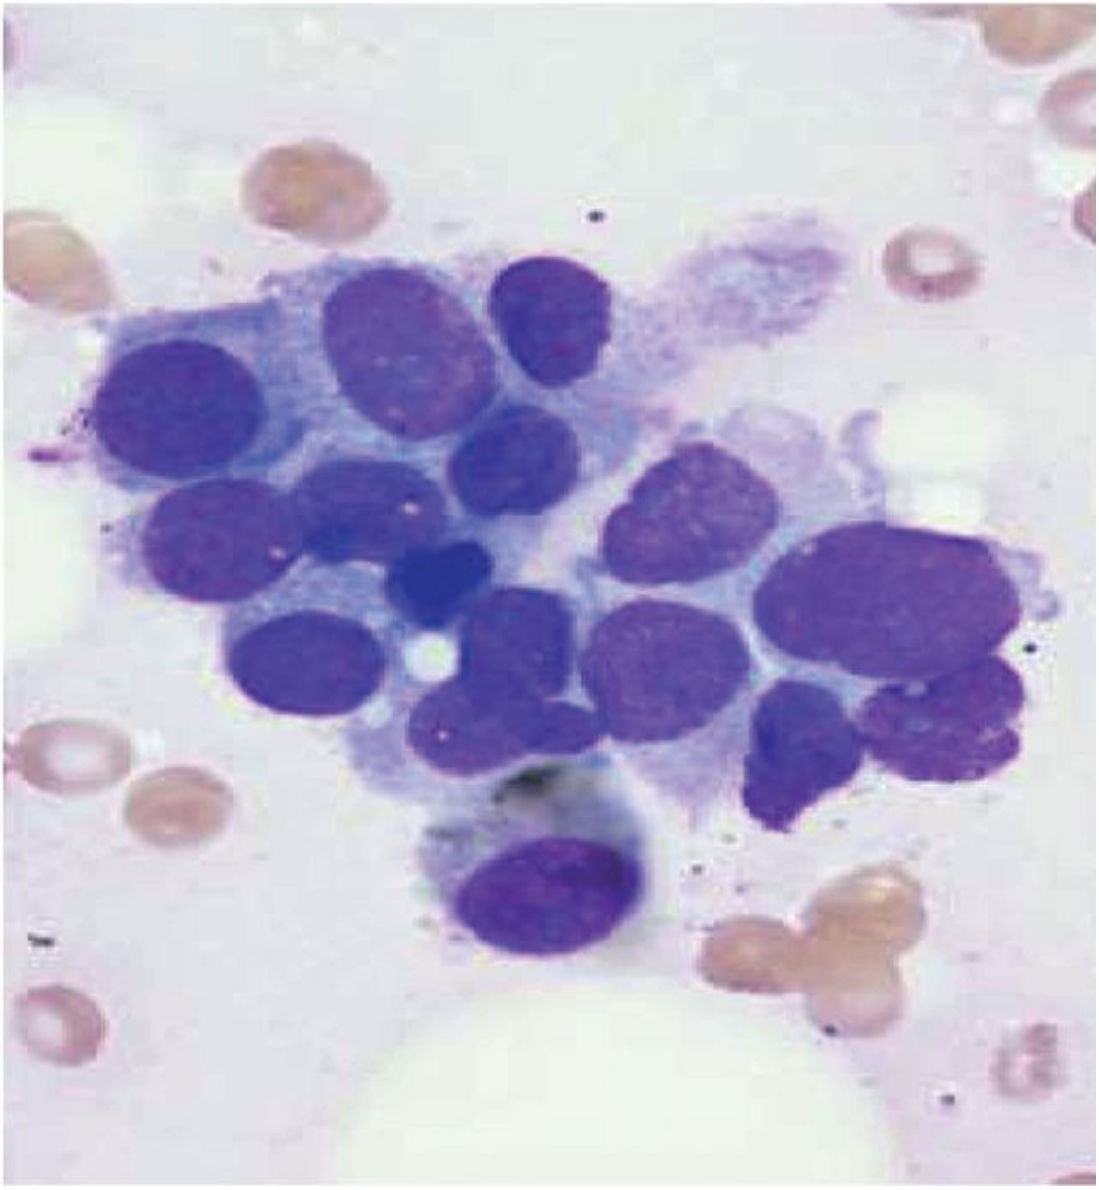
An arrow points to a dark pink clump of cells within a lumen that is lined with bright red cells. The lumen is otherwise white.

(A)



A rounded lump of tissue containing many large nuclei is surrounded by normal tissue with smaller nuclei.

(B)



A small clump of 15 to 20 blue-purple cells.

(C)

Figure 14.2 Histology of metastases in various tissues throughout the body
(A) In the Rip-Tag transgenic mouse model of pancreatic islet cell tumorigenesis (see Figure 13.35), metastasis via the lymph nodes can be encouraged through the forced expression of VEGF-C—a lymphangiogenic factor—in the islet tumor cells. Seen here is a small metastasis of islet cells (*arrow*) within a lymphatic vessel that is lined with endothelial cells (*reddish brown*). (B) A small metastasis of a human breast cancer (*center*) is seen growing within a lymph node associated with one of the lymphatic ducts draining the breast. Note that this metastasis

exhibits features that are characteristic of many primary tumors of the breast; adjacent to this metastasis are numerous lymphocytes in the surrounding lymph duct (*dark nuclei*). (C) The presence of clumps of metastatic carcinoma cells (*blue*) in the bone marrow can be revealed using specific immunohistochemistry to detect cells displaying epithelial markers, which set them apart from the mesenchymal cells naturally present in the marrow. In this particular case, however, the metastatic deposits were revealed by an alternative technique, use of the Wright–Giemsa stain. (A, from S.J. Mandriota et al., *EMBO J*. 20:672–682, 2001. With permission from John Wiley & Sons. B, courtesy of T.A. Ince. C, Fan FS, Yang C-F and Wang Y-F *Case Rep. Oncol. Med.* Article ID 2946409, 2018.)

Such wandering cancer cells are the most dangerous manifestations of the cancer process. When they succeed in founding colonies in distant sites, they often wreak great havoc. The female body can dispense with its mammary glands without losing vital physiological functions, and so almost all primary breast carcinomas do not compromise survival while they are confined to the breast. However, the metastatic colonies that breast cancer cells initiate in the bone marrow can cause localized erosion of bone tissue, resulting in agonizing pain and skeletal collapse. Metastases in the brain may rapidly compromise central nervous system function, while those in the lung or liver are similarly threatening to life because of the vital functions of these organs.

One major puzzle concerns the variable tendencies that different tumors have to metastasize. For reasons that remain obscure, primary tumors formed in certain tissues have a high probability of metastasizing, while those arising in other tissues almost never do so. After primary melanomas penetrate a certain distance downward into the tissue underlying the skin, the presence of metastases at distant sites in the body is almost a certainty. In contrast, basal cell carcinomas of the skin and astrocytomas—primary tumors of the glial cells in the brain—rarely spawn metastases. Another major unresolved issue concerns the metastatic *tropism* cited above: Why do tumors originating in a given organ preferentially seed colonies in particular tissues located elsewhere in the body?

In a variety of human tumor types, the dissemination of cancer cells throughout the body has already occurred by the time a primary tumor is first detected; at the time of initial diagnosis, these scattered cells may be clinically inapparent because they form only minute tumor colonies—micrometastases. Such behavior provokes questions that we will confront in this chapter and in Chapter 17: Do the properties of a primary tumor reveal whether it has broadcast cancer cells throughout the body that will eventually create life-threatening metastatic disease long after the primary tumor has been surgically removed? And equally important, do metastatic growths respond to therapies similarly to the corresponding primary tumors, or have the disseminated

tumor cells in these growths evolved to a state of higher resistance to various forms of therapy?

In this chapter, we confront the processes that create these most aggressive products of tumor progression. These processes initially depend within the primary tumor on complex biochemical and biological changes in cancer cells and in the tumor-associated stroma. Most of the steps of cancer formation, as described in earlier chapters, are understood in considerable detail. In contrast, our understanding of invasion and metastasis is still incomplete, explaining why these late steps of tumor progression represent the major unsolved problems of cancer pathogenesis.

Importantly, extensive efforts have been undertaken to document metastasis-specific mutations, that is, mutant alleles that are present recurrently in the cells forming metastases and are apparently absent in the corresponding primary tumors; such mutations would ostensibly be responsible for driving metastatic dissemination or the outgrowth of already-seeded metastases. Such efforts have consistently failed. These failures provide strong suggestion that, although carcinoma cells acquire a variety of somatic mutations in order to form primary tumors, additional metastasis-specific mutations do not seem to be involved in propelling primary tumor cells to distant sites in the body. This explains why the present chapter describes the mechanisms associated with invasion and metastasis as consequences of the actions of nongenetic (that is epigenetic) regulatory programs that are activated during the course of metastatic progression.

As you will see, this chapter is unusually long and takes numerous excursions, doing so for some very good reasons. Most obvious, metastases are responsible for ∼90% of all cancer-associated deaths. Then, there is the biological complexity of the process. And finally, the nature of invasion and metastasis has left major puzzles unsolved, if only because critical steps in this process have proven elusive experimentally.

OceanofPDF.com

Glossary

primary tumor

Tumor growing at the anatomical site where tumor formation began and proceeded to yield this mass. *See also* **metastasis**.

metastasis

(pl., **- es**; adj., **metastatic**; v. **metastasize**) A neoplastic growth forming at one site in the body, the cells of which derive from a malignancy located elsewhere in the body, such as the site of primary tumor formation. (2) The process leading to the formation of metastases. *See also* **primary tumor**.

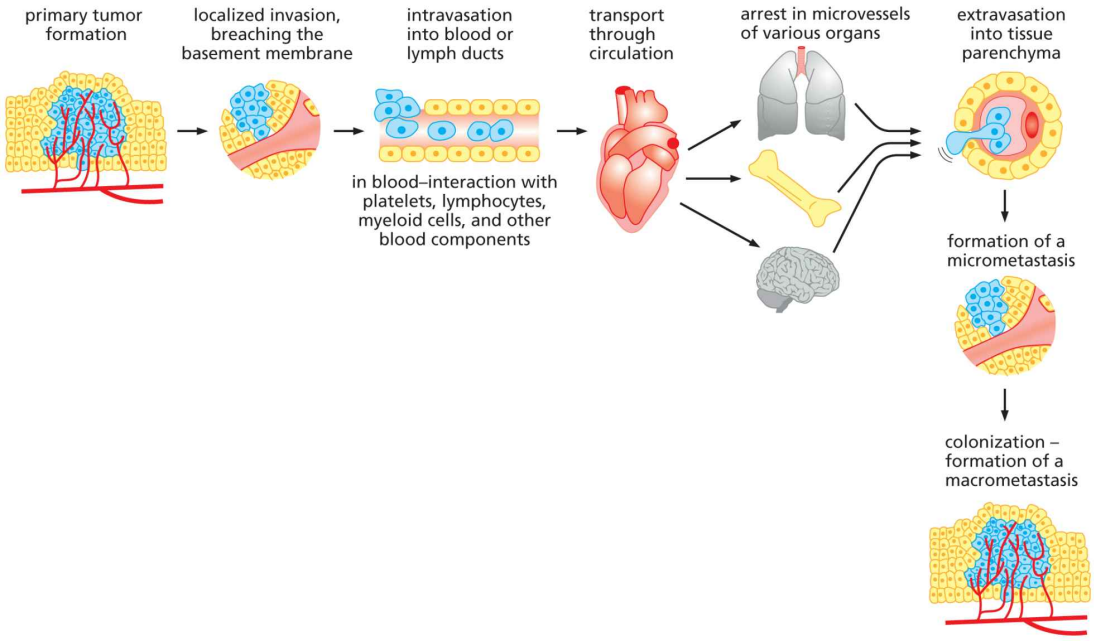
micrometastases

A single cell or small clump of disseminated cancer cells that can only be visualized using one or another form of microscopy. *See also* **macrometastasis**.

OceanofPDF.com

14.1 The invasion–metastasis cascade begins with local invasiveness

The great majority (>80%) of life-threatening cancers occur in epithelial tissues, yielding carcinomas. Consequently, most of our discussions in this chapter, as in the last, will refer to this class of tumors, with the understanding that cancers arising in other tissue types, such as connective and nervous tissues, often follow similar paths when they become invasive and metastatic. Even certain hematopoietic tumors, notably lymphomas, often have an early, localized phase and a later phase during which they become disseminated to distant anatomical sites. The overall process of dissemination, sometimes called the invasion–metastasis cascade, involves a complex succession of steps, which are outlined in **Figure 14.3**. As we proceed through this chapter, we will confront each of these steps, one after the other.



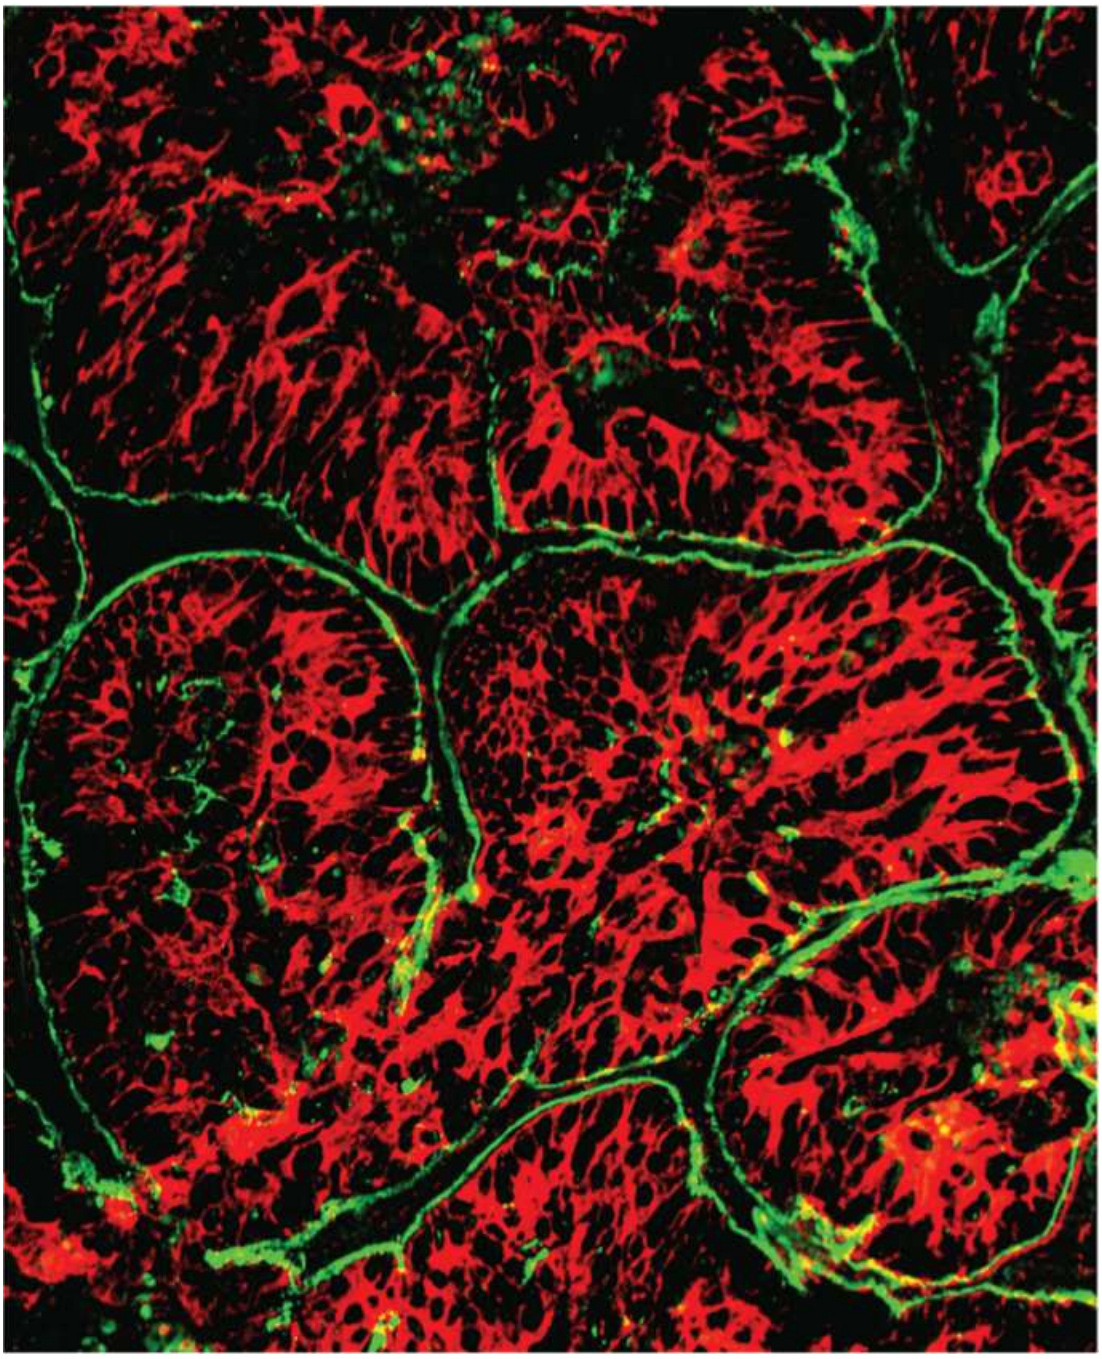
The invasion–metastasis cascade. Primary tumor formation is followed by localized invasion, breaching the basement membrane. This is followed by intravasation into blood or lymph ducts, where in blood–interaction with platelets, lymphocytes, myeloid cells, and other blood components occurs. This is followed by transport through circulation and eventual arrest in microvessels of various organs, such as the lungs, bone tissue, and the brain. The final three steps are

extravasation into tissue parenchyma, formation of a micrometastasis, and colonization–formation of a macrometastasis.

Figure 14.3 The invasion–metastasis cascade This depiction of the invasion–metastasis cascade ascribes seven distinct steps to the overall process. The initial step of localized invasiveness enables *in situ* carcinoma cells to breach the basement membrane. Thereafter, they may intravasate into either lymphatic or blood microvessels; only the latter is illustrated here. The blood may then transport these cancer cells via the general circulation (termed hematogenous dissemination) to distant anatomical sites, where they may be trapped, subsequently extravasate into the tissue parenchyma surrounding blood vessels, and form dormant micrometastases. Micrometastases may, on rare occasion, eventually acquire the ability to colonize the tissue in which they have landed, enabling them to form a macroscopic metastasis. The last step—colonization—seems to be the most inefficient of all. The small probability of successfully completing all steps of this cascade explains the low likelihood that any single cancer cell leaving a primary tumor will succeed in becoming the founder of a distant, macroscopic metastasis. More recent molecular and cell-biological studies suggest an alternative depiction involving two major phases: the first enables the physical dissemination of cancer cells from the core of the primary tumor to the parenchyma of a distant tissue, whereas the second—colonization—depends on the adaptation of disseminated cancer cells to the microenvironment of this tissue. (Adapted from I.J. Fidler, *Nat. Rev. Cancer* 3:453–458, 2003. With permission from Nature.)

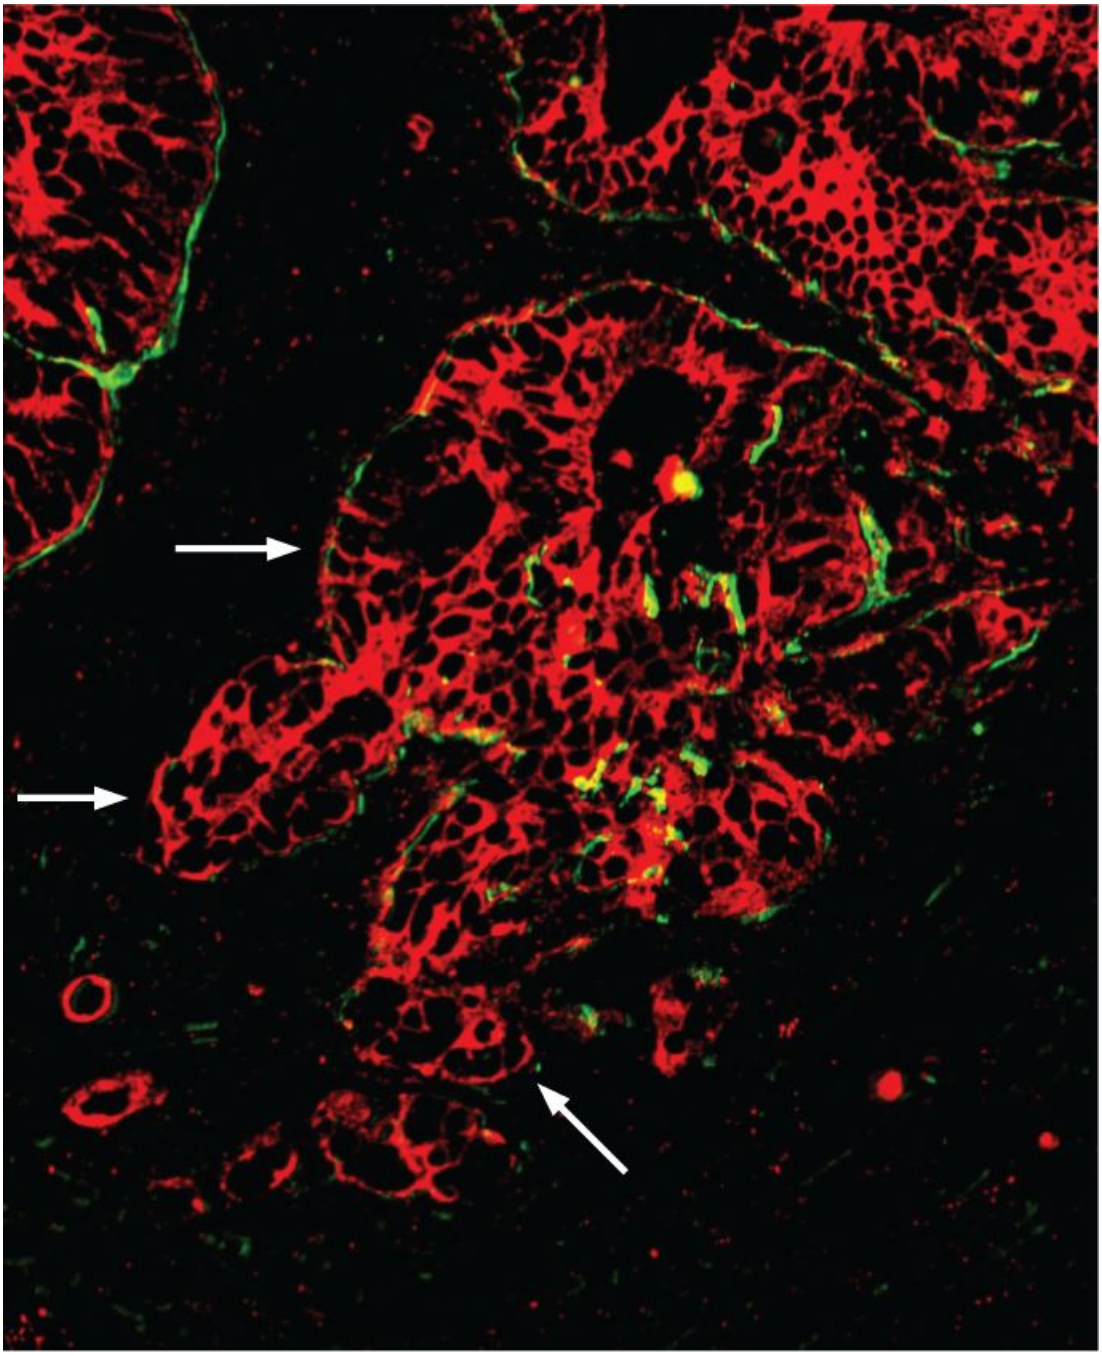
Our focus on carcinomas requires us to draw from earlier discussions of these tumors and the epithelial tissues in which they arise (see, for example, Sections 2.2 and 13.1). To recap briefly, the great majority of epithelial tissues are constructed according to a common set of architectural principles; in most cases, relatively thin sheets of epithelial cells sit atop deep, complex layers of various types of mesenchymal cells forming the stroma. Separating the two groups of cells is the specialized type of extracellular matrix (ECM) known as the basement membrane, sometimes termed the basal lamina (see Figure 2.3A and 13.10). This proteinaceous meshwork is constructed collaboratively by proteins secreted by both epithelial and stromal cells, with most of the basement membrane components being contributed by the epithelial cells.

By definition, carcinomas begin on the epithelial side of the basement membrane (BM) and are considered to be benign as long as the cells forming them remain on this side. Sooner or later, however, many carcinomas acquire the ability to breach the basement membrane (**Figure 14.4A and B**). In certain groups of cancer patients, loss of the BM in their tumors predicts the future course of their disease, specifically their subsequent development of metastatic disease (Figure 14.4C); consequently, loss of the BM is often a prelude to eventual dissemination of cells from the primary tumor.



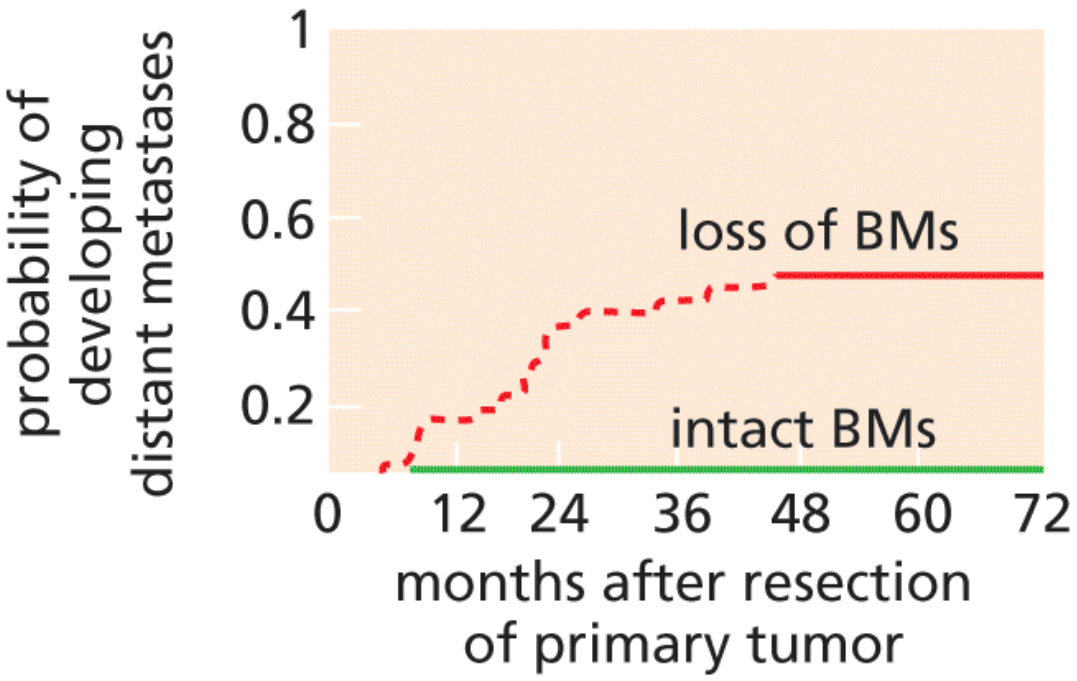
A fluorescence microscopy image in which spongy masses of red tissue are separated from one another by enclosing capsules of green tissue.

(A)



A fluorescence microscopy image in which a spongy mass of red tissue appears to have burst into fragments. There are only traces left of an enclosing capsule of green tissue.

(B)



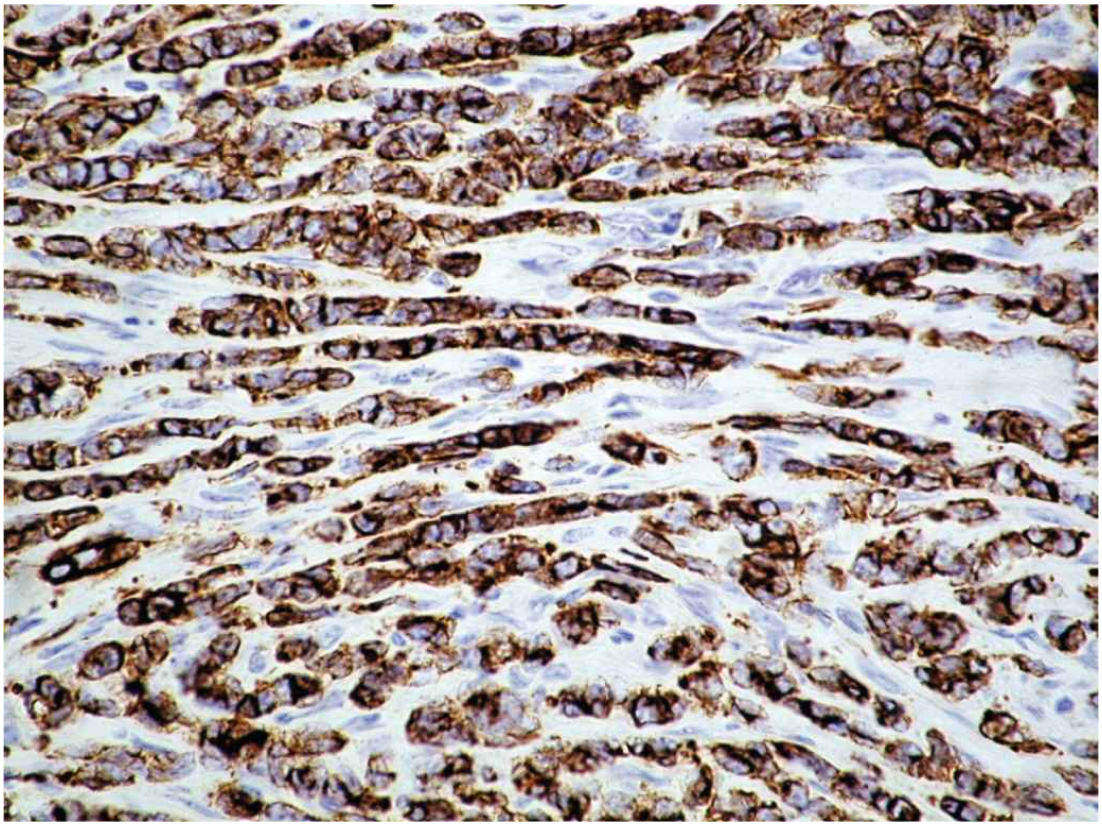
A line graph describing the probability of developing distant metastases as a function of time for two different conditions. With intact basement membranes, the probability remains essentially zero out to 72 months after resection of the primary tumor. With loss of basement membranes, the probability rises to about 50 percent after 48 months and remains at 50 percen thereafter.

(C)

Figure 14.4 Breaching of the basement membrane The basement membrane (BM) can be detected through use of antibodies reactive with laminin, a key component of this membrane (see Figure 13.10C). (A) In the more differentiated, less aggressive portions of a colorectal carcinoma, islands of carcinoma cells labeled with an anti-cytokeratin antibody (*red*) are surrounded by BMs (*green*) that have been detected with an antibody reactive with the α3 chain of laminin. The stroma between islands of carcinoma cells appears *black*. (B) In the portions of the tumor that appear to be less differentiated and more invasive, this staining reveals edges of islands of carcinoma cells (*arrows*) that lack BM, which has been broken down by the invading carcinoma cells and recruited myeloid cells. Now the carcinoma cells are in direct contact with the surrounding stroma. (C) For a group of patients whose high-grade rectal carcinomas (all classified as stage T3) had penetrated at least 5 mm into nearby fatty tissue, the loss of BM around tumor islands directly correlated with the probability of developing distant metastases. Thus, partial or complete loss of BM within their tumors indicated a strong

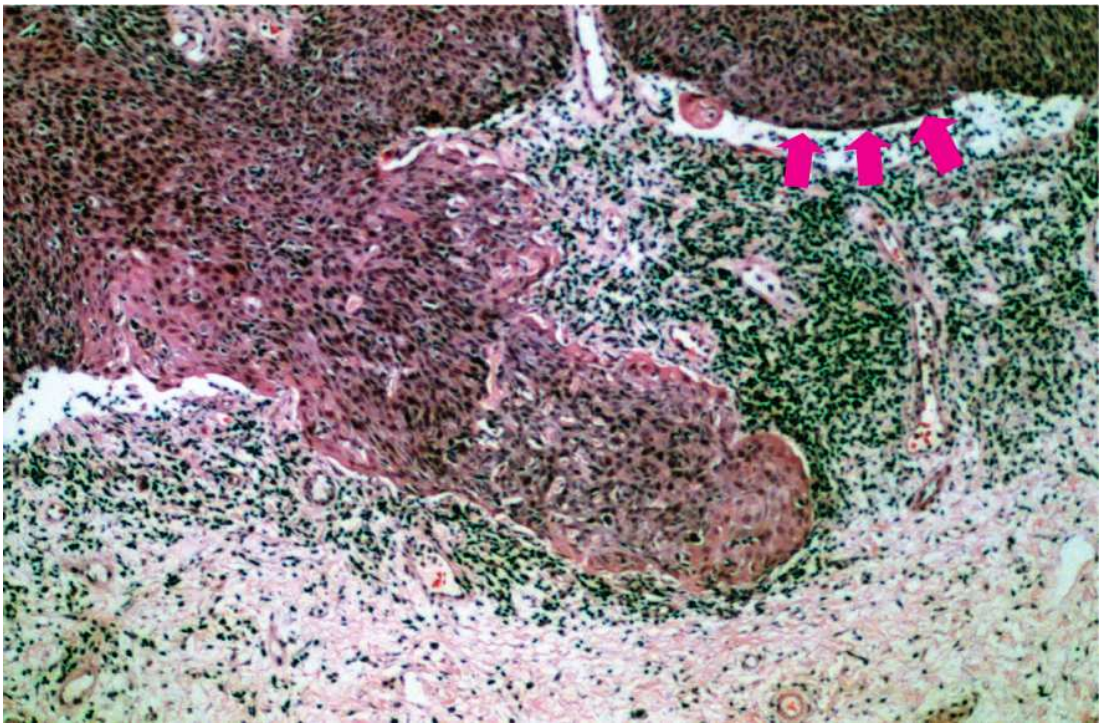
likelihood that metastases would develop during the five years after surgical removal of the primary tumors. (From S. Spaderna et al., *Gastroenterology* 131:830–840, 2006. With permission from Elsevier.)

Having breached the BM, cancer cells begin to invade the nearby stroma singly or in coherent groups, the latter process being called collective invasion (**Figure 14.5**). The tumors spawning these invasive neoplastic cells are now reclassified as malignant. The breakdown of the BM by invading carcinoma cells removes an important physical barrier to the further expansion of tumor cell populations. But in addition, as we learned in the last chapter, by degrading various components of the BM, invasive cells harvest growth and survival factors that have been sequestered by attachment to this specialized extracellular matrix. The invading cohorts of cancer cells that may arise following the breaching of the BM rely on cells at their leading edges that have activated the cell-biological program termed the epithelial–mesenchymal transition (EMT), which we encountered previously in Section 13.3 and will be described in greater detail below.



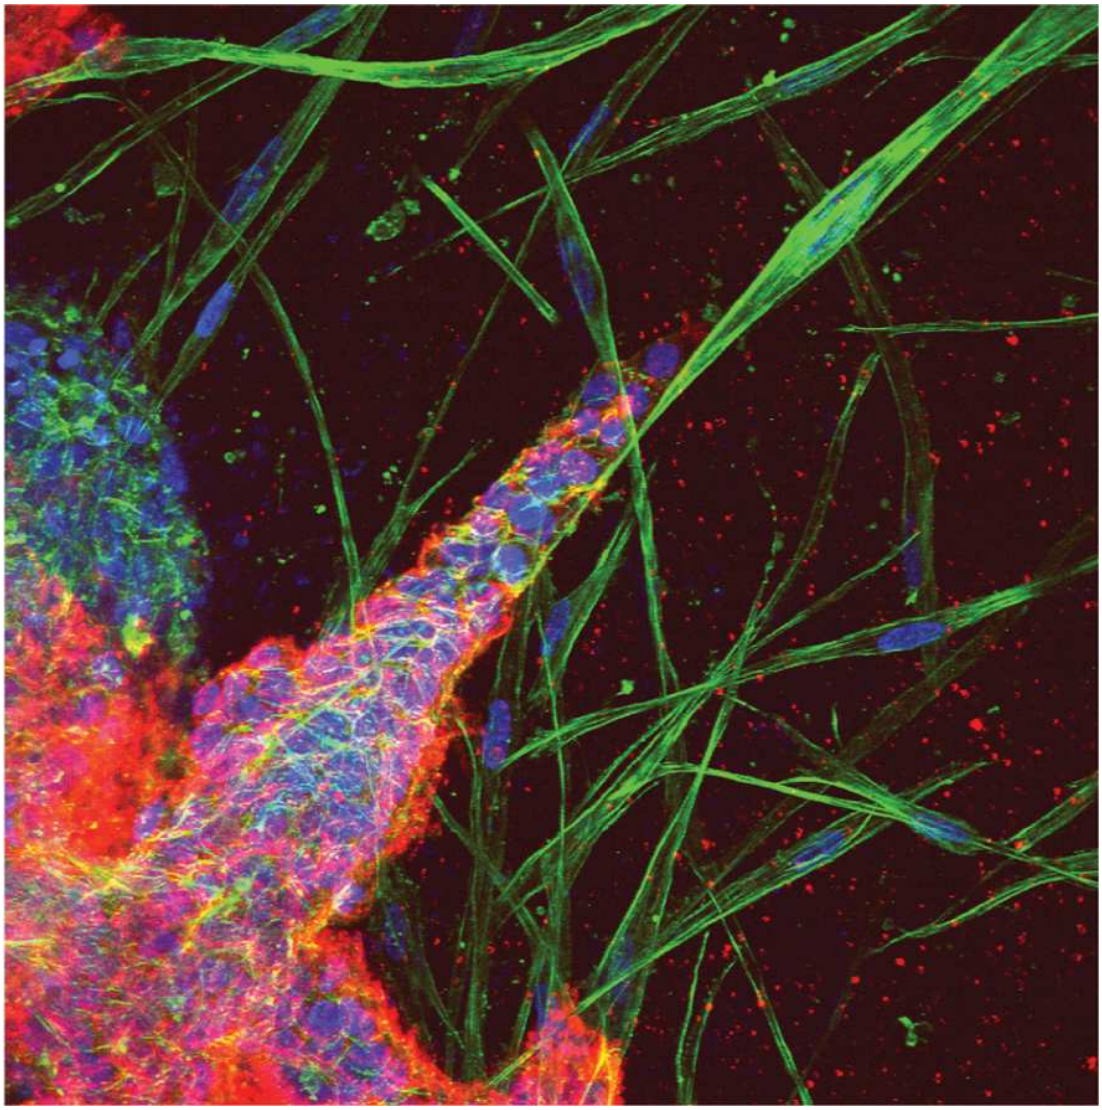
A histology stain image that shows white tissue shot through with horizontal tunnels filled with brown cells.

(A)



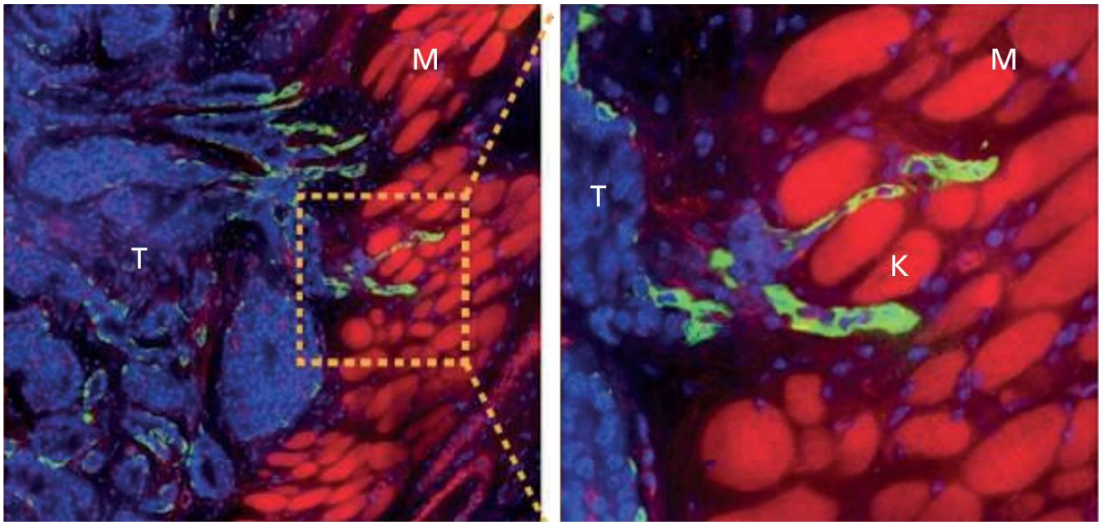
A histology stain image that shows a basement membrane, indicated by pink arrows, separating dark pink cancer cells above from greenish normal stroma below. In the left part of the image, the basement membrane has been breached and a thick tongue of cancer cells projects into the stroma.

(B)



A fluorescence microscopy image shows red tissue in the lower left corner, with a flamelike burst of red projected upward and to the right into tissue that is dark except for long, thin green streaks.

(C)



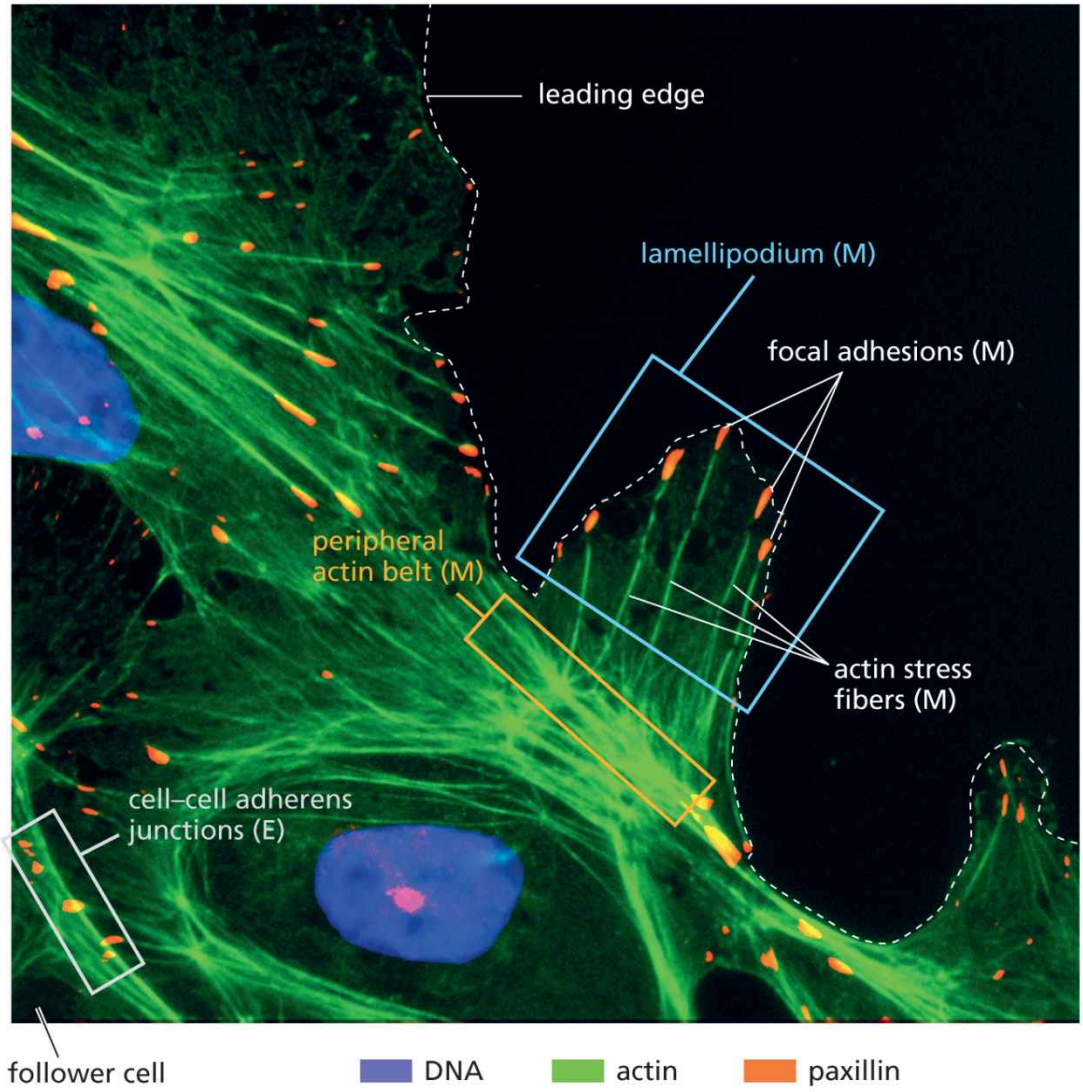
Two fluorescence microscopy images showing tumor cells invading muscle tissue. In the left one, a mass of blue cells marked T is sending a few green tendrils toward a mass of red cells on the right, marked M. The right image is a magnification of part of the left one, showing green tendrils marked K that have penetrated into the red cells.

(D)

Figure 14.5 Patterns of invasion (A) These invasive lobular mammary carcinoma cells (*brown*) have left the primary tumor (*not shown to the left*) and are proceeding rightward, one by one in single file, through channels they have carved in the adjacent stroma (*white, gray*). (B) Far more typical is the coordinated invasion of a phalanx of carcinoma cells, often termed collective invasion. In this squamous cell carcinoma of the cervix, a tongue of many hundreds of cancer cells (*pink, brown*) has breached the basement membrane and is invading the stroma. The latter is characterized by both fibroblasts and inflammatory cells (*dark green*). The basement membrane is the *dark brown, horizontal line* (*pink arrows*) that separates the bulk of the carcinoma cells (*above*) from the stromal cells (*below*) and is uninterrupted except for a capillary and the tongue of invasive cancer cells. (C) Collective invasion can be modeled experimentally *in vitro*. Here, MCF-7 human breast cancer cells were cultured together with fibroblasts in a 3-dimensional (3D) matrix composed largely of collagen. (Such 3D matrices are thought to recapitulate the *in vivo* tissue environment more closely than 2D monolayer culture conditions.) The breast cancer cells, seen here invading through the collagen matrix, continue to adhere to one another via E-cadherin–containing adherens junctions (*red*). The actin stress fibers of the fibroblasts are stained with phalloidin (*green*); cell nuclei are stained with DAPI (*blue*). (D) In the MMTV-PyMT transgenic mouse model of mammary carcinoma pathogenesis, the bulk of the tumor cells (T, *blue, left*) at the invasive edge of a primary tumor are following

highly invasive leader cells (*green*) that have moved from a luminal differentiation state to a basal state, express the basal state-associated cytokeratin 14 marker (K), and have thereby activated a weak form of the EMT program (see Figure 14.12). These leader cells are invading into adjacent muscle tissue (M, *red, right*). (A, courtesy of J. Jonkers. B, courtesy of T.A. Ince. C, from O. Ilina and P. Friedl, *J. Cell Sci.* 122:3203–3208, 2009. With permission from The Company of Biologists. D, from K.J. Cheung, E. Gabrielson, Z. Werb and A.J. Ewald, *Cell* 155:1639–1651, 2013. With permission from Elsevier.)

In the cases of collective invasion, there is evidence that individual leading cells may simultaneously reside in two distinct phenotypic states: the leading halves of each of these cells (facing toward the direction of advance) may exhibit a variety of signs of invasiveness and components of the EMT program, whereas the lagging halves may continue to form adherens junctions with their followers; such junctions ensure the continued attachment of these leaders with the follower cells that form the bulk of the invading cohort (**Figure 14.6**).



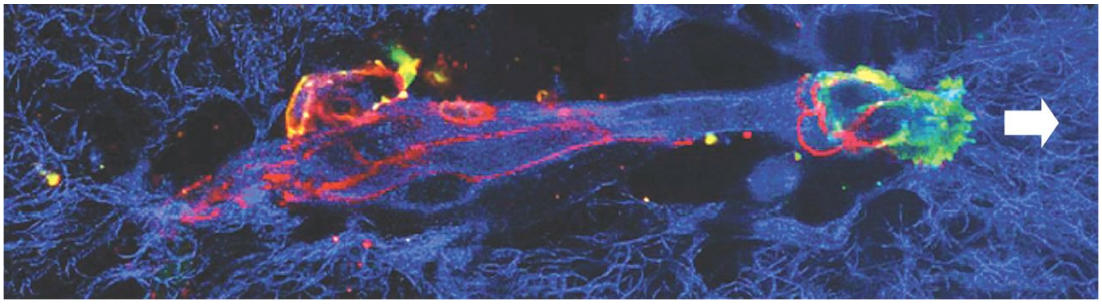
A highly detailed fluorescence microscopy image. Much of the image is crisscrossed by long, straight, green actin fibers, the thickest of which terminate in short orange spots made of paxillin. Some of the green fibers encircle a large nucleus of blue D N A, one of the two nuclei visible in the image. An irregular dashed line labeled, leading edge, separates the colored material from a black region in the upper right corner. A prominent band of green fibers running from the upper left to the lower right, between the nuclei and the leading edge, is labeled, peripheral actin belt, M. A large protrusion into the black region, on the leading edge side of the actin belt, is labeled, lamellipodium, M. Five fingerlike green fibers in this structure are labeled, actin stress fibers, and their orange termination spots along the leading edge are labeled, focal adhesions, M. In the lower left corner of the image is a cell labeled, follower cell. The actin fibers separating this cell from the one with the encircled blue nucleus are labeled, cell–cell adherens junctions, E.

Figure 14.6 Cellular polarization at edge of invading epithelial sheet The cells at the edge of a wounded epithelial sheet undertake to fill the wounded area and restore the integrity of the epithelial sheet. To do so, they activate transiently an EMT program (see Figure 13.15A). As they move into the wound site, they retain tight associations with tightly adhering follower cells (*lower left corner*). This continued association is enabled by their undergoing a form of intracellular polarization, with the sector within the cell that faces the leading edge displaying certain mesenchymal (M) traits, while the sector facing the follower cells retaining epithelial (E) traits, as evidenced by the continued assembly of E-cadherin-containing adherens junctions (*lower left*) formed with follower, fully epithelial cells. Included among the mesenchymal traits are the actin stress fibers (*green*) ending with focal adhesions containing paxillin (*orange*). (Courtesy of P. Savagner.)

Recall that even before carcinoma cells breach the basement membrane, they often succeed in stimulating angiogenesis on the stromal side of the membrane, apparently by dispatching angiogenic factors through this porous barrier to endothelial cells within the stroma (see Figure 13.37B). Signals borne by other soluble factors may also flow through an intact BM in the other direction: inflammatory cells such as macrophages on the stromal side of this membrane may induce initial EMT on the epithelial side (see Section 13.3). Nevertheless, once the BM is broken down, carcinoma cells are placed in a far better position for executing subsequent steps of the invasion–metastasis cascade.

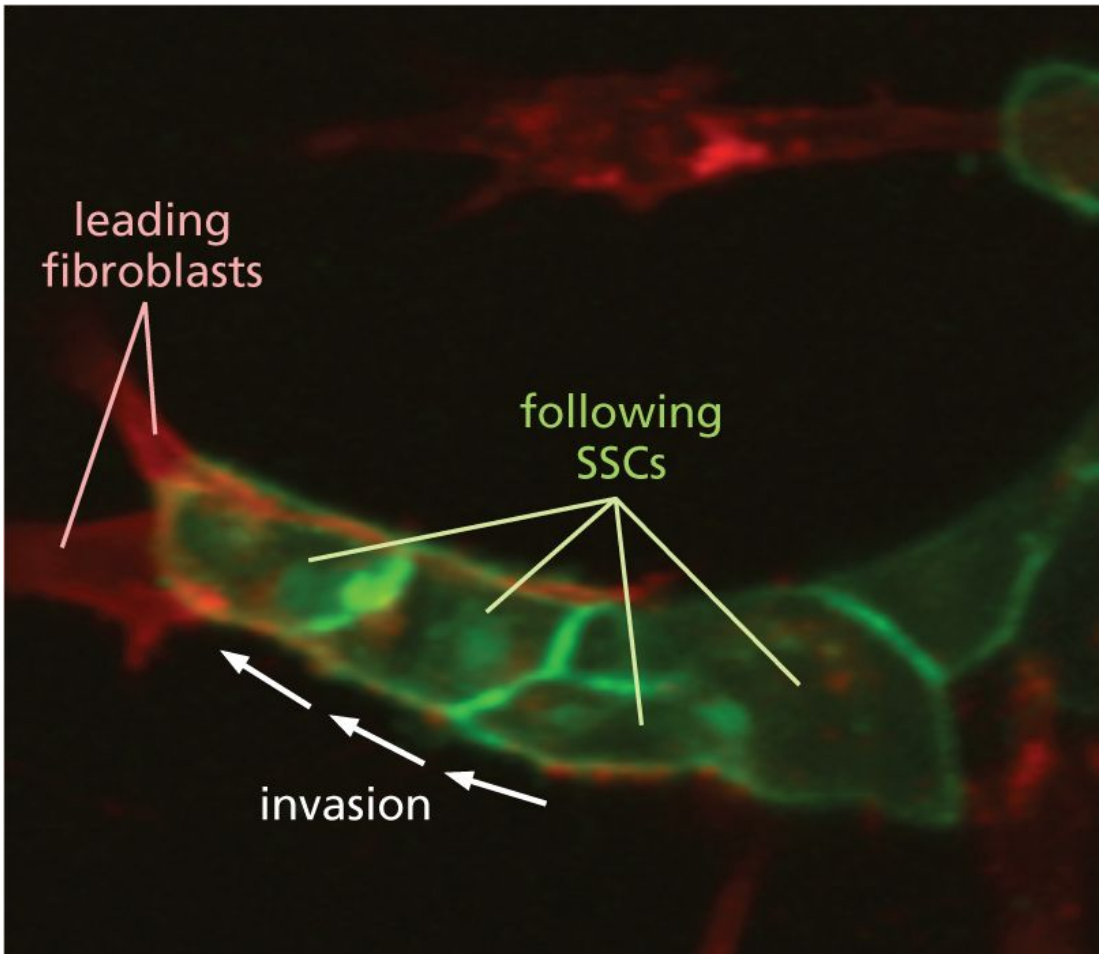
Carcinoma cells invading the stroma can gain direct access to the blood and lymphatic vessels, which are normally found only on the stromal side of the basement membrane. Closer contact with the capillaries affords cancer cells improved access to the nutrients and oxygen carried by the blood (see also Figure 13.40B). In addition, their invasive properties enable these cancer cells to move through the walls and into the lumina (that is, the bores) of blood and lymphatic vessels. This invasion into vessels is often termed intravasation and depends on the ability of individual cancer cells or small clumps of these cells to break away from their neoplastic neighbors and enter into these vessels.

Local invasion seems to depend invariably on the release of secreted proteases, which are required to remodel the extracellular matrix (ECM), thereby carving out space for the advance of cancer cells (**Figure 14.7A**). In some tumors, invading carcinoma cells make their own proteases, such as MMP-2 and MMP-9, while in others a variety of stromal cells, notably fibroblasts and macrophages, are recruited and induced to produce and release these enzymes, allowing flocks of carcinoma cells to follow closely behind them (Figure 14.7B–C).



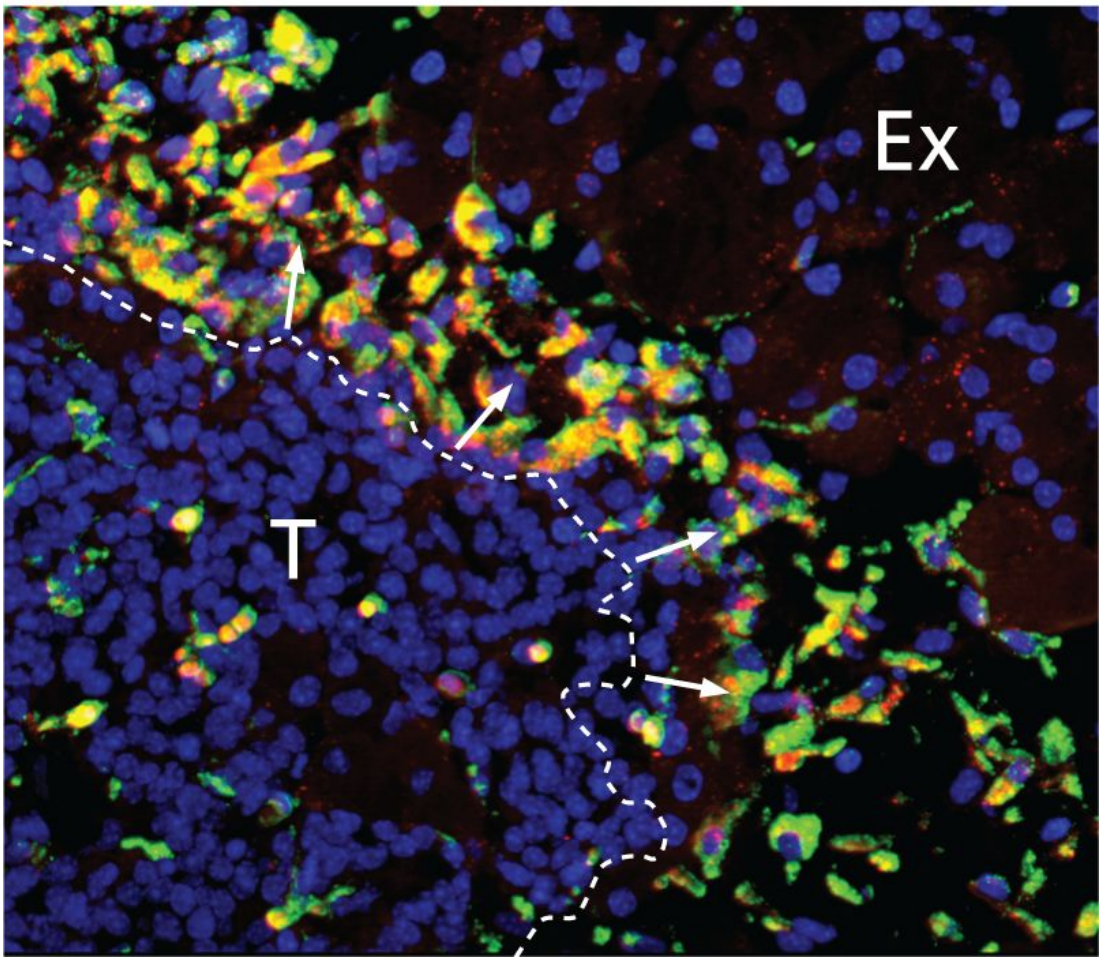
A fluroescence microscopy image that shows a horizontally elongating grouping of cells within a dark blue fibrous matrix. The cells are streaked with red along the left end and middle of the grouping, with a yellow green head on the right. This head is near a right-pointing white arrow that indicates the direction of motion.

(A)



A fluorescence microscopy image of a cluster of cells shaped into a long green curve moving to the left and upward, with white arrows indicating the

direction of invasion. On the left tip are a few small red protrusions labeled, leading fibroblasts. The green curve is labeled, following S S Sees.
(B)



A fluorescence microscopy image of an advancing tumor. A region in the lower left, labeled T, consists mostly of dark blue nuclei with a few specks of green and yellow. Curving around this region is an irregular dashed line. Arrows indicate that this is the leading edge of a tumor advancing upward and to the right, into a region labeled E x. In this region, the cells nearest the tumor's leading edge are lit up in yellow and green. Further away from the leading edge, only blue nuclei are visible in the E x region. They are packed less densely than in the tumor.

(C)

Figure 14.7 Invasion through the extracellular matrix and its control by stromal cells (A) Carcinoma cell invasion requires degradation of the extracellular matrix (ECM), as illustrated by this confocal micrograph of a cohort

of 5–10 melanoma cells that are moving together through a collagen matrix (*blue*); like normal melanocytes, they continue to adhere to one another through adherens junctions that are formed by E-cadherin molecules (*red*). Large gaps in the matrix surrounding the melanoma cells (*black*) indicate areas that have been degraded by the advancing cancer cells or associated stromal cells. At the leading invasive edge (*white arrow*), the melanoma cells are displaying β1 integrins (*green*), which enable them to attach to the still-intact ECM lying ahead in their path. (B) In a variety of tumors, cancer cells recruit and co-opt stromal cells, which clear the invasion path by degrading the ECM, with the carcinoma cells following close on their heels. In this case, human oral squamous cell carcinoma cells (SCCs, *green*) are being led by a small group of carcinoma-associated fibroblasts (*red*) in an *in vitro* experimental model of cancer cell invasion. The direction of invasion by these cells (*arrows*) was determined using time-lapse microscopy. (C) In the Rip-Tag transgenic model of pancreatic islet carcinogenesis (see Figure 13.35), the carcinoma cells forming the leading edge [dashed line at edge of the tumor (T)] recruit macrophages (*green*) and, by stimulating them with interleukin-4 (IL-4), cause them to release cathepsins (*red-orange*), a class of secreted proteases distinct from matrix metalloproteinases (MMPs). Release of these cathepsins at the invasive front of the carcinoma cells is essential for invasion by these cells (*white arrows*) into the adjacent exocrine pancreas (Ex). Cathepsin-producing macrophages are seen here in *yellow*. Nuclei are stained *blue* with DAPI (*blue*). (A, from P. Friedl, Y. Hegerfeldt and M. Tusch, *Int. J. Dev. Biol*. 48:441–449, 2004. With permission from UPV/EHU Press. B, from C. Gaggioli et al., *Nat. Cell Biol*. 9:1392–1400, 2007. With permission from Nature.C, courtesy of B.B. Gadea and J.A. Joyce; from V.L. Gocheva et al., *Genes Dev*. 24:241–255, 2010. With permission from Cold Spring Harbor Laboratory Press.)

OceanofPDF.com

Glossary

invasion–metastasis cascade
: A succession of steps that enables primary tumor cells to spawn metastases, doing so via local invasion, intravasation into blood or lymphatic vessels, dissemination to distant tissues, extravasation into the parenchyma of those tissues, formation of micrometastases, and ultimately colonization leading to the formation of macroscopic metastases.

benign
: (1) Describing a growth that is confined to a specific site within a tissue and gives no evidence of invading adjacent tissue. (2) Referring to an epithelial growth that has not penetrated through the basement membrane.

collective invasion
: Process whereby a cohesive mass of invasive cancer cells invades in a coordinated fashion into nearby tissue.

malignant
: Describing a growth that shows evidence of being locally invasive and possibly even metastatic.

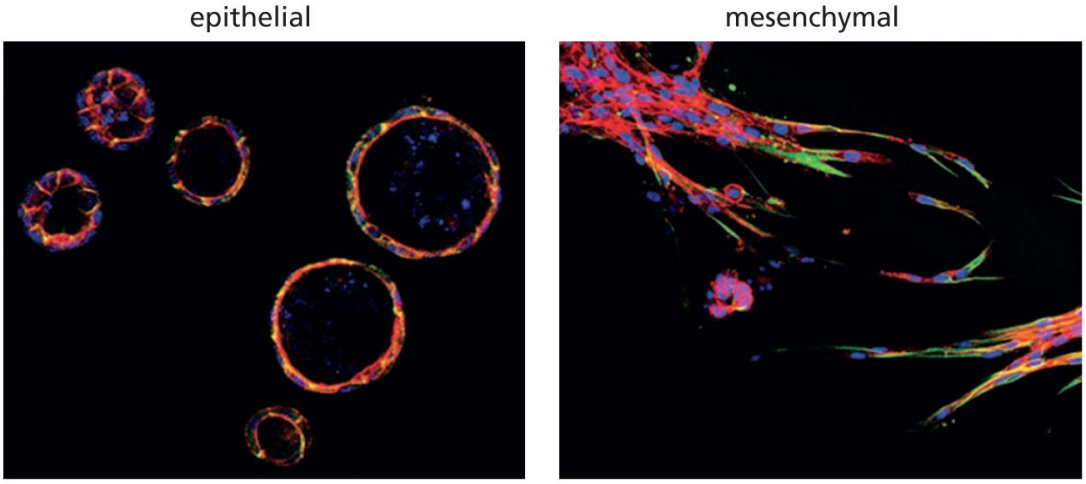
intravasation
: Process of invading into a blood or lymphatic vessel from the surrounding tissue. *See also* **extravasation**.

OceanofPDF.com

14.2 Epithelial–mesenchymal transitions profoundly reshape the phenotypes of carcinoma cells

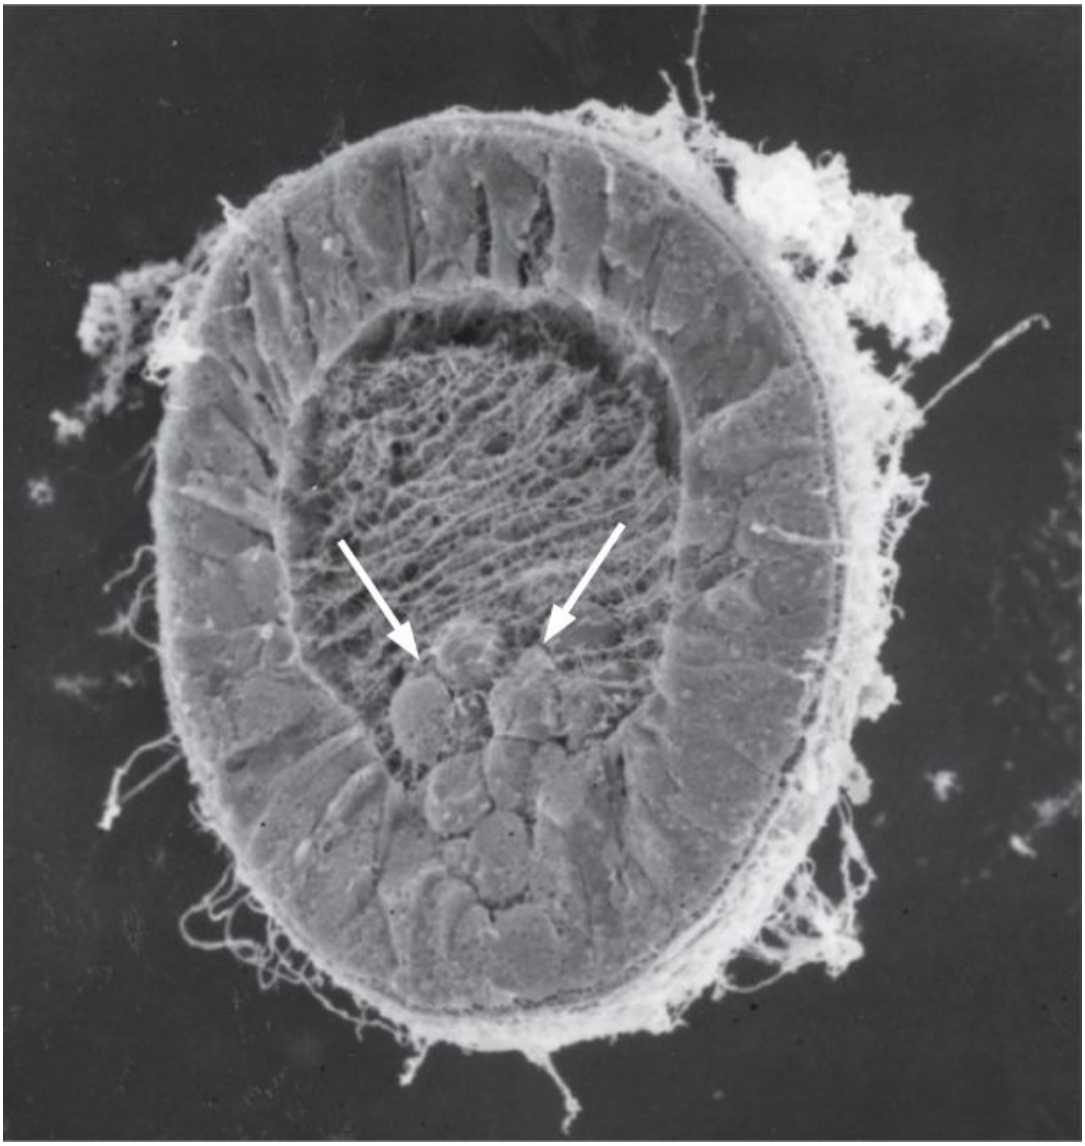
The first of the many steps leading to metastasis—the acquisition of local invasiveness—involves major changes in the phenotype of cancer cells within the primary tumor. As before, we will focus this discussion on epithelial tissues and the carcinomas that they spawn. The organization of the epithelial cell layers in normal tissues is incompatible with the motility and the invasiveness displayed by malignant carcinoma cells (see Figure 2.15), yet elements of this epithelial organization plan continues to be respected in many primary carcinomas. In these tumors, well-organized sheets of epithelial cells are present, although their overall topology may be quite different from that of comparable normal epithelia (see, for example, Figure 2.5).

In order to acquire motility and invasiveness, carcinoma cells must shed many of their epithelial phenotypes, detach from epithelial sheets, and undergo a drastic alteration—the epithelial–mesenchymal transition (EMT), which was mentioned in the context of wound healing (see Section 13.3). Recall that an EMT involves the shedding by epithelial cells of their characteristic morphology and gene expression pattern and the assumption of a shape and transcriptional program more characteristic of mesenchymal cells (**Figure 14.8A**). (The EMT represents a cell-biological "program," in that it involves the coordinated changes of the expression of hundreds of genes and thus proteins, with the implication that this program is templated directly or indirectly by a cell's genome and its developmental history.)



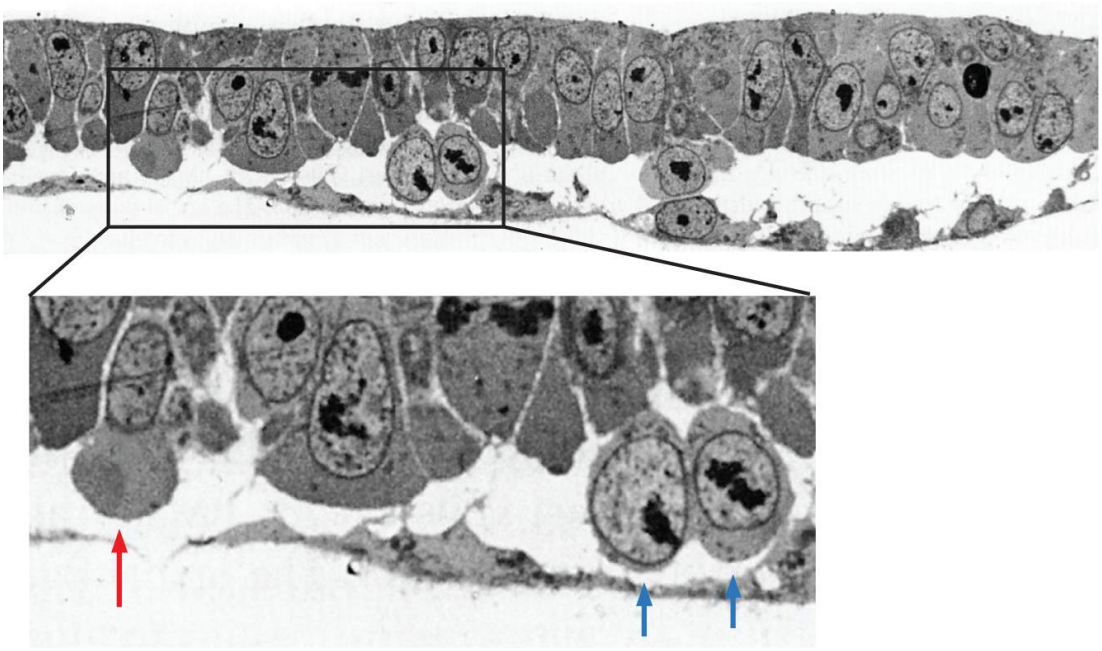
Two fluorescence microscopy images. On the left, epithelial cells have formed rings colored in various shades of orange, with blue nuclei visible. On the right, mesenchymal cells have formed into long, multicolored spiky structures, again with blue nuclei visible.

(A)



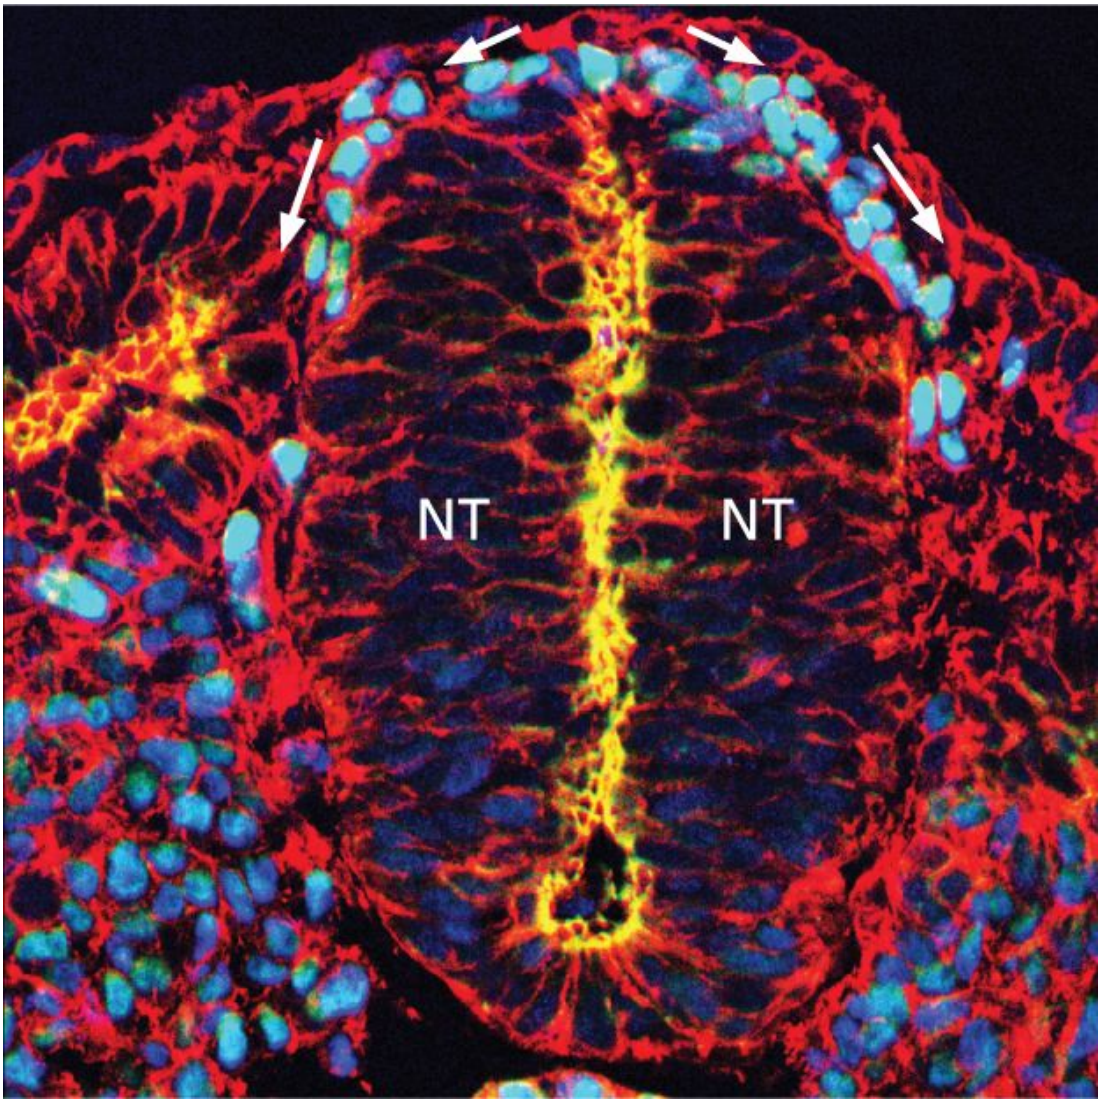
A scanning electron micrograph of a circular embryo. The edges have a thick border, and inside the hollow center is a fibrous mass. White arrows point to small clumps at the bottom of this hollow.

(B)



A scanning electron micrograph of a horizontal layer of cells shown in cross section, with one portion also shown enlarged. In this portion, three cells hang below the rest. One, marked by a red arrow, protrudes downward while the nucleus remains higher up. In the other two, marked by blue arrows, the nuclei have descended and the cells appear ready to detach.

(C)



A fluorescence microscopy image showing a round red structure with a vertical yellow line in the center. It is surrounded by spongy red tissue and blue nuclei, which white arrows indicate as moving downwards from the top of the circle along the edges. On either side of the yellow line is the label, N T

(D)

Figure 14.8 The epithelial–mesenchymal transition and embryogenesis (A) Epithelial (MDCK; Madin-Darby canine kidney) cells form ducts when propagated *in vitro* in 3D-matrices designed to model the *in vivo* microenvironment (*left*). However, when grown under identical conditions, MDCK cells forced to express the Prrx1 EMT-TF form networks of mesenchymal cells (*right*). Note that the dramatic morphological changes are accompanied by the acquisition of motility and invasive properties (*not shown*). (Nuclei revealed

by DAPI staining, *blue*; actin filaments, *red*; E-cadherin (epithelial marker), *yellow-green*, left panel; vimentin (mesenchymal marker), *green*, right panel.) (B) This scanning electron micrograph shows the delamination of cells from the primitive ectoderm of a sea urchin embryo (*white arrows*) and their migration into the interior of the embryo—the process of gastrulation. These cells have become round and acquired motility in anticipation of their forming the rudiments of the mesoderm—changes associated with an epithelial–mesenchymal transition (EMT). They are migrating along strands of extracellular matrix in the blastocoel of this early embryo. (C) The process of gastrulation in mammals, such as in the early rabbit embryo studied here, is superficially quite different but depends on very similar processes. As revealed by this transmission electron micrograph, one cell of the primitive ectoderm (also termed epiblast; lower panel, *red arrow*) is in the midst of undergoing an EMT, while two other cells (*blue arrows*) have already delaminated from the epiblast and become mesenchymal, thereby initiating the formation of mesodermal tissues. (D) Certain cells derive from the upper region of the neural tube (NT, *center*) and can be immunostained for the Sox 9 transcription factor. These cells (*light blue, top*) arise in the embryonic neural crest of chordates and undergo an EMT, delaminate from this epithelium, acquire motility and invasiveness, and disperse (*white arrows*) throughout the embryo, where they form melanocytes, much of the peripheral nervous systems, and much of the skeleton of the face. The neural epithelium is immunostained for N-cadherin (*yellow*). All cells are stained with phalloidin to reveal their actin cytoskeleton (*red*) and with DAPI to indicate their nuclei (*dark blue*). (A, from M.A. Nieto, *Science* 342:1234850, 2013. With permission from AAAS. B, from G.N. Cherr et al., *Microsc. Res. Tech*. 22:11–22, 1992. With permission from John Wiley & Sons. C, from C. Viebahn, B. Mayer and A. Miething, *Acta Anat. (Basel)* 154:99–110, 1995. With permission from Karger. D, courtesy of J. Briscoe; see also J. Yang and R.A. Weinberg, *Dev. Cell* 14:818–829, 2008.)

In its normal manifestations, the EMT is used in specific morphogenetic steps occurring during embryogenesis, when tissue remodeling depends on EMTs executed by various types of epithelial cells (**Table 14.1**). During one of the steps of gastrulation, for example, individual cells peel away from the ectoderm and migrate inward toward the center of the embryo to form the mesoderm, the precursor of mesenchymal tissues, including (in chordates) fibroblasts and hematopoietic cells. This conversion of ectodermal cells, which at this stage are arrayed in an epithelial cell layer, to those having a mesodermal phenotype involves an EMT (Figure 14.8B and C). At the same time, the cells undergoing an EMT acquire the ability to translocate from one location (the outer cell layer) to another (the interior) within the embryo.

Table 14.1 Examples of EMTs during mouse embryonic development

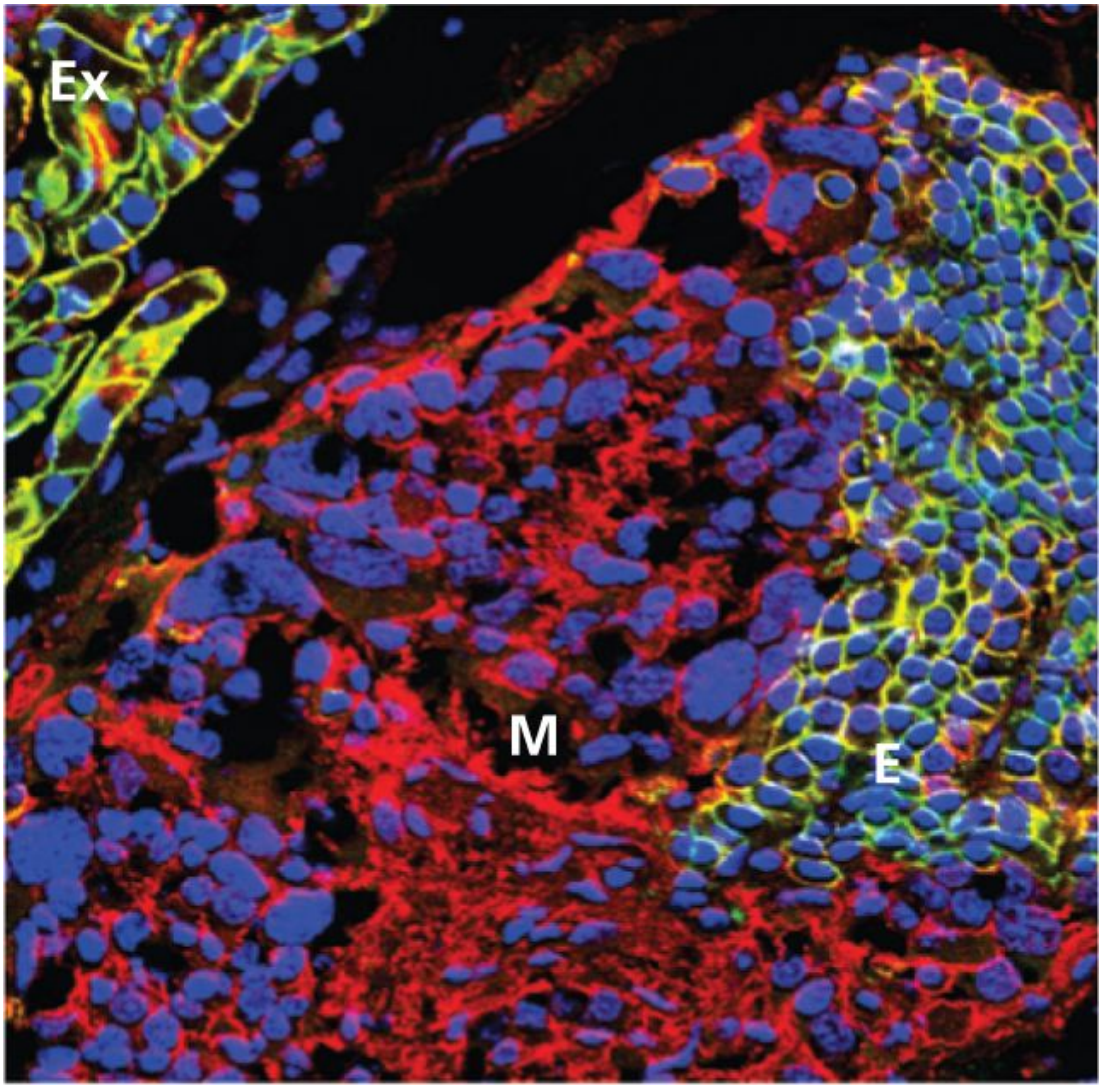
	Transition	
Process	**From**	**To**
gastrulation	epiblast	mesoderm
prevalvular mesenchyme in the heart	endothelium	atrial and ventricular septum
neural crest cells	neural plate	neural crest cells, which can yield bone, muscle, peripheral nervous system
somitogenesis	somite walls	sclerotome
palate formation	oral epithelium	mesenchymal cells
Müllerian duct regression	Müllerian tract	mesenchymal cells

Adapted from P. Savagner, *BioEssays* 23:912–923, 2001.

The migration of neuroepithelial cells from the neural crest into the mesenchyme of early vertebrate embryos also depends on a transformation of cell phenotype that can best be described as an EMT (Figure 14.8D). Similarly, the migration of myogenic precursor cells (the progenitors of muscle cells) from the dermomyotome of the early embryo to the limb buds depends on an EMT-like transformation of cell phenotype. Even late steps in morphogenesis, such as the formation of the palate, take advantage of the powers of EMT programs (**Supplementary Sidebar 14.1**). All of these processes bear a striking resemblance to the EMT undertaken by the epithelial cells at the edge of a wound that has damaged an epithelial cell sheet; these cells must undergo a transient EMT in order to migrate into the wound site and close the gap in the epithelial cell sheet that was created by the wounding process (see Figure 13.15A).

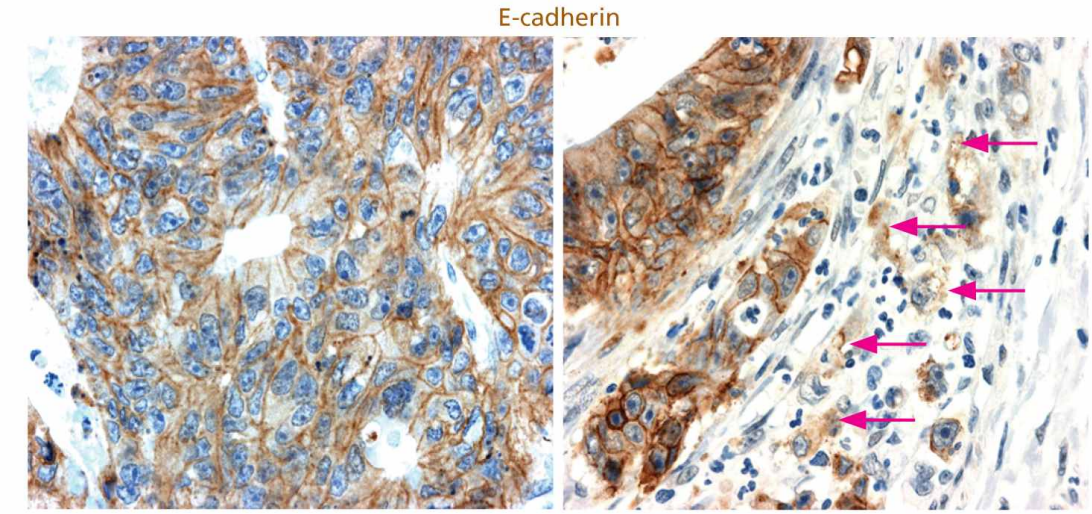
Hence, EMT programs play important roles in two aspects of normal physiology—developmental morphogenesis and wound healing.

As described below, an EMT can also be seen at the edges of carcinomas that are invading adjacent tissues (**Figure 14.9**; see also Figure 14.5D). This pathological process is very similar to the EMTs occurring during early embryogenesis and wound healing. It is plausible, though hardly proven, that all types of carcinoma cells must activate components of an EMT program in order to become motile and invasive.



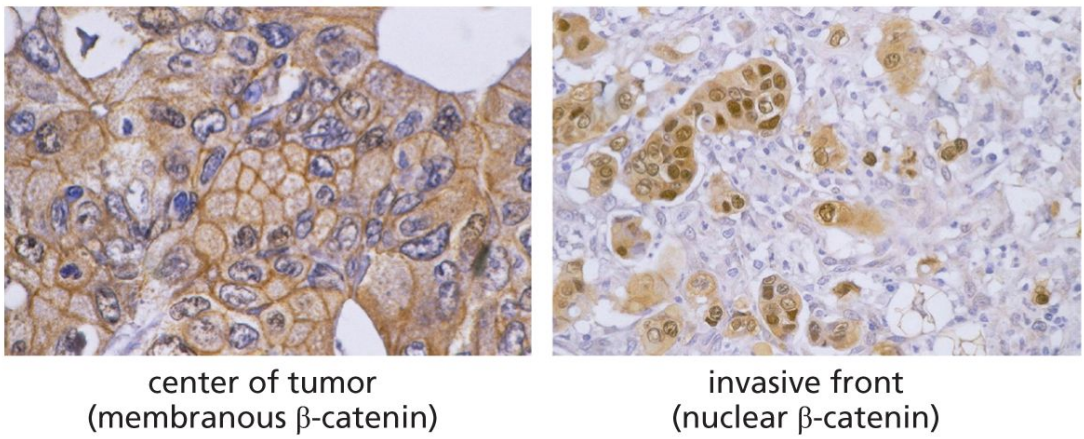
A fluorescence microscopy image of epithelial and mesenchymal pancreatic cancer cells. The epithelial cells, on the right, are labeled E. They have small, close-packed blue nuclei that are surrounded by green and yellow. The mesenchymal cells, on the left, are labeled M. They have larger, more loosely packed blue nuclei that are surrounded by red.

(A)



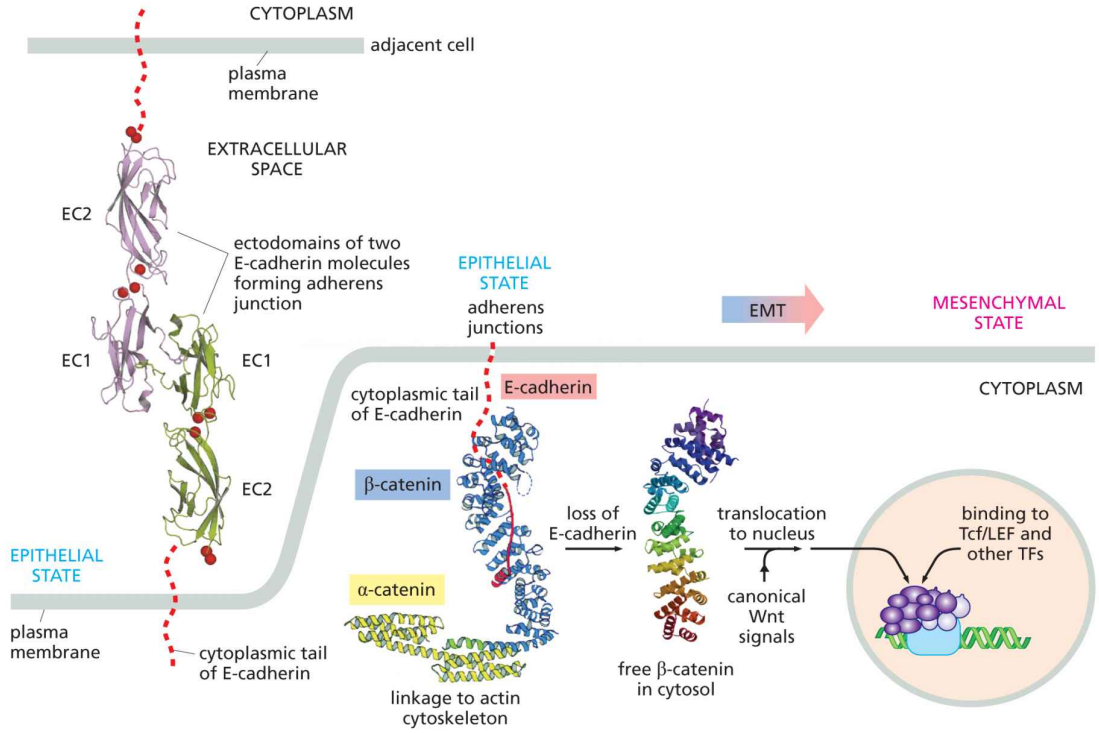
Two histology stain images in which brown indicates the presence of E-cadherin. In the image on the left, cells with large, pale blue nuclei and brown cytoplasms cling together. In the image on the right, there are dark brown streaks on the left, but most of the image to right of those streaks is filled with tissue in which the nuclei are smaller and the cytoplasms are mostly clear, with just patches of light brown here and there, marked by arrows.

(B)



Two histology stain images in which brown indicates the presence of beta-catenin. In the image on the left, labeled center of tumor, membranous beta-catenin, cells with blue nuclei and brown cell walls crowd thickly together. In the image on the right, labeled invasive front, nuclear beta-catenin, isolated patches of brown cells with dark brown nuclei are surrounded by cells of normal tissue.

(C)



A schematic of the epithelial-mesenchymal transition. Initially, a cell in the epithelial state is linked to another cell by the ectodomains of two E-cadherin molecules forming an adherens junction. Each molecule has an E C 1 domain at the head, where the junction occurs, an E C 2 domain in the middle, and a cytoplasmic tail that penetrates that molecule's plasma membrane. Within the cytoplasm, the tail is linked via beta-catenin and alpha-catenin to the cell's actin cytoskeleton. Loss of E-cadherin leads to free beta-catenin in the cytosol. Under the influence of canonical W n t signals, the free beta-catenin translocates to the nucleus, where it binds to T c f slash L E F and other T Effs. The completes the transition to the mesenchymal state.

(D)

Figure 14.9 Epithelial–mesenchymal transition at the invasive edge of a tumor (A) In the Rip-Tag transgenic mouse model of pancreatic islet carcinogenesis (see Figure 13.35), neoplastic cells undergo an EMT that enables them to invade the surrounding exocrine pancreas (Ex). Carcinoma cells at the far right continue to reside in an epithelial state (E), exhibit E-cadherin staining (*green*), and in many places exhibit overlapping β-catenin staining (*red*). The overlap of these two proteins, indicating their co-localization in adherens junctions, appears as *yellow*. Those carcinoma cells that have undergone an EMT

and become more mesenchymal (M) have lost E-cadherin staining and show greatly increased levels of cytoplasmic β-catenin staining. Nuclei are stained *blue* with DAPI. (B) Colon carcinoma cells at the invasive edge of a primary human tumor undergo changes in gene expression and the localization of certain proteins. Although E-cadherin (*brown*) is strongly expressed on the plasma membranes of cells in the core of a primary tumor, where it forms adherens junctions (*left panel*) that delineate the associations between adjacent cells, its expression decreases substantially in individual invasive cells at the edge of this tumor (*pink arrows, right panel*) and is no longer localized to their plasma membranes, indicating that it no longer participates in forming adherens junctions. (C) Tumor cells in the center of this colon tumor (*dashed lines, left panel*) express β-catenin (*dark red*) under their plasma membranes and diffusely throughout the cytoplasm, whereas tumor cells at the invasive edge (*right panel*) show intense β-catenin staining in their nuclei. (D) The ectodomain of E-cadherin displayed by an epithelial cell dimerizes with the ectodomain of a second E-cadherin molecule displayed by an adjacent epithelial cell (*left*). Calcium ions, which are essential for the normal secondary structure and rigidity of the ectodomains, are shown as *red balls*. At the same time, the cytoplasmic tail of E-cadherin is linked via β-catenin and several other molecules to the actin cytoskeleton. β-Catenin also functions in the cytoplasm as a key intermediary in the Wnt signaling pathway (see Section 6.10). Loss of E-cadherin from the plasma membrane liberates β-catenin molecules, which may then accumulate in the cytoplasm and, under the influence of Wnt-initiated signals, migrate to the nucleus and associate with Tcf/LEF and other transcription factors, thereby inducing expression of genes orchestrating the EMT program. (A, from M. Herzig et al., *Oncogene* 26:2290–2298, 2007. With permission from Nature. B, courtesy of T. Brabletz. C, courtesy of T. Brabletz and T. Kirchner. D, from T.A. Graham et al., *Cell* 103:885–896, 2000, PDB: 2BCT; and from E. Parisini et al., *J. Mol. Biol.* 373:401–411, 2007. Both with permission from Elsevier.)

The strong resemblance between the pathological process of tumor invasiveness and normal steps of embryogenesis and wound healing suggests a mechanistic model that is supported by extensive evidence gathered in recent years: the complex program of cellular reorganization exhibited by invasive carcinoma cells depends on the reactivation of a latent behavioral program whose expression is usually confined to early embryogenesis and to damaged adult tissues. Following this thinking, once carcinoma cells acquire access to an expressed EMT program, they can exploit it to profoundly change their own morphology, motility, and ability to invade nearby cell layers. This model implies that the multiple changes in cell phenotype associated with invasiveness, some of which are described below, need not be acquired piecemeal by carcinoma cells. Instead, these cells simply activate a morphogenetic program that is

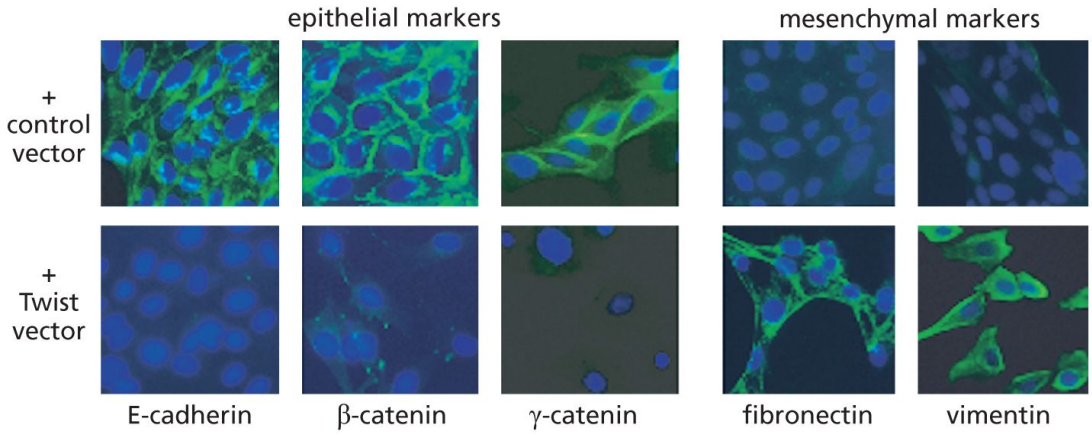
already encoded in their genomes. (This logic echoes our earlier discussion in Section 13.3 of epithelial–stromal interactions, where we argued that cancer cells co-opt entire wound-healing programs in order to acquire an activated stroma.)

The normal and pathological versions of the EMT involve, in addition to changes in shape and the acquisition of motility, fundamental alterations in the gene expression profiles of cells (**Table 14.2**). Expression of E-cadherin and cytokeratins—hallmarks of epithelial cell protein expression—is repressed, while the expression of vimentin, an intermediate filament component of the mesenchymal cell cytoskeleton, is induced (**Figure 14.10**). Epithelial cells that have undergone an EMT often begin to make fibronectin, an extracellular matrix protein that is normally secreted only by mesenchymal cells such as fibroblasts. At the same time, expression of a typical fibroblastic marker—N-cadherin—is often acquired in place of E-cadherin.

Table 14.2 Cellular changes associated with an epithelial–mesenchymal transition

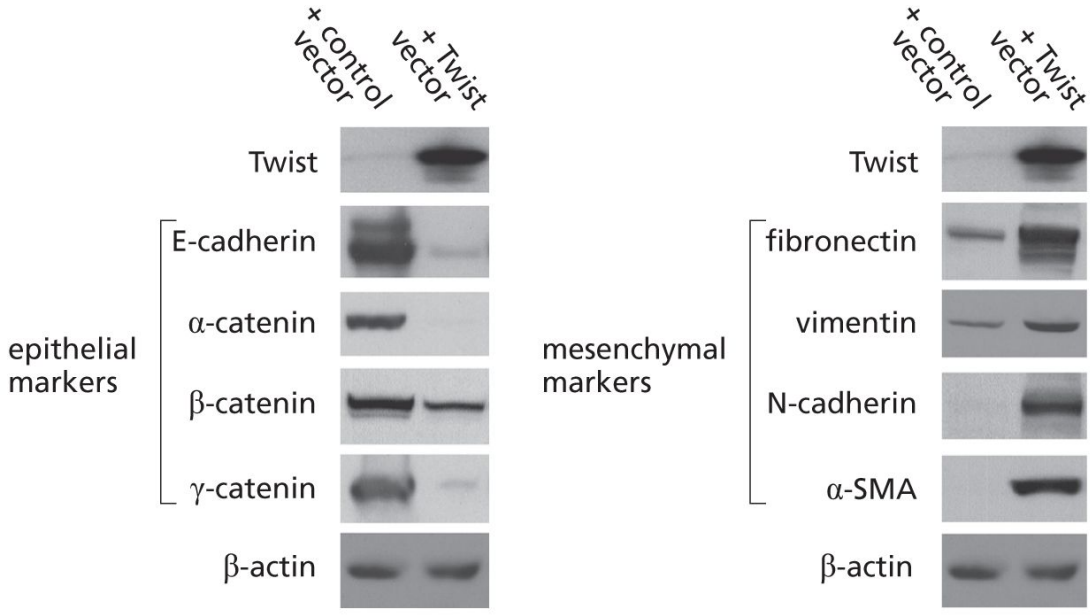
Loss of
cytokeratin (intermediate filament) expression
tight junctions and epithelial adherens junctions involving E-cadherin
epithelial cell polarity
epithelial gene expression program
Acquisition of
fibroblast-like shape
motility
invasiveness

Loss of
increased resistance to apoptosis
increased resistance to radiotherapy
mesenchymal gene expression program including EMT-inducing transcription factors
mesenchymal adherens junction protein (N-cadherin)
protease secretion (MMP-2, MMP-9)
vimentin (intermediate filament) expression
fibronectin secretion
PDGF receptor expression
$\alpha_v\beta_6$ integrin expression
stem cell-like traits



A 2 by 3 grid of immunofluorescence images depicting the results of adding either control vector or twist vector in the presence of one of three epithelial markers, namely E-cadherin, beta-catenin, and gamma-catenin. To the right is a 2 by 2 grid of images depicting the results of adding either control vector or twist vector in the presence of one of two mesenchymal markers, namely fibronectin and vimentin. In all cases, blue nuclei are visible, but these are surrounded by green only when a control vector is added where an epithelial marker is present, or when a twist vector is added when a mesenchymal marker is present.

(A)



Two sets of immunoblot tests. In the left test, there is a channel for control vector and a channel for twist vector. Six proteins are tested, namely Twist,

the four epithelial markers E-cadherin, alpha-catenin, beta-catenin, and gamma-catenin, and beta-actin. In the right test, the same two channels are again used to test six proteins, namely Twist, the four mesenchymal markers fibronectin, vimentin, N-cadherin, and alpha-S M A, and beta-actin.
(B)

Figure 14.10 Biochemical changes accompanying the EMT As discussed later, EMT programs can be induced by several pleiotropically acting transcription factors. Shown here are the effects of expressing the EMT-inducing Twist transcription factor in MDCK (Madin–Darby canine kidney) cells, which are widely used to study epithelial cell biology. (A) These immunofluorescence analyses indicate that expression of epithelial markers, specifically E-cadherin, β-catenin, and γ-catenin, is repressed, whereas expression of mesenchymal markers, specifically vimentin and fibronectin, is induced by ectopic expression of Twist. Note that in epithelial cells that have not been induced to enter into an EMT, E-cadherin, β-catenin, and γ-catenin are located at the interfaces between adjacent cells, where they form adherens junctions. Although functional studies indicate the activation of transcription by nuclear β-catenin in mesenchymal cells, this is usually difficult to observe by immunofluorescence because β-catenin accumulates only to low steady-state levels in the nucleus. (B) Immunoblots confirm the results of immunofluorescence, but in a more quantitative fashion. Lysates of control MDCK cells are analyzed in the left channels, while lysates of MDCK cells forced to express Twist are analyzed in the right channels. β-Actin, whose expression is unaffected by the EMT, is used here as a control to ensure that equal amounts of cell lysate have been analyzed in all cases. α-SMA, α-smooth muscle actin. (A and B, from J. Yang et al., *Cell* 117:927–939, 2004. With permission from Elsevier.)

Of all these proteins, the transmembrane E-cadherin molecule plays the dominant role in influencing epithelial versus mesenchymal cell phenotypes. Recall our earlier encounters with E-cadherin and its role in enabling epithelial cells to adhere laterally to one another (see Figures 6.19A and 13.14). In normal epithelia, the ectodomains of E-cadherin molecules extend from the plasma membrane of one epithelial cell to form complexes with other E-cadherin molecules protruding from the surface of an adjacent epithelial cell. This enables homodimeric (and higher-order) bridges to be built between adjacent cells in an epithelial cell layer, resulting in the adherens junctions that are so important to the structural integrity of epithelial cell sheets (see Figure 13.14D).

The cytoplasmic domains of individual E-cadherin molecules are tethered to the actin fibers of the cytoskeleton via a complex of α- and β-catenins (see Figure 14.9D) and other ancillary proteins. The actin cytoskeleton, for its part, provides tensile strength to

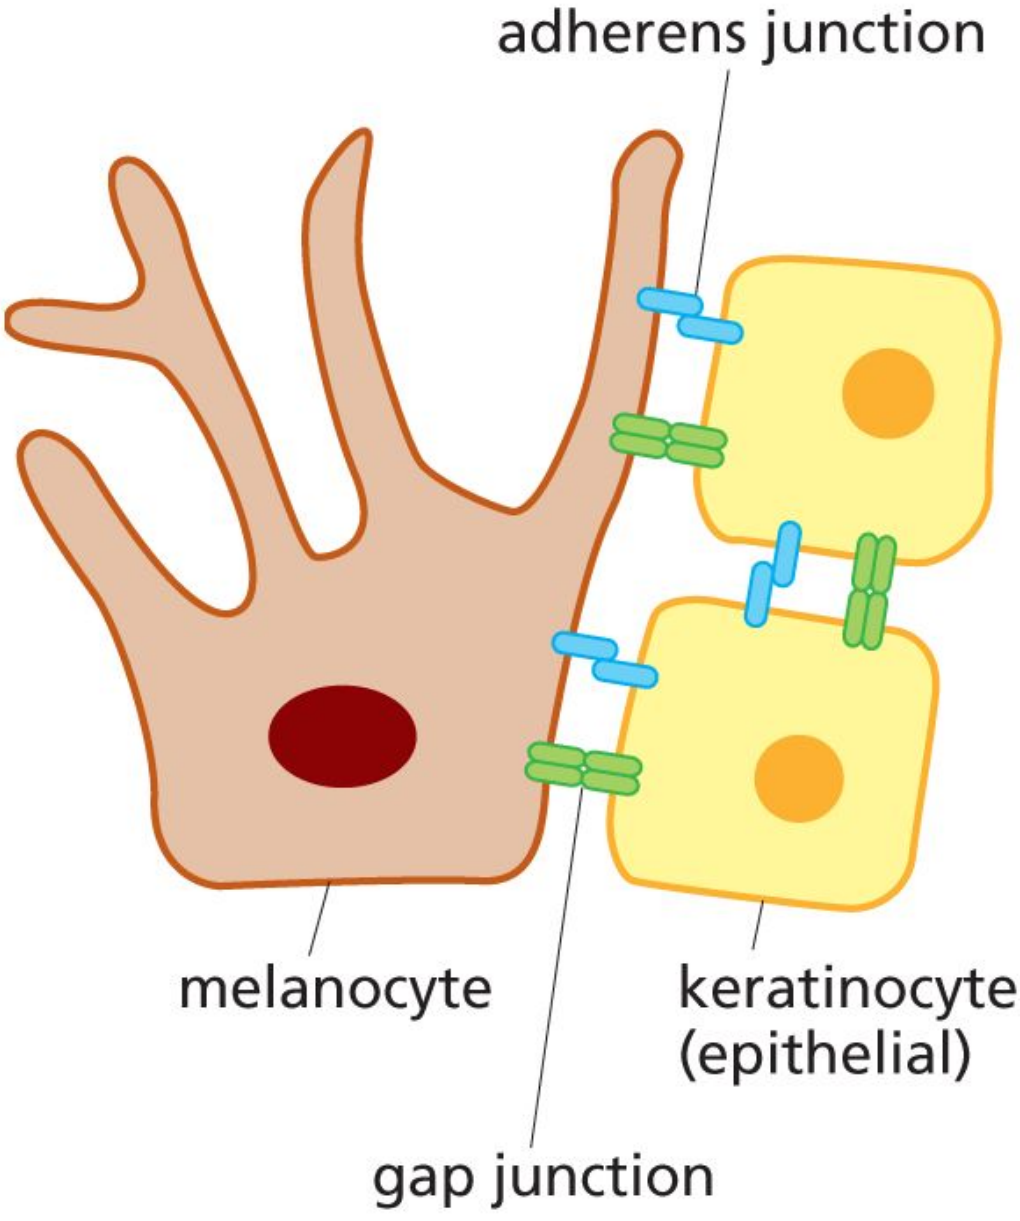
the cell. Hence, by knitting together the actin cytoskeletons of adjacent cells, E-cadherin molecules help an epithelial cell sheet resist mechanical forces that might otherwise tear it apart. Once E-cadherin expression is suppressed, many of the other cell-physiological changes associated with the EMT seem to follow suit. Some experiments indicate that simply by suppressing the expression of the E-cadherin protein, cells acquire a more mesenchymal morphology and increased motility. Yet other cell–cell physical interactions in both normal and neoplastic tissues are mediated by other members of the large family of cadherin proteins encoded in the human genome. For example, the binding of normal and neoplastic epithelial cells to the endothelial cells forming microvessels depends on homotypic interactions mediated by cadherin 5, that is, interactions between two identical molecules displayed by two closely apposed cells.

The pivotal role of E-cadherin in the acquisition of malignant cell phenotypes is further supported by observations indicating that the *CDH1* gene, which specifies E-cadherin, is repressed by promoter methylation in certain invasive human carcinomas (see Table 7.2) and in others by transcriptional repressors; this gene can also be inactivated by reading-frame mutations. For example, an analysis of 26 human breast cancer cell lines indicated that 8 had mutations that led to inactivation of E-cadherin gene expression, 5 had truncating mutations in the E-cadherin reading frame, and 3 had in-frame deletions resulting in the expression of mutant E-cadherin molecules at the cell surface. By now, loss of E-cadherin expression or expression of mutant E-cadherin proteins has been documented in advanced carcinomas of the breast, colon, prostate, stomach, liver, esophagus, skin, kidney, and lung. Finally, mutant germ-line alleles of the *CDH1* gene result in familial gastric cancer (see Table 7.1).

Additionally, in studies of several types of carcinoma cells that had lost E-cadherin expression, re-expression of this protein (achieved experimentally by introduction of an E-cadherin expression vector) strongly suppressed the invasiveness and metastatic dissemination of these cancer cells. Together, these diverse observations indicate that E-cadherin levels are key determinants of the biological behavior of epithelial cancer cells and that the cell-to-cell contacts constructed by E-cadherins impede invasiveness and hence metastasis.

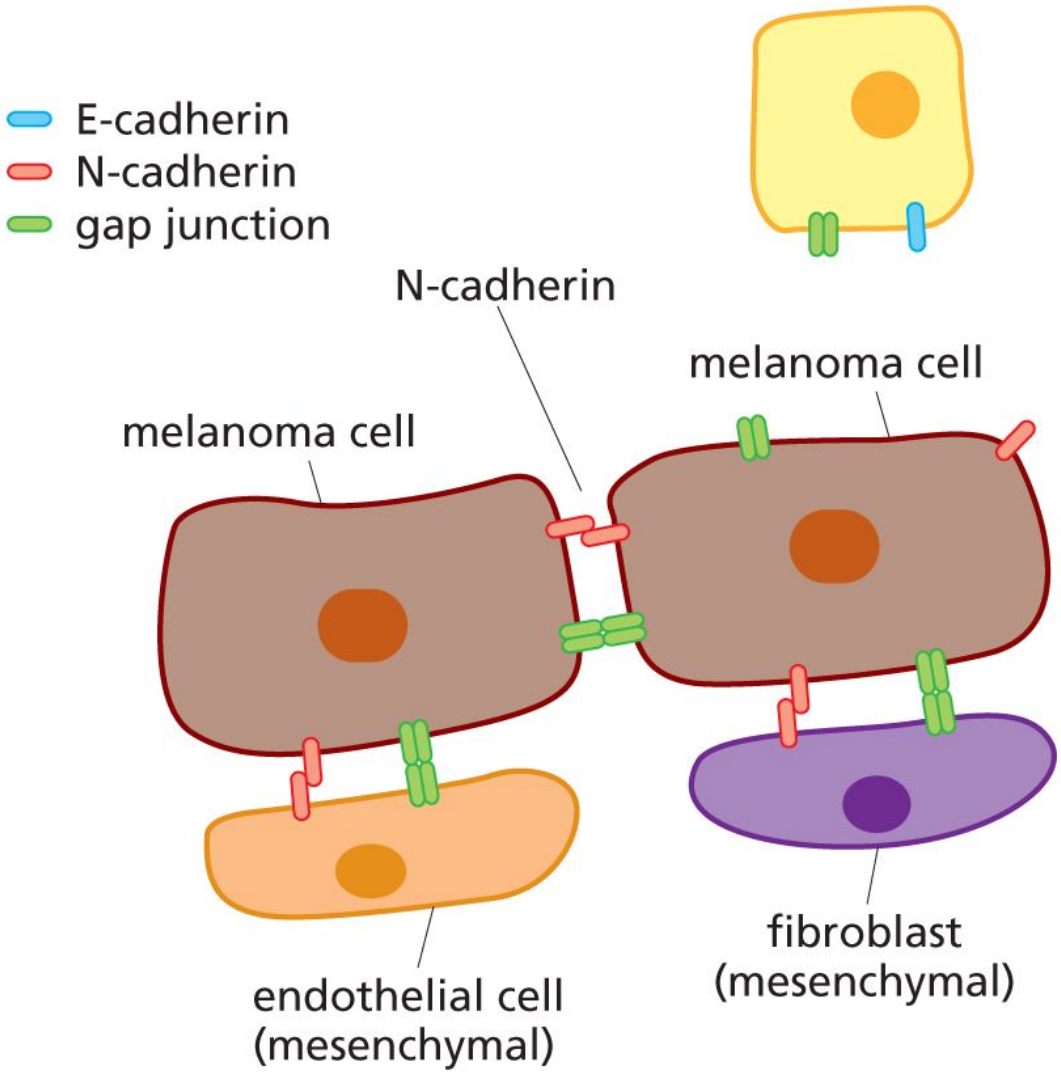
Like E-cadherin, the N-cadherin that is produced in its stead during the course of an EMT participates in homophilic interactions. Consequently, the N-cadherin molecules expressed on the surface of a carcinoma cell that has undergone an EMT increase the affinity of this cancer cell for the stromal cells that normally display N-cadherin, notably the fibroblasts in the stroma underlying the epithelial cell layer. This association seems to help invading carcinoma cells insert themselves amid stromal cell populations. Precisely the same dynamics have been proposed to explain how melanomas develop: normal melanocytes express E-cadherin, which binds them to the skin keratinocytes around them; melanoma cells—the transformed derivatives of

melanocytes—express N-cadherin, which facilitates their invasion of the dermal stroma of the skin and their association with its fibroblasts and endothelial cells (**Figure 14.11**). Moreover, E-cadherin:N-cadherin interactions have recently been documented that violate the simple rule limiting cadherins strictly to homophilic interactions. The non-homophilic interactions are less strong and, being more transient, may also help the initial invasion of more epithelial carcinoma cells into the stroma.



A melanocyte with a highly irregular shape lies alongside two epithelial keratinocytes that are generally square in shape. Each cell is joined to each of

the others by an adherens junction that involves two E-cadherins, and by a gap junction.
(A)



A keratinocyte is shown floating free, and two rectangular melanoma cells are joined end-to-end by a gap junction and a junction formed by two N-cadherins. One of the melanoma cells is also joined, along its long side, to a mesenchymal endothelial cell, again by a gap junction and a junction formed by two N-cadherins. The other melanoma cell is similarly joined to a mesenchymal fibroblast.

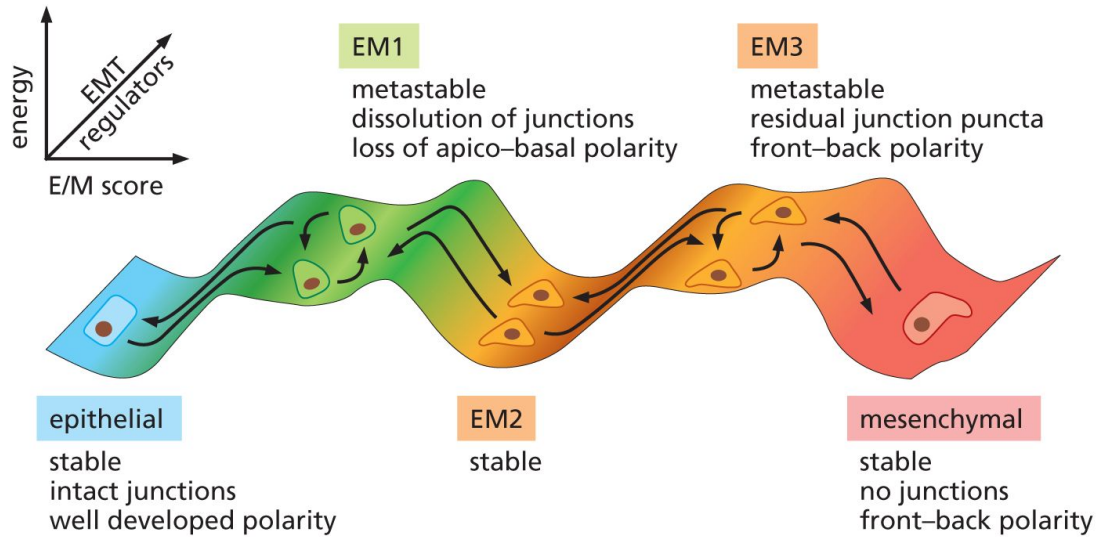
(B)

Figure 14.11 Cadherin shifts and melanoma cell invasiveness Melanomas are among the most malignant tumors because of their tendency to metastasize widely

once they reach a certain stage of tumor progression. This behavior is attributable, in part, to the reactivation of a cell-biological program that enabled the migratory behavior of their neural crest ancestors (see Figure 14.8D). The shift from E- to N-cadherin expression, which occurs when melanocytes (A) become transformed into melanoma cells (B), has been proposed to facilitate invasion of the stroma, since the shutdown of E-cadherin expression (*green*) enables these cancer cells to extricate themselves from their keratinocyte neighbors in the epidermis, while its replacement by expression of N-cadherin (*reddish pink*) allows these tumor cells to form homotypic interactions with various types of mesenchymal cells, such as fibroblasts and endothelial cells, that reside in the stroma of the skin (i.e., the dermis). Of note, the EMT-inducing Slug transcription factor (see Figure 14.19B) plays a key role in activating aggressive behavior in melanoma cells. (Adapted from N.K. Haass, K.S.M Smalley and M. Herlyn, *J. Mol. Histol*. 35:309–318, 2004. With permission from Springer.)

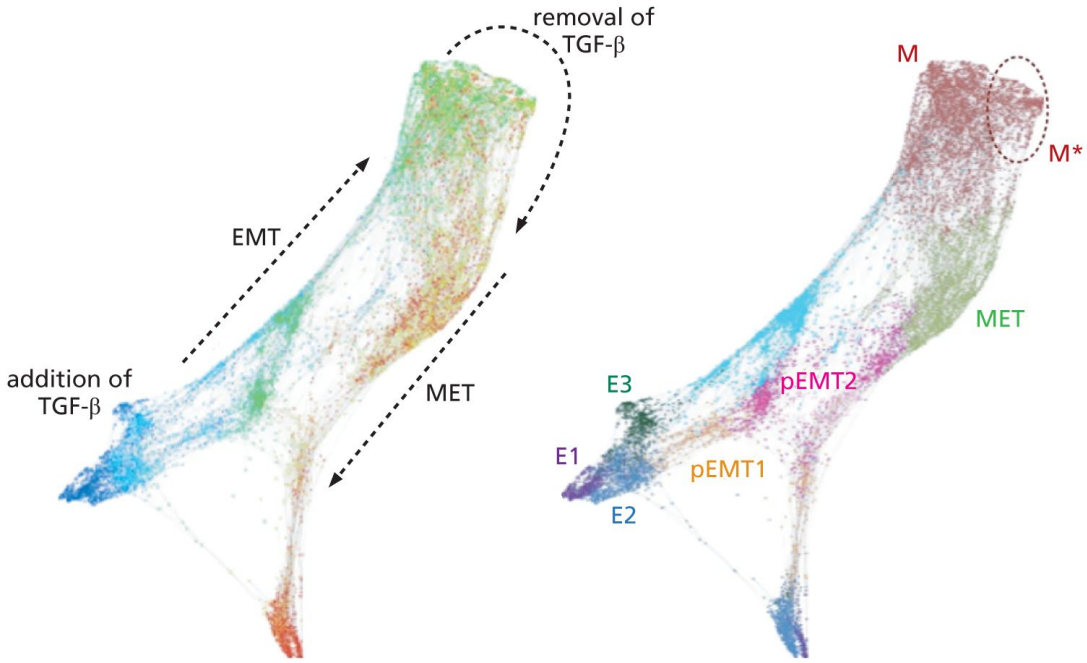
The intermolecular homophilic bonds formed between pairs of N-cadherin molecules are weaker than those formed by E-cadherin homodimers. This helps to explain why cell surface N-cadherin molecules actively favor cell motility and thus behave very differently from their E-cadherin cousins, which work to immobilize cells within epithelial cell layers. This point is driven home by experiments in which expression vectors are used to force high levels of N-cadherin expression in otherwise-normal cultured epithelial cells. Such ectopic expression causes the epithelial cells to acquire motility and invasiveness, as indicated by their ability to break through a reconstructed extracellular matrix introduced into a culture dish.

Finally, we should note that the above description of the EMT program is simplistic in at least one very important way: the cancer cells in human carcinomas that have activated an EMT program rarely advance all the way toward a fully mesenchymal state. Instead, they proceed only partway down the road, resulting in a “partial EMT” in which these neoplastic cells co-express certain retained epithelial markers together with newly acquired mesenchymal ones. Hence, the EMT program does not operate as a binary switch that alternates between extreme epithelial and mesenchymal poles. Instead, its actions are manifested by the entrance of cells into a spectrum of phenotypic states arrayed along an epithelial–mesenchymal axis, with the possibility that cells can rapidly interconvert between these intermediate states depending on contextual signals that they may be receiving (**Figure 14.12**). Indeed, it is unclear whether an EMT program, as it operates in spontaneously arising tumors, ever transports a carcinoma cell all the way into a highly mesenchymal state such as that of a typical fibroblast.



A ribbon-like continuum of cell states in which progression left to right represents E slash M score and vertical elevation represents energy. The ribbon starts at the bottom left with epithelial cells, which are stable and characterized by intact junctions and well-developed polarity. Moving right, the ribbon rises to E M 1 cells, which are metastable and characterized by dissolution of junctions and loss of apico–basal polarity. Further right, the ribbon descends to E M 2 cells, which are stable. It then rises again to E M 3 cells, which are metastable and characterized by residual junction puncta and front–back polarity. Finally, the ribbon descends again to mesenchymal cells, which are stable and characterized by no junctions and front–back polarity.

(A)



Two images, both showing an upward curve from left to right with a long, thir downward protrusion from the center of each curve. On the left image, the bottom left of the curve is labeled addition of T G F beta, the path upwards is labeled E M T, the curving path across the upper right is labeled removal of T G F beta, and the path back downards towards the protrusion is labeled M E T On the right image, identical in shape but differently colored, there are colorec regions labeled E1, E2 and E3 on the bottom left of the curve; a region labelec p E M T 1 to the left of the protrusion; a region labeled p E M T 2 above the protrusion; a region labeled M E T to the right and above the protrusion; and a region labeled M on one side and M star on the other in the upper right where the curve ends.

(B)

Figure 14.12 Multiple intermediate states between epithelial and mesenchymal phenotypes (A) As depicted here, the EMT does not operate as a binary switch that conveys cells between two alternative states—highly epithelial and highly mesenchymal. Instead, multiple intermediate states with differing proportions of epithelial and mesenchymal traits intervene between the two extreme endpoints of this spectrum of phenotypes. The interconversions between phenotypic states are represented as movements between states plotted on a free energy diagram, with cells residing in a stable or metastable fashion in energy minima. While the mesenchymal state is indicated at the right of this spectrum, in reality spontaneous activation of an EMT program in carcinoma cells during the course of tumor progression rarely if ever generates fully mesenchymal cells. (B)

Mass cytometry uses the analytical tools of mass spectrometry to detect isotope-coupled antibody molecules, enabling the simultaneous detection of dozens of different antibody-bound antigens in a biological sample. The resulting multi-dimensional protein expression profiles are presented in a way that collapses multi-dimensional measurements into the 2-dimensional images shown here. The *left* image indicates the course of entrance into successive phenotypic states of cells following application of TGF-β (which induces an EMT program), whereas the reversal of those phenotypes and the return to a more epithelial state following withdrawal of TGF-β is indicated by MET. The *right* image indicates distinct phenotypic states that were assigned to cell populations as they passed between epithelial and mesenchymal cell states. (A, from M.A. Nieto, R.Y.-J. Huang, R.A. Jackson and J.P. Thiery, *Cell*, 166:21–45, 2016. With permission from Elsevier. B, from L.G. Karacosta, B. Anchang, N. Ignatiadis et al., *Nature Commun*. 10:5587, 2019. Glossary

gastrulation
: An early stage of embryogenesis in which cells of the outer ectodermal layer invaginate into the interior of the embryo, where they serve subsequently as precursors of the endodermal and mesodermal cell layers.

vimentin
: Intermediate filament protein of the cytoskeleton of mesenchymal cells such as fibroblasts.

homotypic
: (1) Referring to interactions between two cells of the same type; *see also* **heterotypic**. (2) Referring to interactions between two or more molecules of the same type.

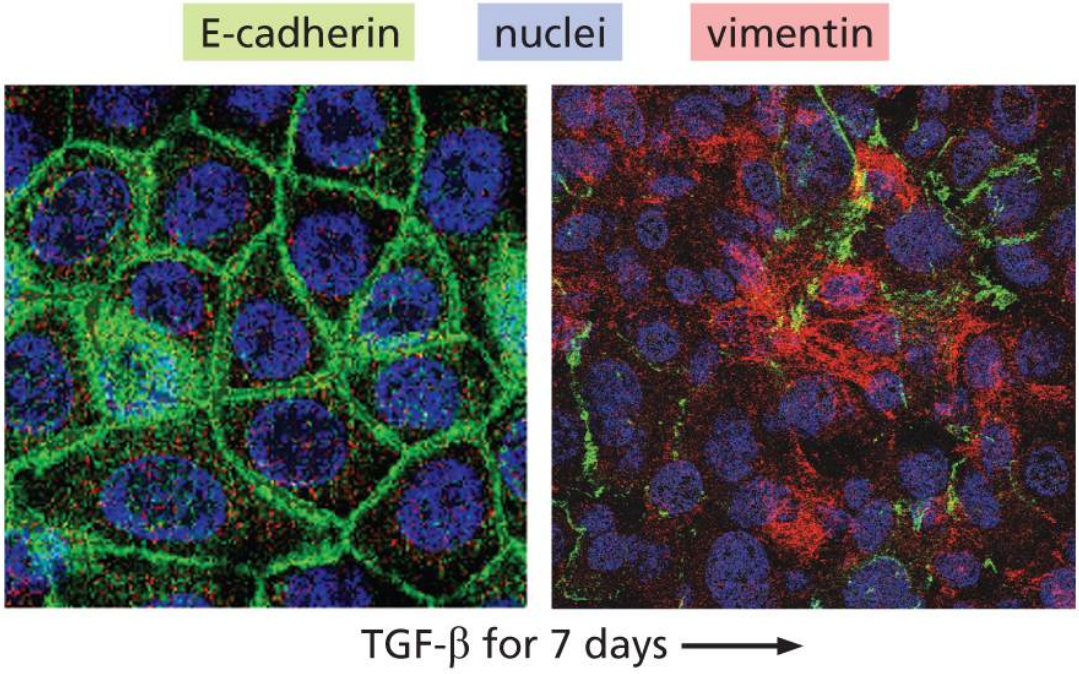
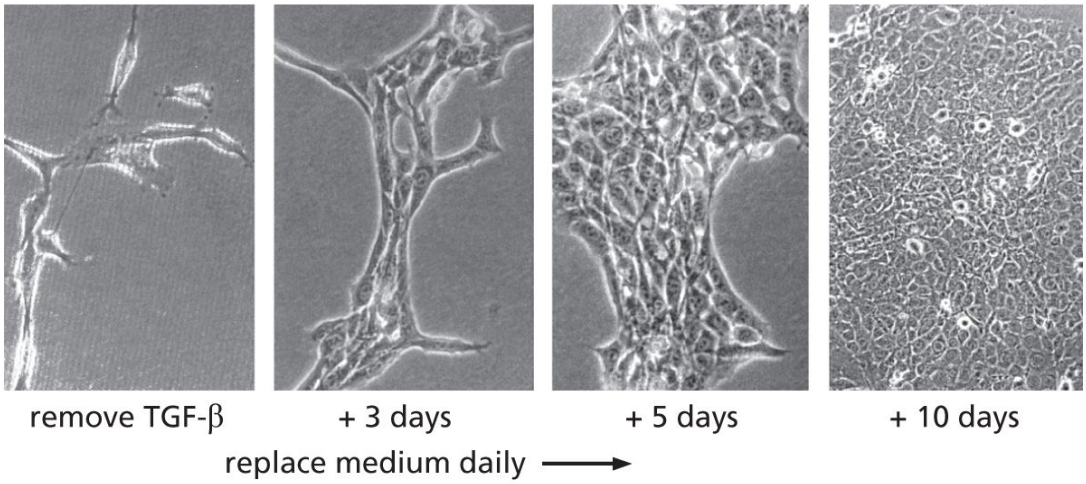
14.3 Epithelial–mesenchymal transitions are often induced by contextual signals

Stepping back for a moment, much of the thinking described above could be traced back to pioneering experiments carried out in Austria in the mid-1990s, which extended earlier research on the role of EMT in embryogenesis into the area of cancer pathogenesis. As was demonstrated at the time, exposure of *ras*-transformed EpRas mouse mammary epithelial cells (MECs) to TGF-β resulted in the progressive loss of epithelial morphology and a reduction of epithelial markers, including cytokeratins and E-cadherin (**Figure 14.13**). At the same time, these transformed cells acquired mesenchymal protein markers, such as vimentin, and assumed a morphology resembling that of fibroblasts—all of the hallmarks of the EMT studied earlier by developmental biologists.



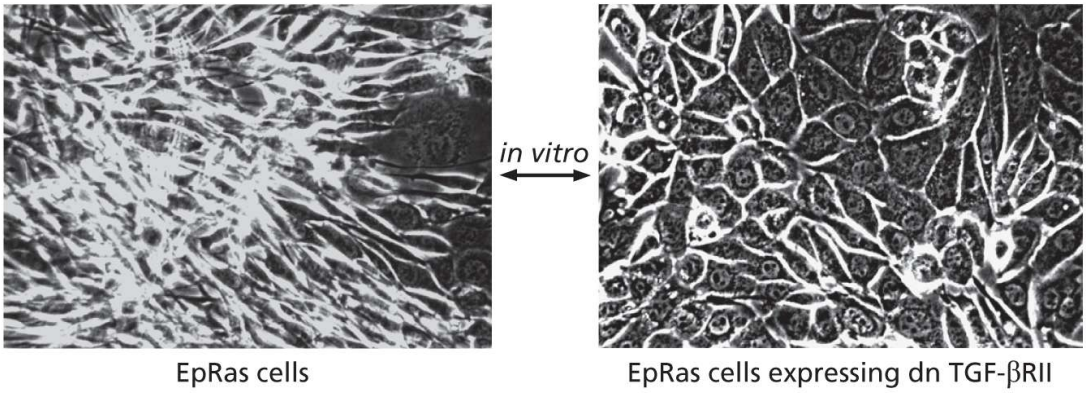
Two fluorescence microscopy images in which E-cadherin appears in green, vimentin in red, and nuclei in blue. On the left, the regions between tightly packed blue nuclei are green. On the right, after 7 days' exposure to T G F-beta, the green is largely gone and there are now scattered patches of red between and overlying the blue nuclei.

(A)



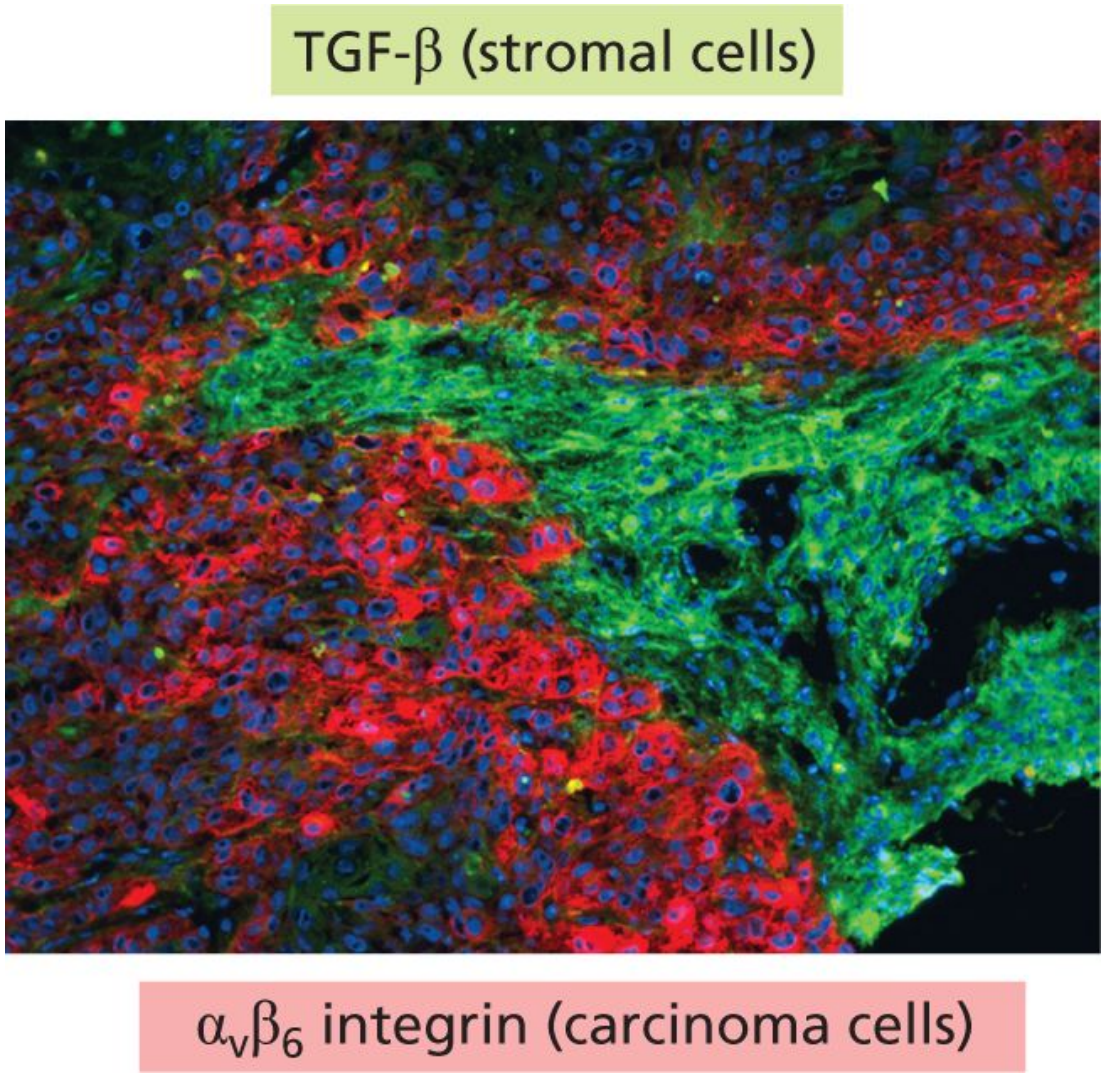
A sequence of four grayscale microscope images. In the first, a few cells are visible, in a shape like a nude tree branch. At this point, T G F beta is removed. With growth medium being replaced daily, the cell cluster is shown at 3, 5 and 10 days, over which time it grows dramatically. By day 10, the cluster is a mass of hundreds of tightly packed cells.

(B)



Two grayscale in vitro microscopy images. On the left, E p R a s cells are dramatically elongated. On the right, E p R a s cells expressing d n T G F-beta R2 have a more rounded appearance.

(C)



A fluorescence microscopy image of a tissue sample. On the left are carcinoma cells, whose red color signifies the presence of alpha v beta 6 integrin. On the right is stroma, whose green color signifies the presence of T G F-beta.

(D)

Figure 14.13 Control of the EMT by TGF-β and its effects on tumorigenic cells Immortalized mouse mammary epithelial cells (MECs) of the EpH4 cell line were transformed into EpRas tumor cells by introducing a *ras* oncogene. (A) EpRas cells (*left panel*) usually have an epithelial, cobblestone-like appearance and express E-cadherin (*green*) at their cell–cell junctions. However, when cultured for 7 days in the presence of TGF-β1 (*right panel*), they undergo an EMT and assume an elongated fibroblastic appearance (*not visible here*). In addition, they suppress expression of E-cadherin and express instead vimentin (*red*),

thereby shifting from an epithelial to a mesenchymal gene expression program. Nuclei are stained *blue* with DAPI dye. (B) Thereafter, EpRas cells maintain the EMT-induced mesenchymal, fibroblast-like state through their own production of and response to TGF-β1 (i.e., via autocrine signaling; *not shown*). However, as seen here, when these cells are cultured in a medium that lacks added TGF-β1 and their growth medium is changed daily (to remove any TGF-β that they may have secreted into the medium and have accumulated), their appearance gradually reverts to an epithelial cobblestone phenotype, as shown after 3, 5, and 10 days of culture (*left to right*), indicating that they have undergone a mesenchymal–epithelial transition (MET). (C) Use of a dominant-negative (dn) type II TGF-β receptor (which effectively blocks autocrine TGF-β signaling) provides further proof that autocrine TGF-β signaling by EpRas cells is required to maintain their residence in a mesenchymal state. When this signaling is blocked by expression of this mutant receptor, the mesenchymal appearance of the EpRas cells (*left*) is replaced by an epithelial appearance (*right*), indicating that they have undergone an MET. (D) Detroit 562 human pharyngeal carcinoma cells growing in a tumor express the $\alpha_v\beta_6$ integrin (*red*; see Figure 14.14C), indicative of their having undergone an EMT, whereas TGF-β (*green*) is produced by cells in the nearby tumor-associated stroma. The $\alpha_v\beta_6$ displayed by the tumor cells can be deployed to activate the latent form of TGF-β produced by the stromal cells, thereby creating a self-sustaining, positive-feedback loop (since the activated TGF-β is a strong inducer of the EMT and thus of additional expression of $\alpha_v\beta_6$ integrin by the carcinoma cells, yielding even more activated TGF-β). (A, from E. Janda et al., *J. Cell Biol*. 156:299–314, 2002. With permission from Rockefeller University Press. B, from M. Oft et al., *Genes Dev*. 10:2462–2477, 1996. With permission from Cold Spring Harbor Laboratory Press. C and D, courtesy of D.R. Leone, B.M. Dolinski and S.M. Violette, Biogen MA Inc.)

Provocatively, once these *ras*-transformed cells underwent an EMT, they began to produce their own TGF-β1; this TGF-β1, acting via an autocrine positive-feedback signaling loop (see Figure 5.8C), allowed them to maintain their mesenchymal phenotype for extended periods of time, long after the inciting TGF-β was withdrawn from their culture medium. If they were prevented, however, from accumulating concentrations of TGF-β1 in their immediate surroundings, then they would lapse back to an epithelial state (Figure 14.13B). A similar reversion to an epithelial state was achieved through inhibition of signaling by a key TGF-β1 receptor displayed by these cells (Figure 14.13C; see also Figure 5.15). Moreover, maintenance of TGF-β autocrine signaling through a positive-feedback loop was apparently amplified by the $\alpha_v\beta_6$ integrin, which is displayed characteristically as one component of the EMT program and serves to activate latent TGF-β sequestered in the extracellular space (Figure 14.13D). Figure 14.13D also reveals that TGF-β is often produced in

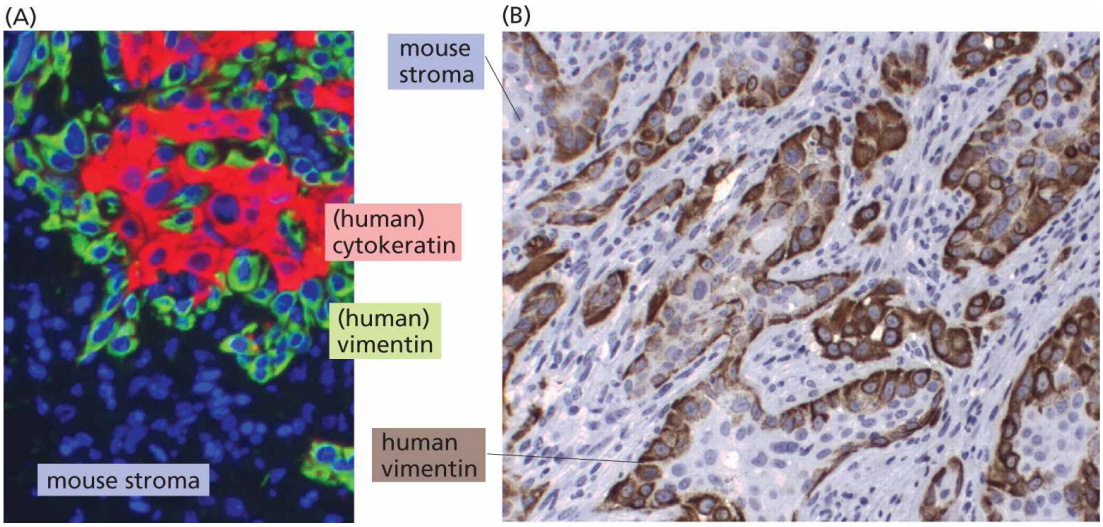
abundance by the tumor-associated stroma. These experiments, taken together, demonstrated that TGF-β signaling could conspire with oncogenes frequently found in human cancers—members of the *ras* gene family—to force epithelial cancer cells to undergo an EMT.

In retrospect, this work established three principles that were to guide research into the EMT-cancer connection in the quarter century that followed. First, that a contextual signal that is abundant in many human carcinomas could serve as the trigger of EMT and the resulting formation of more-mesenchymal carcinoma cells. Second, that the resulting cells could thereafter retain their more-mesenchymal phenotype through autocrine signaling. Finally, that this residence in a quasi-mesenchymal state was only metastable, in that it could be reversed by interrupting certain positive-feedback controls such as the TGF-β-dependent autocrine loop (see Figure 14.13C).

The prominent role of TGF-β in actively promoting the aggressiveness of malignant cancer cells contrasts starkly with our earlier discussions of its anti-proliferative effects (see Section 8.10 and **Supplementary Sidebar 14.2**). In Chapter 8, we learned that this cytokine could block the advance of cells through the cell cycle, often preventing forward march through the G_1 phase of the cell cycle. In this chapter we encounter TGF-β in an entirely different role in which it actually *fosters* tumor progression by activating EMT programs. The resolution of this apparent paradox comes from an understanding of the effects of somatic mutations acquired during primary tumor formation, such as acquisition of a *ras* oncogene or inactivation of the *Rb* tumor suppressor gene. Both of these changes, as well as other similarly acting mutations, render a carcinoma cell resistant to the cytostatic effects of TGF-β, permitting its EMT-inducing effects to manifest themselves.

Strong support for the notion that TGF-β can favor malignant cell behavior is provided by numerous studies in which the levels of tumor-associated TGF-β (often TGF-β1) have been found to rise in parallel with increasing degrees of tumor invasiveness and general aggressiveness. Indeed, high levels of TGF-β, both within the tumor mass and in the general circulation, augur poorly for the long-term survival of a cancer patient.

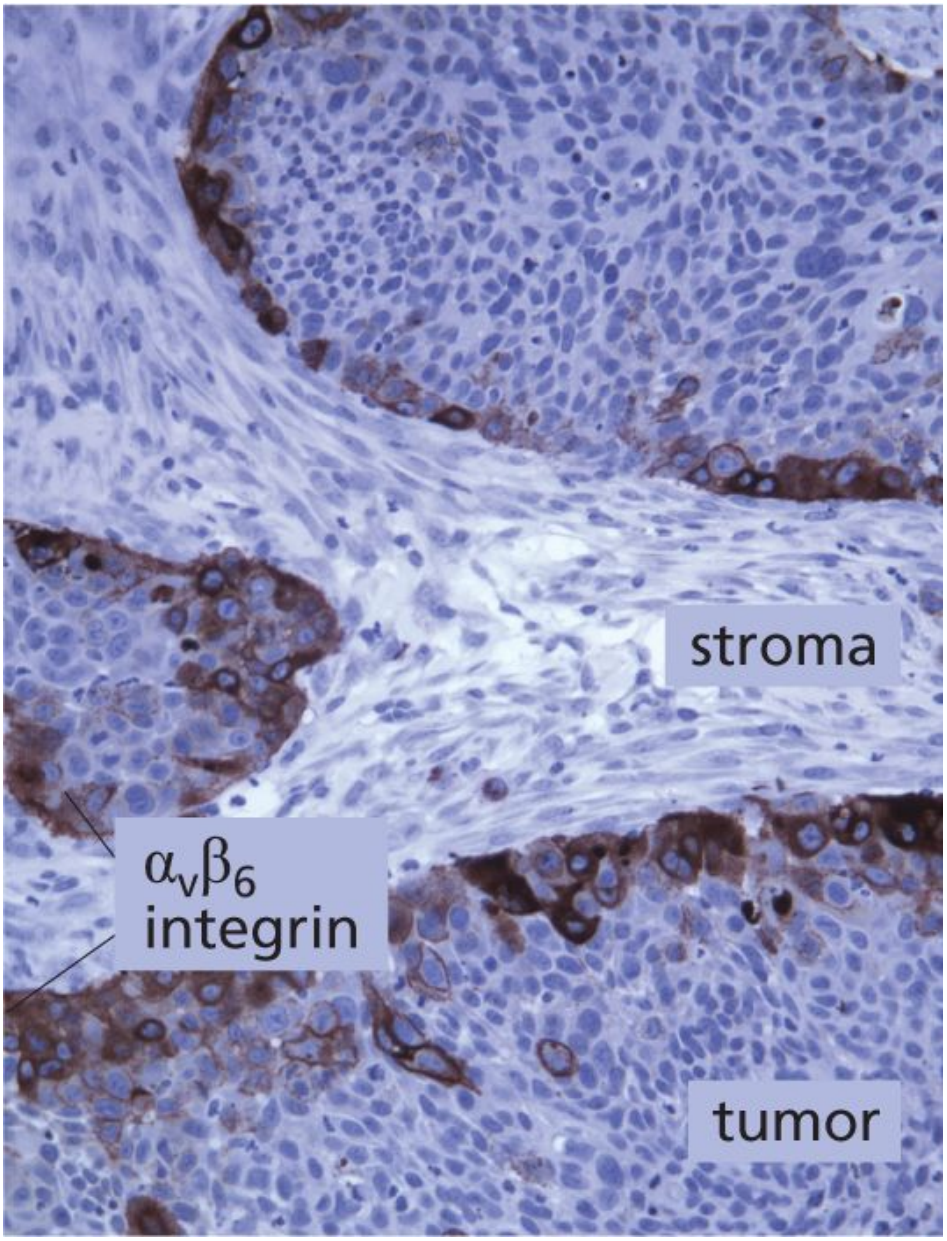
In the years that followed the early EMT–TGF-β experiments, studies of the localization within a tumor of the carcinoma cells that underwent an EMT reinforced the notion that contextual signals are often important in triggering the expression of EMT programs in carcinoma cells. As seen in **Figure 14.14**, carcinoma cells in close contact with the surrounding stroma activate their EMT programs, whereas those residing in the interior of islands of carcinoma cells (and thus shielded from direct contact with stroma) fail to do so. The notion that these “edge cells” have indeed activated components of their EMT program is supported by the observations that these cells also exhibit changes in a collection of other proteins expressed following experimental induction of EMT programs in cultured cells.



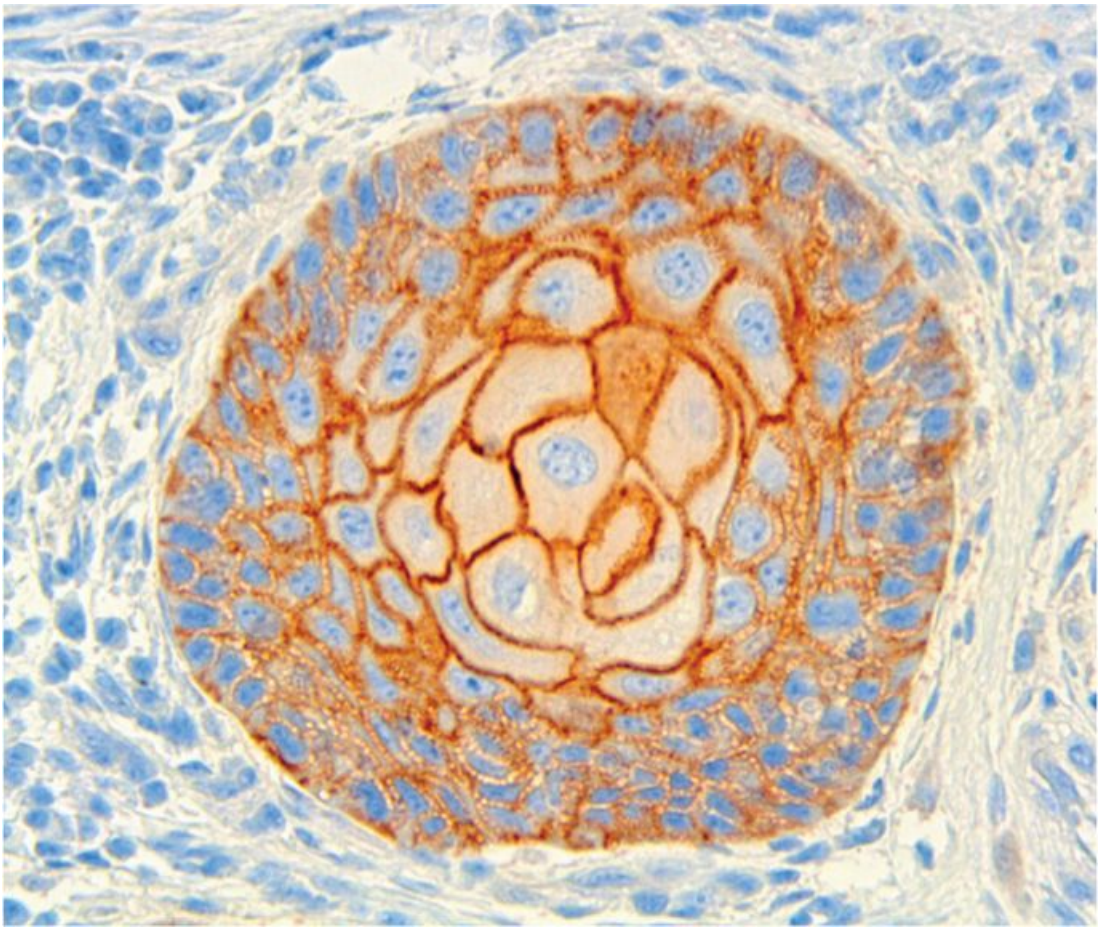
A fluorescence microscopy image showing human tumor cells with bright red and green cytoplasms, and mouse stroma cells with only blue nuclei visible. The human cells in direct contact with the mouse stroma are green, indicating the presence of vimentin. They surround the cells that are red, indicating the presence of cytokeratin.

A histology stain image in which blue-gray mouse stroma cells are infiltrated with many moderately-sized patches of cells whose brown color indicates the presence of human vimentin.

(C)

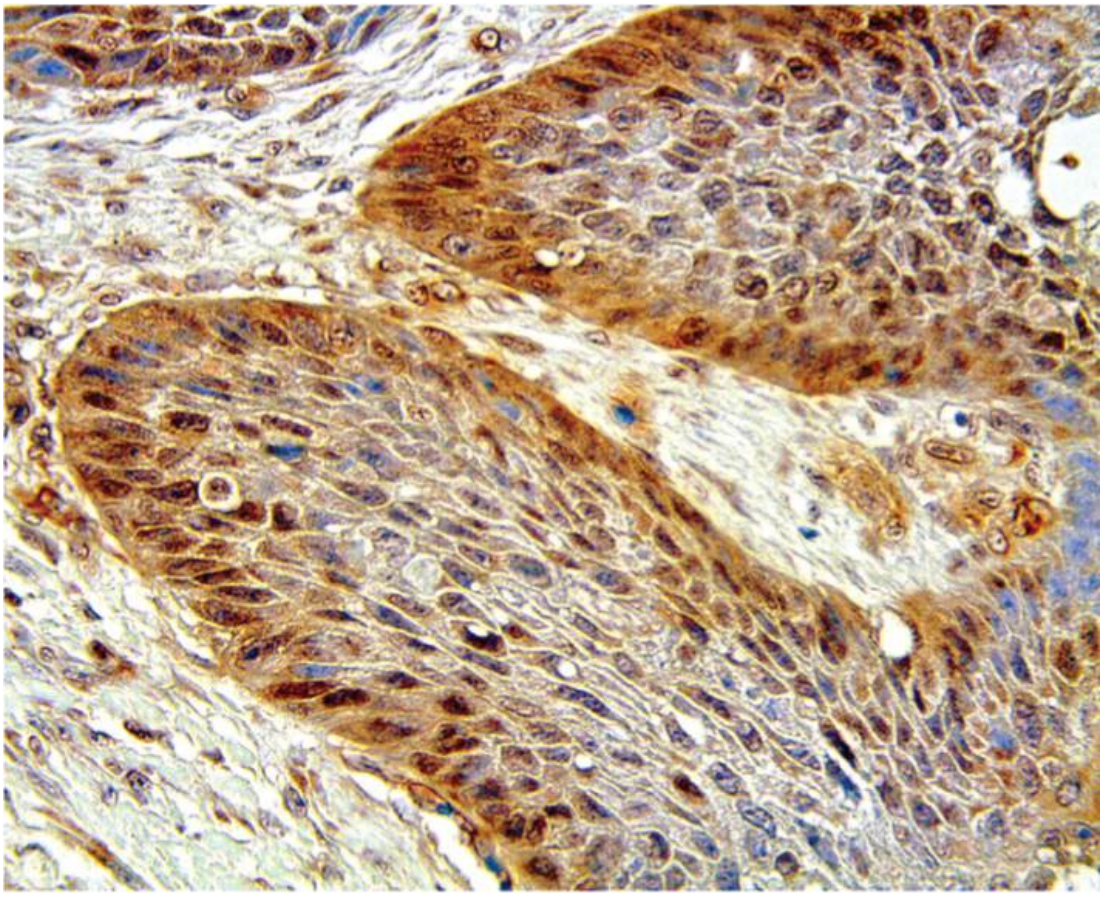


A histology stain image showing dark blue tumor masses within lighter blue stroma tissue. The tumors are dark brown edges, indicating the presence of alpha v beta 6 integrin.



A histology stain image showing a circular mass of light brown cells surrounded by tissue in which only pale blue nuclei are visible. The cells in the center of the mass are large and the nuclei are not prominent. The cells near the edge of the mass are smaller and the blue nuclei are prominent.

(D)



A histology stain image showing dark brown tumor tissue invading lighter brown stroma from the right. The tumor tissue is darkest brown where the tumor and stroma make contact.

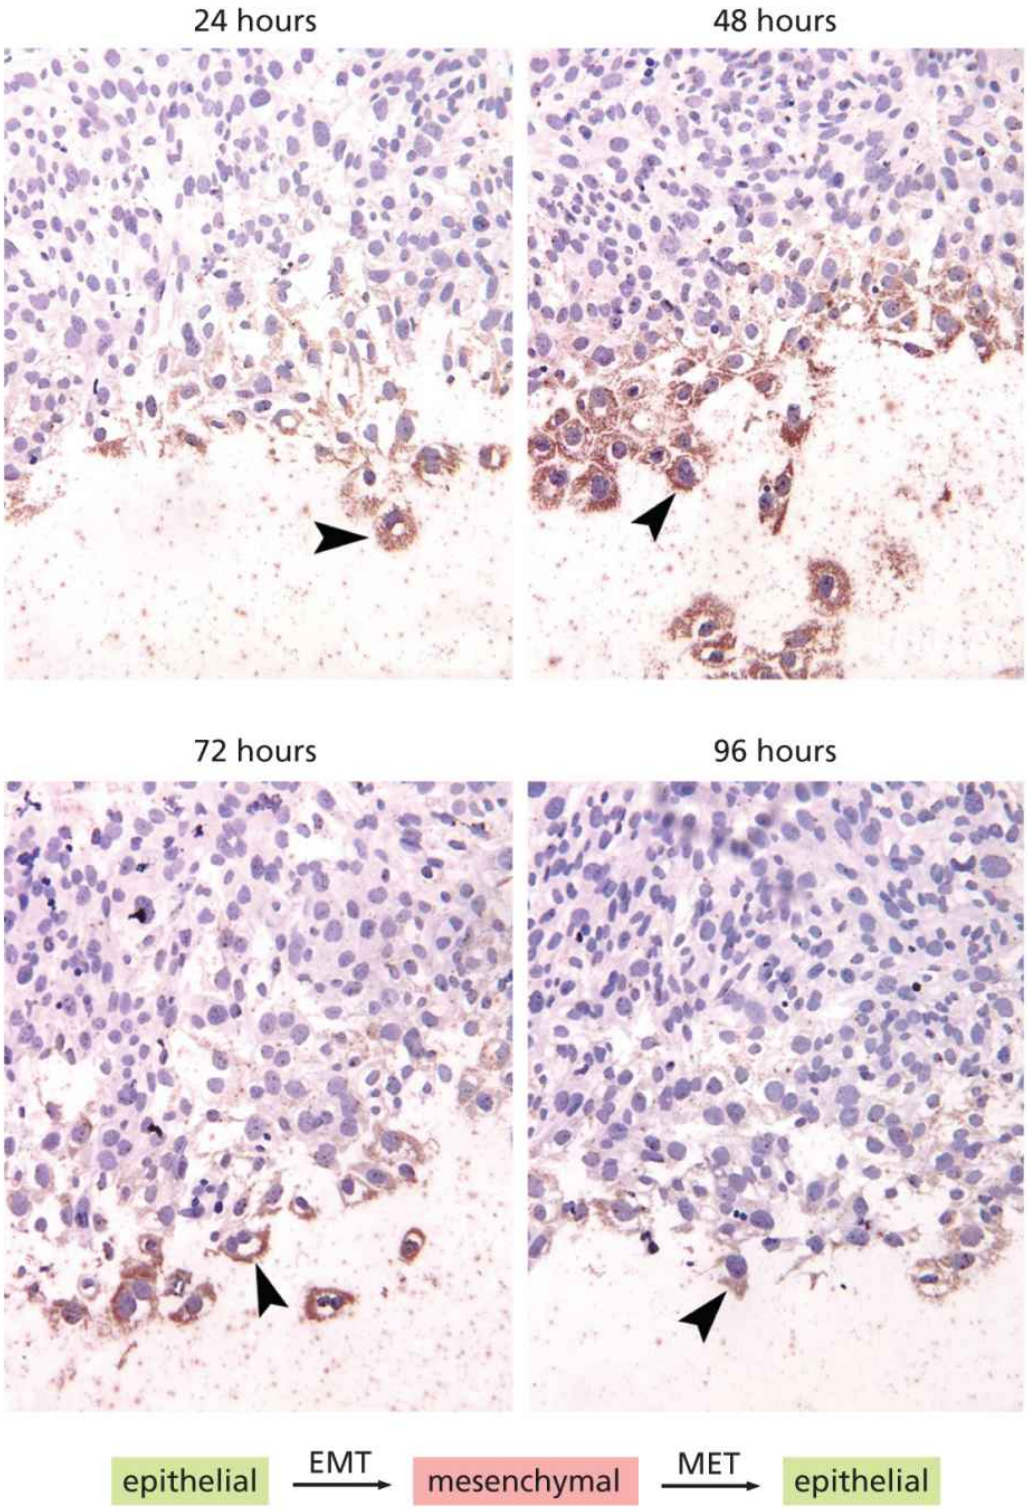
(E)

Figure 14.14 Manifestations of the EMT at the interface between tumor epithelium and stroma (A) Experimentally transformed human mammary epithelial cells (MECs) were implanted in an immunocompromised mouse host. The cytokeratin-positive human carcinoma cells (*red*) toward the center of the tumor mass are not in direct contact with the surrounding mouse stromal cells, whose presence is indicated only by their DAPI-stained nuclei (*blue*). However, many of the human MECs that are in contact with the stroma have undergone an EMT, as indicated by their loss of cytokeratin staining (*red*) and their display instead of human-specific vimentin (*green*). [The use of antibody that specifically recognizes human (and not mouse) vimentin ensures that the green cells at the invasive edge derive from the engrafted human cells rather than from the mouse host.] Moreover, some of these cancer cells at the invasive edge have lost the cuboidal shape of the epithelial cancer cells and have assumed, instead, a more

elongated, fibroblastic shape. (B) A tumor formed by the same strain of transformed human MECs described in panel B is seen here at lower magnification. The display of human vimentin (*dark brown*), which indicates passage through an EMT, is limited to cells that are in direct contact with the surrounding stroma. Conversely, tumor cells in the interior of these islands do not display human vimentin and have presumably remained in an epithelial state. (C) The expression of the $\alpha_v\beta_6$ integrin is associated with the EMT program. This integrin is expressed in epithelial tissues that are undergoing wound healing or suffering chronic inflammation; it is also seen at the invasive edge of carcinomas. In a xenografted tumor formed by SCC-14 human pharyngeal carcinoma cells, expression of the $\alpha_v\beta_6$ integrin is exhibited by carcinoma cells at the invasive edge of the tumor (*dark brown*) that are in direct contact with the tumor-associated stroma, suggesting that stromal signals are responsible for its expression in epithelial cells. (D) In this human oral squamous cell carcinoma (OSCC), intense expression of p120 catenin (*light brown*), another component of the adherens junction, is limited to the center of this island of carcinoma cells, whereas cells closer to the surrounding stroma (*light blue nuclei*) have lost p120 catenin and thus the adherens junctions typical of epithelial cells. Cell nuclei are stained *blue* with hematoxylin. (E) In another OSCC, matrix metalloproteinase-2 (MMP-2, *brown*), which is up-regulated during passage through an EMT and deployed by some carcinoma cells to facilitate invasion, is also seen to be expressed preferentially near the stroma. (A, courtesy of K. Hartwell and T.A. Ince. B, courtesy of T.A. Ince. C, courtesy of D.R. Leone, B.M. Dolinski and S.M. Violette, Biogen MA Inc. D and E, from M. Vidal et al., *Am. J. Pathol*. 176:3007–3014, 2010. With permission from Elsevier.)

To summarize, in the primary tumor, a "reactive stroma" forms during the long course of primary tumor formation and, once formed, releases EMT-inducing signals (among them TGF-β) back to nearby carcinoma cells, which indeed are the neoplastic cells that previously were responsible for provoking the formation of the reactive stroma in the first place.

These observations and others like them (see Figure 14.14 C–E) clearly indicate the involvement of contextual signals experienced by carcinoma cells at the outer edges of islands of these cells. Actually, these signals may be of several types: In addition to soluble factors released by stromal cells, epithelial cells at the edges of these islands may sense that they no longer enjoy direct interactions on all sides with epithelial neighbors; the absence of a full complement of epithelial–epithelial homotypic interactions (**Figure 14.15**) might, on its own, induce them to activate an EMT program.

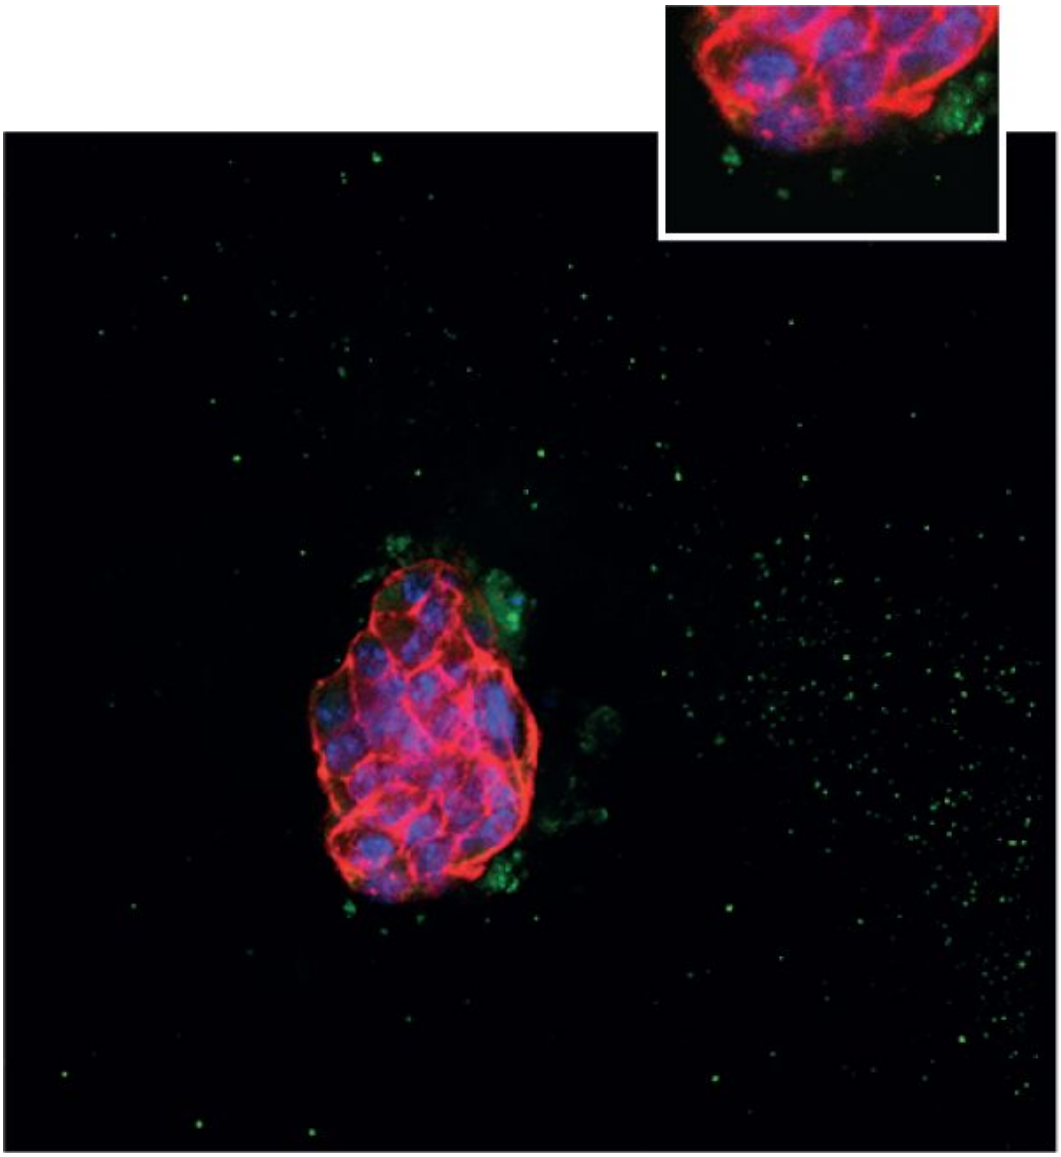


A sequence of four histology stain images, taken at 24-hour intervals, in which cells transition from epithelial to mesenchymal and then back to epithelial. In the first image, at the 24 hour mark, a few cells at the edge of the tissue sample are brown and starting to separate from the main body of cells. At the 48 hour mark,

many cells at the edge of the sample are brown, and some have fully separated. At the 72 hour mark, the only brown cells are a few detached ones. At the 96 hour mark, no cells are detached and hardly any brown is visible.

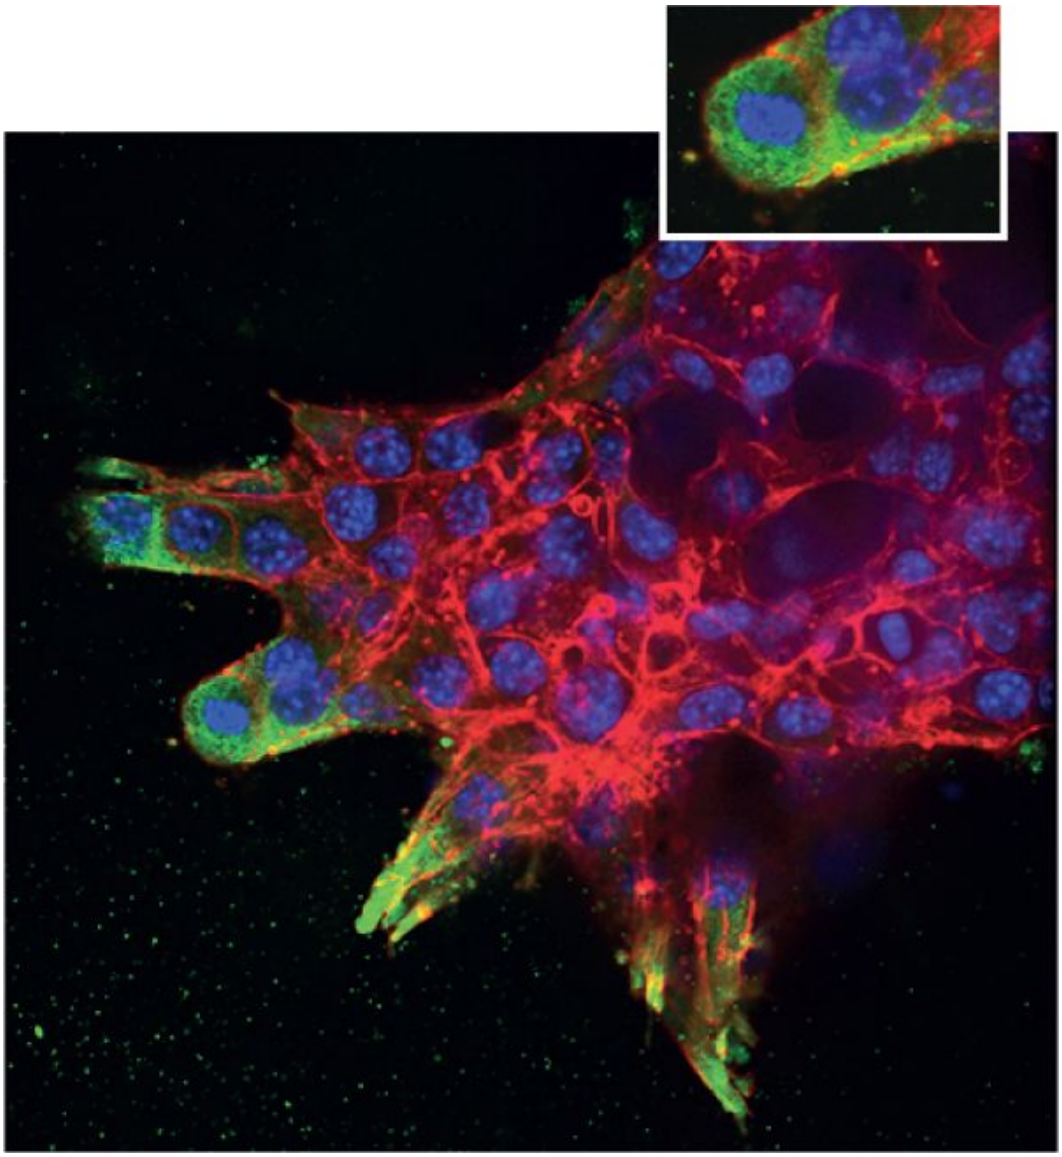
Figure 14.15 Transient expression of an EMT-inducing transcription factor in wound healing Expression of the Slug transcription factor is induced transiently in a monolayer culture of keratinocytes that has been wounded by scraping away a swath of cells. As seen here, 48 hours after wounding, keratinocytes at the edge of the wound induce expression of the Slug EMT-TF (*dark brown*) as they separate from the contiguous monolayer and begin to make their way as individual cells into the wound site (*bottom of each panel*), doing so in order to reconstruct an intact monolayer. By 96 hours, most of these cells cease expressing Slug and become integrated into a continuous monolayer. Hence, cells that initially underwent an EMT under the influence of the Slug EMT-TF in order to fill in and cover the wound site subsequently undergo an MET (mesenchymal–epithelial transition) in order to revert to the epithelial phenotype of their ancestors and reassemble a contiguous epithelial sheet. (From P. Savagner et al., *J. Cell Physiol*. 202:858–866, 2004. With permission from John Wiley & Sons.)

The extracellular matrix (ECM) assembled by cells in the stroma also contributes to EMT induction. Some research implicates direct contact of carcinoma cells with collagen type I, which is present in abundance in the ECM of the stroma but is absent in the epithelial compartment of the tumor, as another that favors EMT induction. Equally important is the *physical state* experienced by carcinoma cells: stromal cells may construct a stiff ECM that induces carcinoma cells to activate components of their EMT program (**Figure 14.16**). At the level of signal transduction biochemistry, Twist, a transcription factor and organizer of EMT programs, is liberated from its site of cytoplasmic sequestration and allowed to migrate to the nucleus, where its EMT-promoting powers can be exercised. Similarly, the expression of Snail, another EMT-inducing transcription factor, is significantly increased in response to stiffness of the ECM as is TGF-β autocrine signaling.



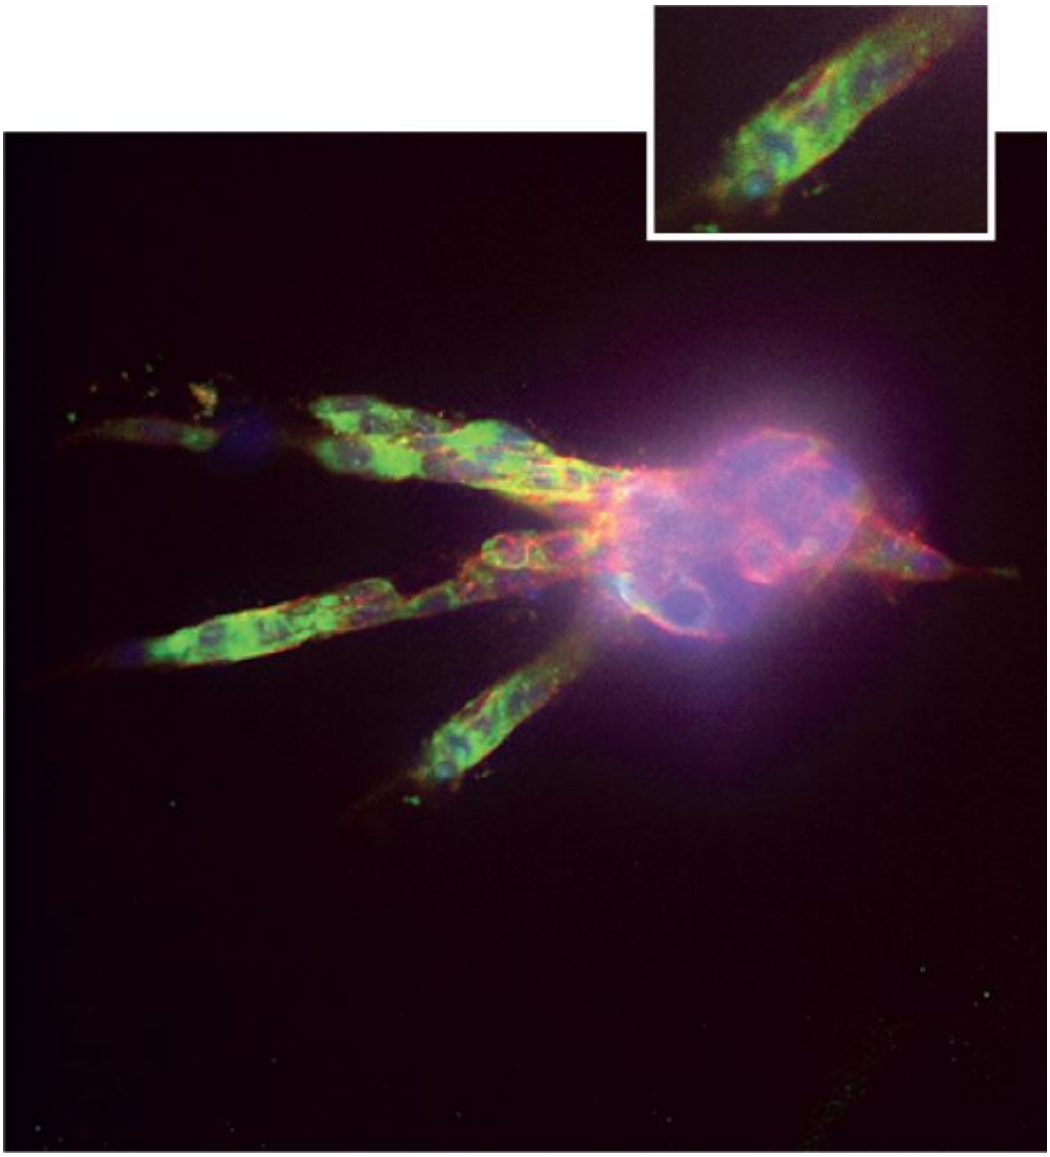
A fluorescence microscopy image of a small, globular cluster of cells with blue nuclei and red cytoplasms. Two or three green areas are barely visible.

(A)



A fluorescence microscopy image of a large cluster of cells that takes the shape of a hand with splayed stubby fingers. Most of the cluster consists of cells with blue nuclei and red cytoplasms. The tips of the stubby fingers, however, are green and yellow.

(B)



A fluorescence microscopy image of a cluster of cells that looks like a hand with three long, bony fingers. The palm is a fuzzy bluish pink. The fingers are yellow-green.

(C)

Figure 14.16 TGF-β and stiff extracellular matrix conspire to activate EMT markers Mammary carcinoma cells from the MMTV-PyMT mouse model of adenocarcinoma pathogenesis were propagated *in vitro* in collagen I gels having different degrees of stiffness in the presence or absence of added TGF-β. The gels model one aspect of the extracellular matrix (ECM) encountered by such gels during tumor pathogenesis. The expression of the RNA encoding the Snail EMT-TF was gauged by use of a recombinant construct in which the promoter of the

Snail gene drove expression of a YFP fluorescent reporter (*green*). In each panel, a higher magnification section of an interface between the introduced carcinoma cells and the surrounding gel is provided in the *top right.* (A) In a soft collagen I, the introduced carcinoma cells formed small noninvasive spheroids. (B) However, if the gel into which the cells were introduced was constructed to provide a relatively stiff surrounding matrix, these colonies began to extend small invasive fingers that expressed the *Snail* RNA at elevated levels. (C) If the introduced cells were propagated in a stiff gel, as in (B), that also contained TGF-β1, then long, highly invasive *Snail*-positive fingers were extended into the gel. (From A.H. Mekhdjian, F. Kai, M.G. Rubashkin et al., *Mol. Biol. Cell* 28:1467–1488, 2017.)

The major class of EMT-inducing signals involves a large cohort of soluble factors that, like the growth factors described in Chapter 5, are released by cells of the reactive stroma and impinge on nearby carcinoma cells located at the outer edges of epithelial cell masses, TGF-β being only one of them. Numerous observations implicate a variety of other factors, including Wnts, TNF-α (tumor necrosis factor-α), EGF (epidermal growth factor), HGF (hepatocyte growth factor), IGF-1 (insulin-like growth factor-1), as well as interleukins 6 and 8. It is likely that these stromal signals act in various combinations to induce epithelial cells to activate their previously latent EMT programs (**Table 14.3**). This raises the question of why this signaling became so complex during the course of metazoan evolution (**Supplementary Sidebar 14.3**).

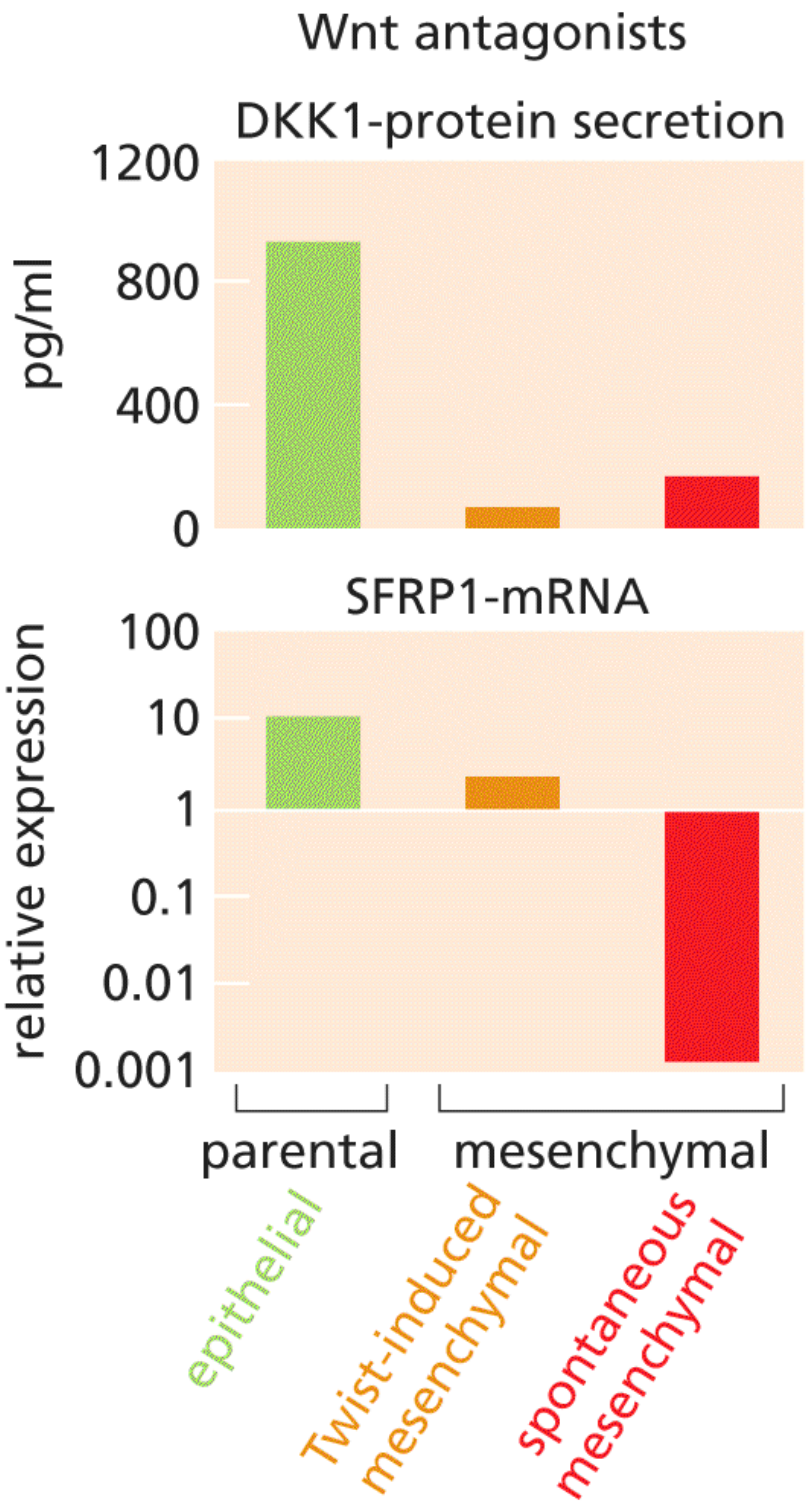
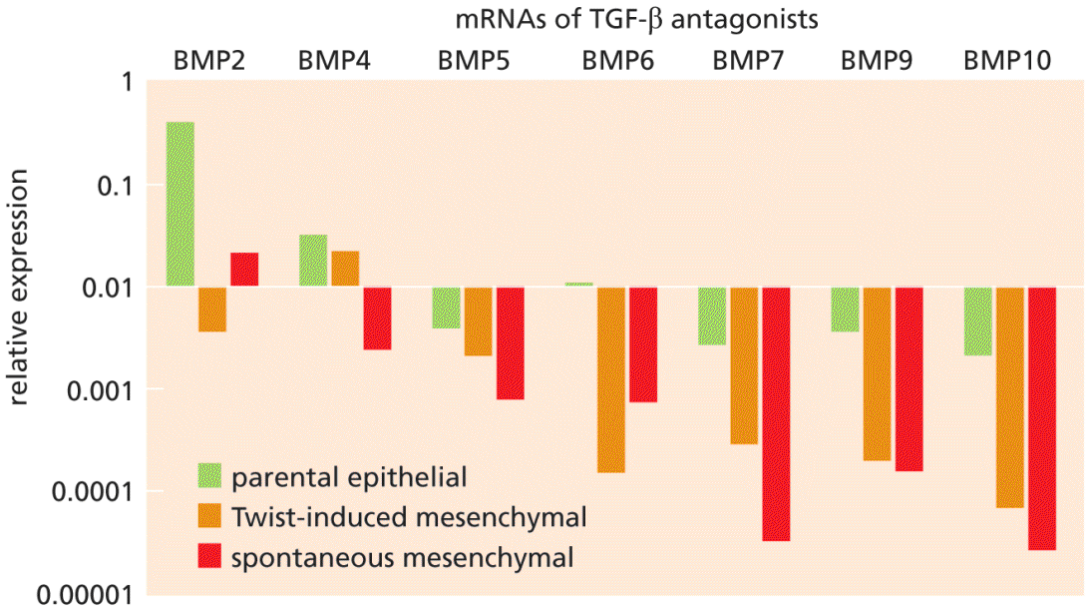
collagen type1

This theme of combinations of signals working through paracrine and autocrine signaling channels was supported by experiments in 2011, which extended the notion of collaborating EMT-inducing signals (**Figure 14.17**). Study of the growth factors that were secreted by cells that spontaneously entered into a more mesenchymal state revealed three classes of signaling proteins that appear to collaborate in various ways to actively maintain ongoing residence in this state: canonical Wnt proteins and non-canonical Wnt proteins (see Section 6.10), and the aforementioned TGF-β (see Section 6.12). Ongoing secretion and resulting autocrine stimulation by these factors were essential for continued maintenance of the mesenchymal phenotype. Conversely, if these autocrine signaling loops were interrupted by physiological inhibitors of these signaling loops, cells would revert to and rest in an epithelial state.



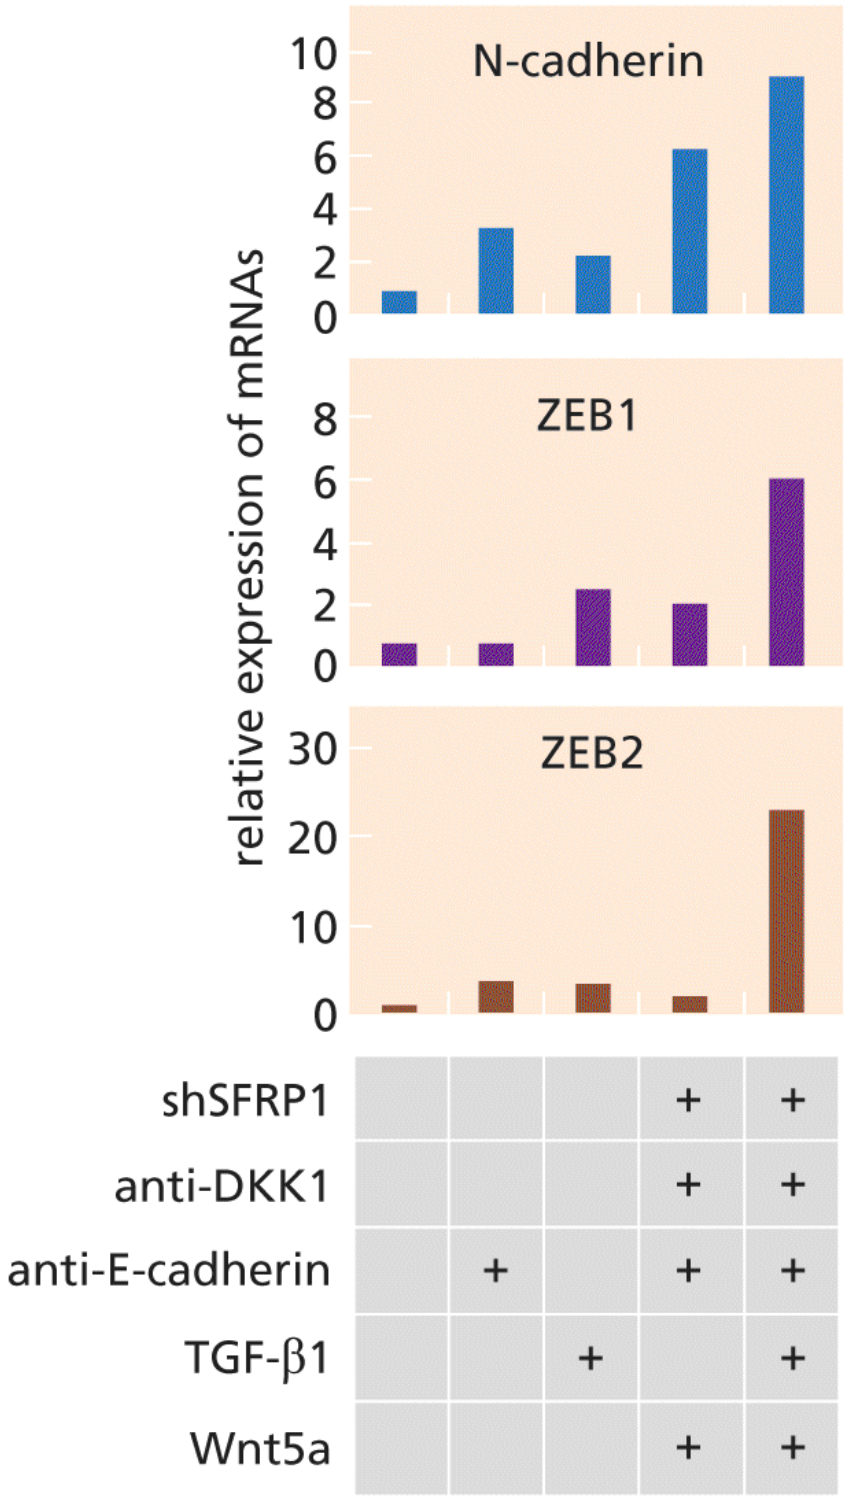
Two bar graphs under the heading W n t antagonists. The upper graph shows D K K 1-protein secretion in picograms per milliliter to be much higher for parental epithelial cells than for either Twist-induced or spontaneous mesenchymal cells. The lower graph shows that relative expression of S F R P

1-m R N A in parental epithelial cells is an order of magnitude higher than in Twist-induced mesenchymal cells and several orders of magnitude higher than in spontaneous mesenchymal cells.
(A)



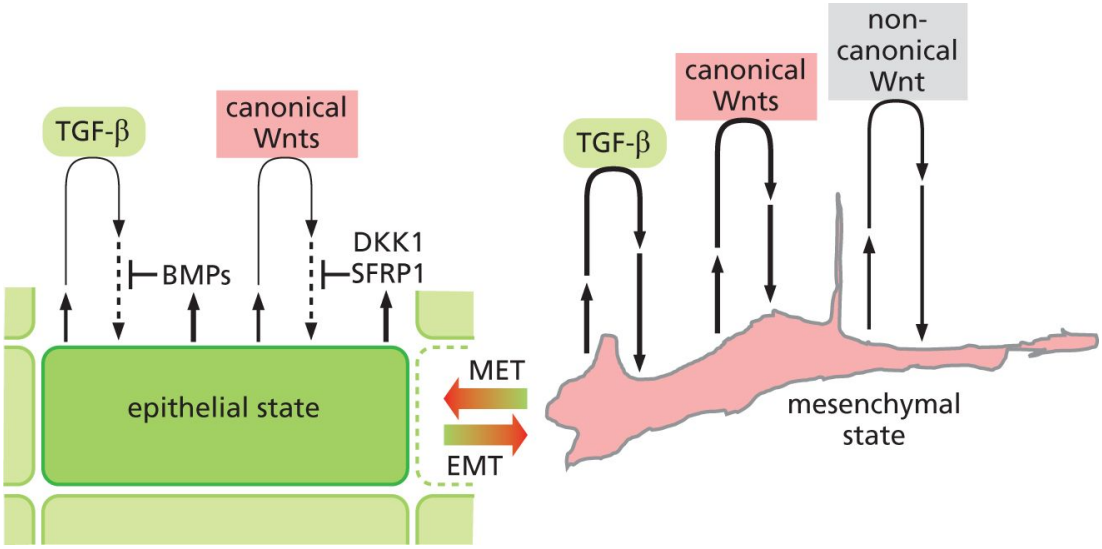
A bar graph which compares the relative expressions of seven different m R N Ayze of T G F-beta antagonists, in parental epithelial, twist-induced mesenchymal, and spontaneous mesenchymal cells. The seven T G F-beta antagonists are B M Pees 2, 4, 5, 6, 7, 9 and 10. Relative expression is consistently higher in epithelial cells than in either type of mesenchymal cell.

(B)



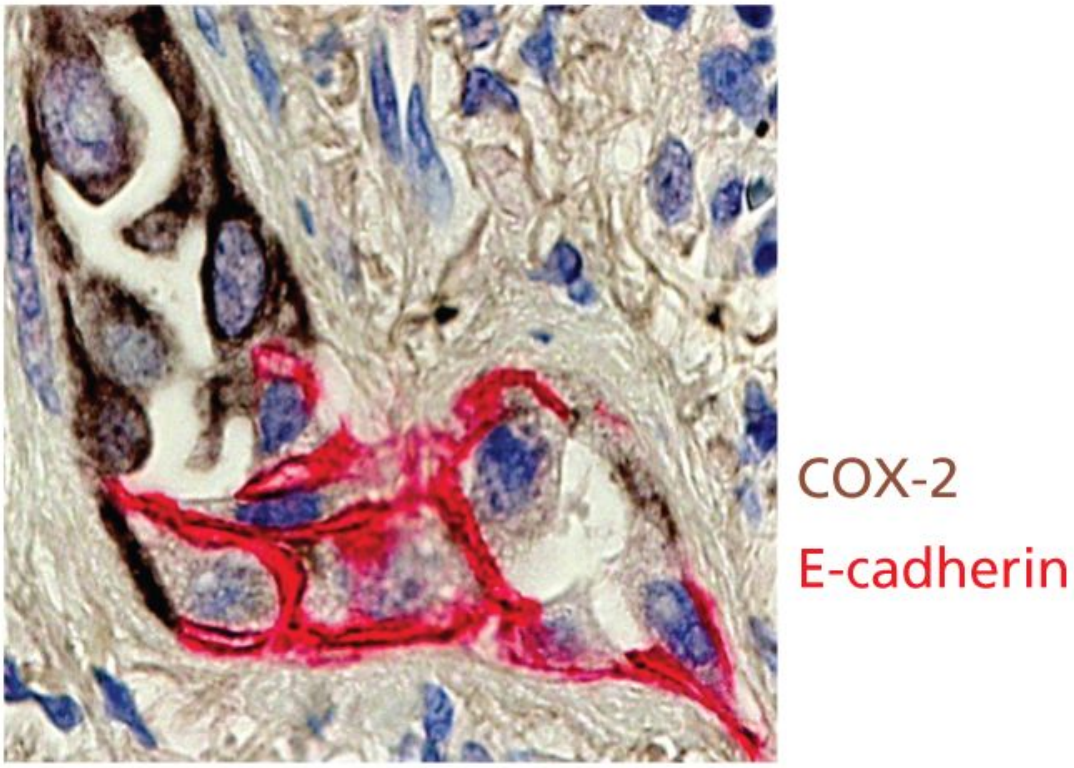
Three bar graphs describing the relative expression of m R N Ayze encoding N-cadherin, ZEB 1, and ZEB 2, under five different conditions identified as s h S F R P 1, anti-D K K 1, anti-E-cadherin, TGF-beta1, and W n t 5 a. Expression is strongest when all five conditions are present.

(C)



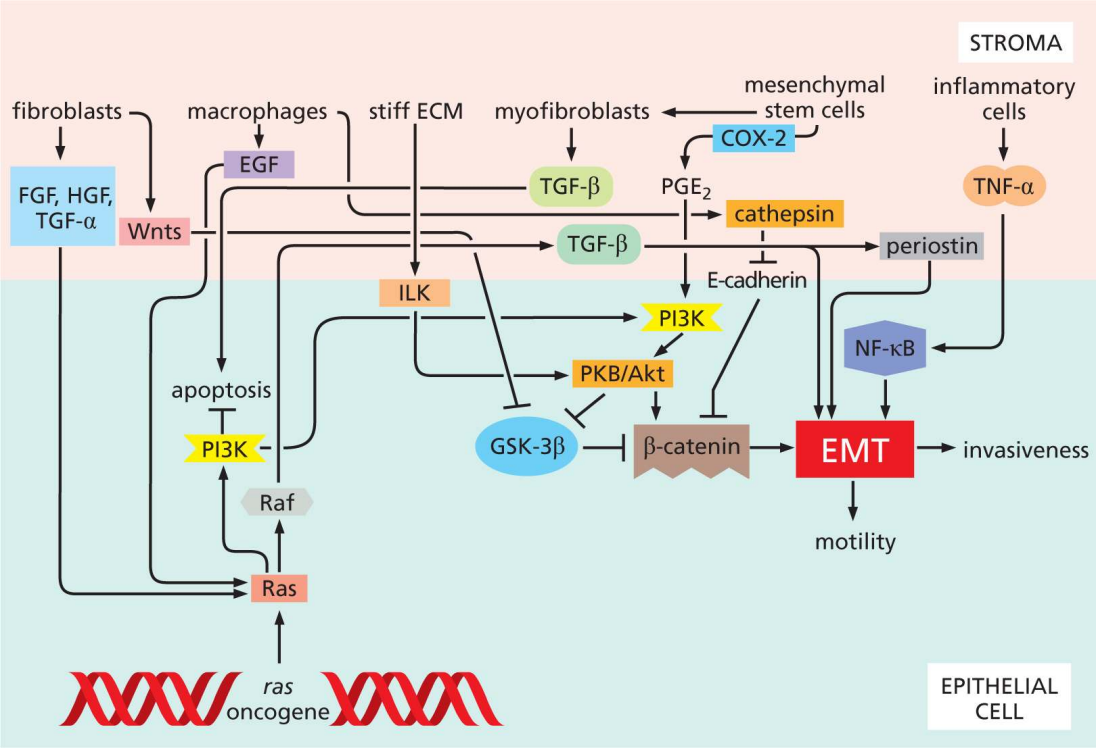
A schematic showing a cell in the orderly epithelial state and in the irregular mesenchymal state. In the epithelial state, the cell secretes T G F-beta and canonical W n tees, but B M Pees inhibit the T G F-beta from acting back on the cell, and D K K 1 and S F R P 1 inhibit the W n tees from acting back on the cell. In the mesenchymal state those inhibitors are not present, and secreted T G F-beta and canonical W n tees act back on the cell, as does non-canonical W n t.

(D)



A histology image in which cells that express COX-2 are brown and cells that express E-cadherin are bright red. These appear within tissue that is otherwise pale and nondescript.

(E)



A schematic summary of the complex signaling that goes on within and between an epithelial cell and stroma to induce the epithelial cell to transition into a mesenchymal state, which increases invasiveness and motility. Within the epithelial cell, the prime initiator is an r a s oncogene. Contributing initiators in the stroma include fibroblasts, macrophages, stiff extracellular matrix, myofibroblasts, mesenchymal stem cells, and inflammatory cells.

(F)

Figure 14.17 Multiple signals collaborate to induce and then maintain the mesenchymal state Immortalized HMLE human mammary epithelial cells (parental cells) entered into the mesenchymal state either spontaneously or by the forced expression of the Twist EMT-TF (EMT-inducing transcription factor). The parental cells secreted significant amounts of TGF-β1, canonical Wnts, and non-canonical Wnts. (A) However, the secreted Wnts were unable to activate autocrine signaling because these epithelial cells release significant amounts of the DKK1 and SFRP1 inhibitors of Wnt signaling (*green*). When cells moved from the epithelial to the mesenchymal state (*orange*, *red*), the levels of these two Wnt inhibitors decreased greatly. (B) TGF-β autocrine loops were similarly blocked in the parental epithelial cells by the secretion of an array of BMPs (bone morphogenetic proteins) that function to blunt TGF-β signaling. Entrance into the mesenchymal state resulted in strong decreases in the expression of the mRNAs encoding these TGF-β inhibitors. Ongoing autocrine signaling was required to

maintain expression of a variety of mesenchymal phenotypes, because their expression could be reduced in the mesenchymal cells through the addition of the SFRP1 and DKK1 recombinant proteins to the culture medium (*not shown*). (C) Entrance into the mesenchymal state can be triggered in mammary epithelial cells in culture by disrupting adherens junctions with an anti-E-cadherin antibody (which liberates β-catenin), the shutdown of SFRP1 mRNA function (through an shRNA), the addition of a DKK1-neutralizing antibody, the addition of large amounts of TGF-β1, and the addition of Wnt5a (a non-canonical Wnt) to the growth medium. Passage through an EMT and entrance into the mesenchymal state were gauged here by measuring levels of mRNAs encoding N-cadherin and two key EMT-TFs—Zeb1 and Zeb2. "+" denotes the addition of a component to this EMT-inducing cocktail, whereas absence of a component is indicated by a blank square in the *gray* matrix *below*. If the epithelial cells were exposed to this induction cocktail for more than a week, they would maintain their mesenchymal phenotype indefinitely in the absence of further such treatment (*not shown*). (D) These observations among others suggest that residence in the mesenchymal state is maintained following passage through an EMT by the actions of these three autocrine signaling loops (*right*). In the epithelial state (*left*), however, while cells secrete TGF-β and canonical Wnts, the ability of these factors to function in an autocrine manner is blocked by the concomitant secretion of inhibitors—BMPs, DKK1, and SFRP1. Hence, when cells undergo an EMT, they shut down production of BMPs and the Wnt inhibitors, thereby creating a permissive extracellular environment for the firing of EMT-inducing autocrine signaling loops. In addition, upon passing through an EMT, such cells express greatly elevated levels of non-canonical Wnt proteins, which also operate thereafter in an autocrine fashion. The residence of cells in the resulting mesenchymal state is maintained in a metastable fashion, because interrupting the three autocrine loops forces cells to revert to an epithelial state. It is not known whether similar dynamics apply to epithelial cells from other tissues. (E) The stromal cells in inflamed tissues and in many tumors release prostaglandin E_2 (PGE_2), which can induce an EMT in epithelial cells and thereby may complement or reinforce the stromal signals released by Wnts and TGF-β (see Panels D and F). In this non-small-cell lung carcinoma (NSCLC), the mutually exclusive expression of the E-cadherin epithelial marker (*red*) and COX-2, the enzyme that produces PGE_2 (*dark brown*), is apparent at high magnification. COX-2–positive carcinoma cells tended to be discohesive, i.e., in the process of separating from other carcinoma cells. Other work (*not shown*) indicates that expression of E-cadherin and the Zeb1 EMT-inducing transcription factor was mutually exclusive in these tumors. (F) A summary of the existing literature reveals numerous cross-connections that begin to explain why and how EMT programs are induced by combinations of heterotypic signals. This diagram presents a highly simplified view of the signaling channels that originate in the stroma and influence epithelial cancer cells

to undergo a partial or complete EMT. It is likely that an EMT program is usually triggered in response to a convergence of signals that carcinoma cells receive from the stroma together with intracellular signals, such as those released by a *ras* oncogene, as indicated here. The precise identities of these stromal signals and their combinatorial mechanisms of action remain to be elucidated. In the longer term, the interactions depicted in this diagram must be integrated with those indicated in panels A, B, and C, an undertaking that is impossible at present, given the dearth of available information. (A–C, from C. Scheel et al., *Cell* 145:926–940, 2011. With permission from Elsevier. E, from M. Dohadwala et al., *Cancer Res*. 66:5338–5345, 2006. With permission from American Association for Cancer Research.)

In addition, these experiments reinforced the notion that, although an EMT program can be triggered initially by paracrine signals originating in the nearby stroma, once an EMT program is kindled, it can be self-sustaining through autocrine signaling. By revealing the importance of combinations of EMT-inducing signals in triggering activation of this program, studies like this one also suggested the converse: that individual heterotypic signals are usually not capable on their own of triggering such activation. Moreover, biochemical studies of the intracellular signaling circuitry of mammalian cells (Figure 14.17F) suggest how these diverse signals collaborate with one another to induce and maintain expression of EMT programs.

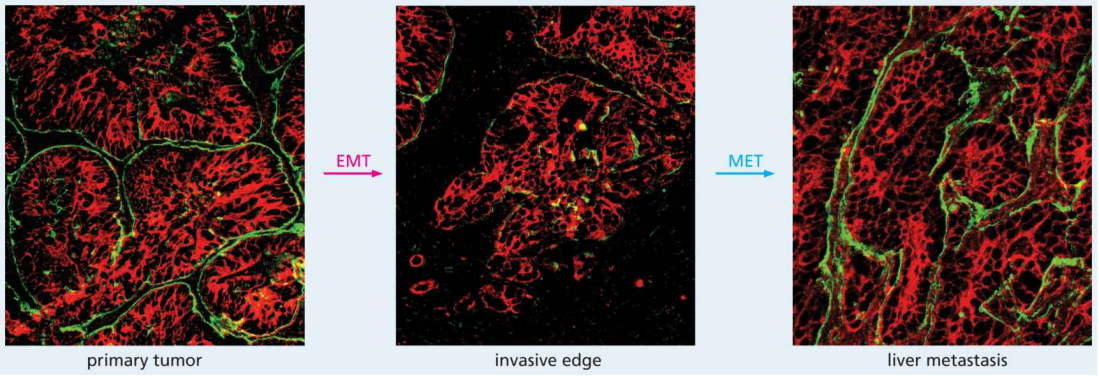
Compounding these normal processes are genetic and epigenetic alterations acquired by carcinoma cells during primary tumor formation that are likely to increase their *responsiveness* to these various contextual signals and thereby influence the way that EMT programs alter carcinoma cell phenotypes. For example, some experiments indicate that cancer cells that have lost p53 function are more responsive to various EMT-inducing signals, and that the *ras* oncogene activated in various human tumors triggers the production and release of TGF-β, which amplifies the TGF-β of stromal origin to facilitate induction of an EMT. Moreover, the extent of EMT expression exhibited by a variety of human tumor cell lines that are propagated as pure populations *in vitro* (in which heterotypic signals are absent) is echoed by the degree of expression of the same EMT programs when corresponding tumor types are growing in human cancer patients. Findings such as these suggest that each type of cancer cell tends to revert to its own characteristic "set point" in the absence of EMT-inducing heterotypic signals (**Supplementary Sidebar 14.4**).

The early research on TGF-β and the reversibility of the EMT (see Figure 14.13B and C) have found echoes in research on the histories of carcinoma cells as they advance down the road toward a highly malignant growth state. Thus, during the development of many carcinomas, once carcinoma cells leave the primary tumor, having completed the EMT-driven steps of invasion and dissemination, as described below, they often

revert back to a more epithelial phenotype by passing through the reverse process—the mesenchymal–epithelial transition (MET) mentioned in the last chapter (**Sidebar 14.1**).

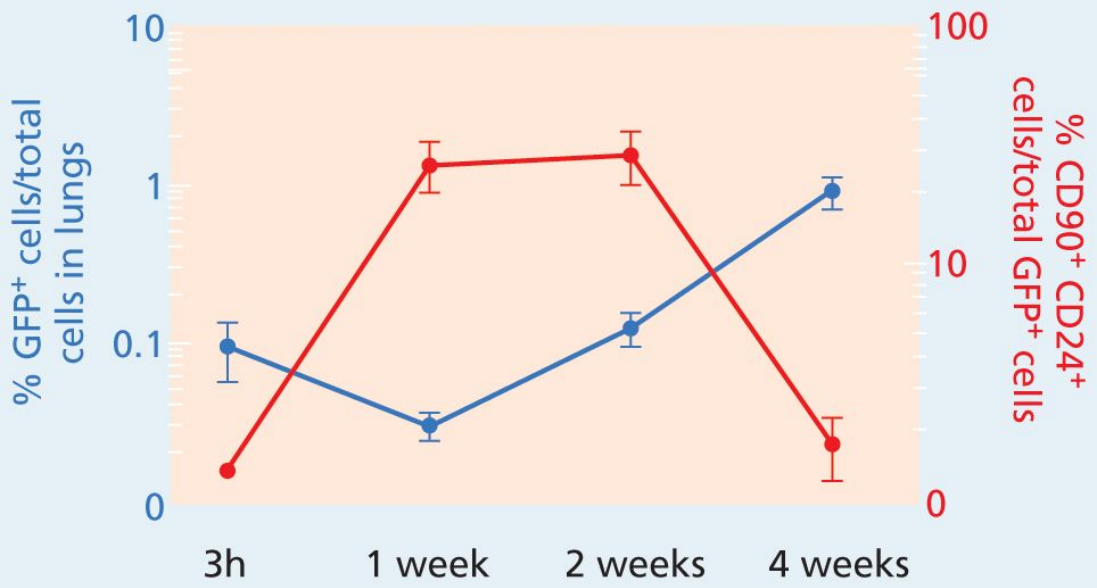
Sidebar 14.1 Reversal of the EMT at sites of metastasis

Although EMT programs may play a central role in enabling the dissemination of primary tumor cells to distant sites in the body, the reversal of these EMT programs that is often observed in subsequently arising metastatic carcinoma colonies may actually be essential to the robust outgrowth of these colonies (**Figure 14.18**). Multiple lines of experimental evidence support this notion. Thus, the histology of primary tumors often indicates a largely epithelial phenotype (Figure 14.18A), whereas the invasive edges of these tumors, which contain the presumed precursors of disseminated tumor cells, show loss of basement membrane, this structure normally serving as a key hallmark of residence in the epithelial state. However, the metastases that ultimately are formed provide clear indication of a basement membrane and a histology that closely resembles that of the primary tumor, indicating a reversion from a more mesenchymal to a more epithelial state. Similarly, in a mouse transgenic model of mammary carcinoma development, experimentally seeded, metastatic carcinoma cells initially show a low representation of cell surface markers indicative of the mesenchymal state. However, the representation of these more mesenchymal cells soon increases more than tenfold as the metastases grow out, but weeks later, as the metastatic colonies expand, the mesenchymal cells once again become a small minority of the cells in these metastases (Figure 14.18B).



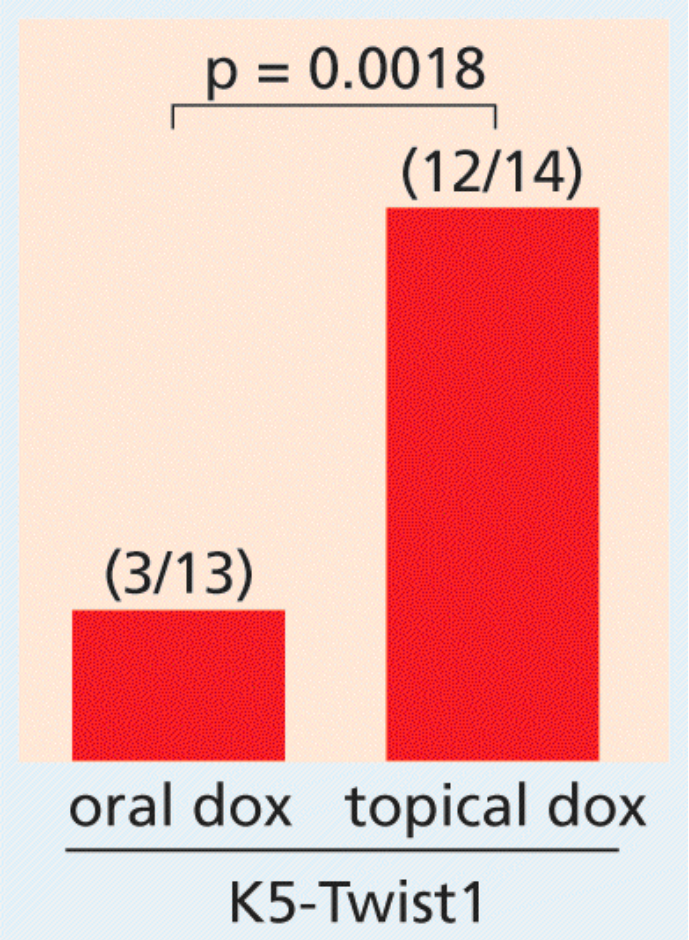
Three fluorescence microscopy images. In the first one, labeled primary tumor, spongy masses of red tissue are separated from one another by enclosing capsules of green tissue. In the second one, labeled invasive edge, cells that have undergone E M T make up a spongy mass of red tissue that appears to have burst into fragments. There are only traces left of an enclosing capsule of green tissue. In the third image, labeled liver metastasis, cells that

have undergone M E T appear much like those in the first image, with spongy masses of red tissue separated from one another by enclosing capsules of green tissue.
(A)



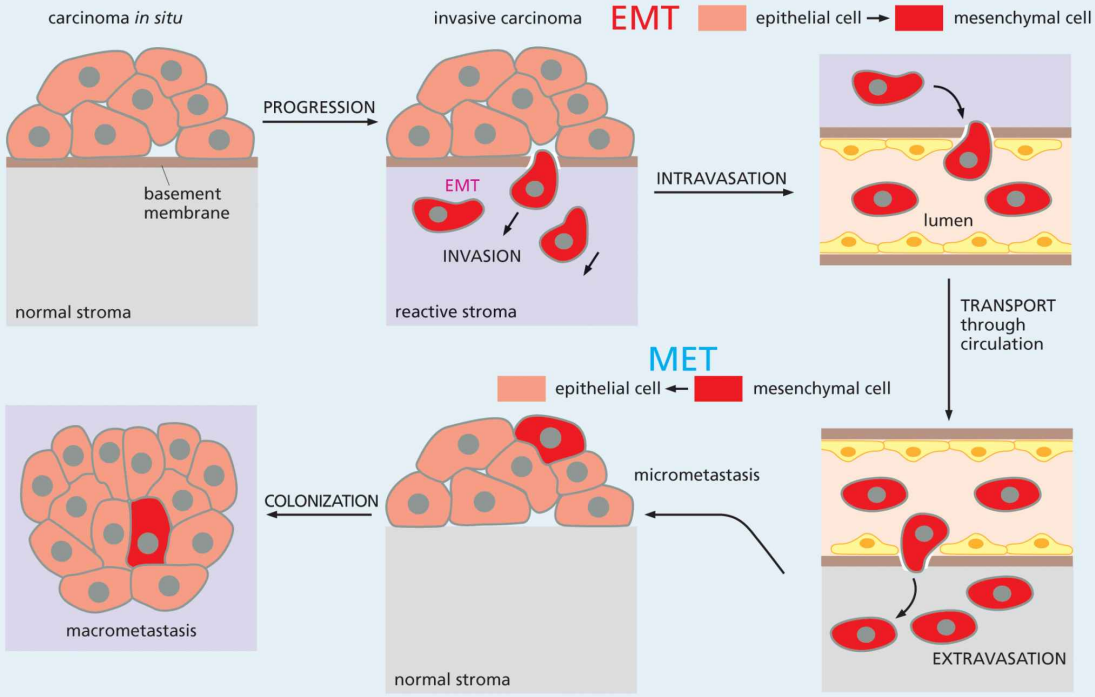
A line graph with time on the horizontal axis, from 3 hours to 4 weeks, and two quantities on the vertical axis. A blue line shows that the count of G F P positive cells, as a percent of the total cells in the lungs, starts at 0.1, initially falls, then rises to 1 by 4 weeks. A red line shows that the count of C D90 positive, C D24 positive cells, as a percent of G F P positive cells, starts out low, rises as high as 1, and then falls again.

(B)



A bar graph showing that 12 of 14 K 5-Twist 1 mice treated with topical doxycycline developed tumors, while only 3 of 13 K 5 -Twist 1 mice treated with oral doxycycline developed tumors. The significance level of this difference was p = 0.0018.

(C)



A model of E M T followed by M E T. Initially, an intact basement membrane separates a carcinoma in situ above, consisting of epithelial cells, from normal stroma below. Following progression, cells undergoing epithelial-mesenchymal transition breach the basement membrane and invade the stroma, which becomes reactive. Through intravasation, these cells pass through the walls of blood vessels and enter the blood stream. After transport to a new location through circulation, the mesenchymal cells undergo extravasation back into normal stroma, where through micrometastasis they form a new tumor. At this point most but not all of the cells revert to the epithelial state. The tumor now grows into a macrometastatis.

(D)

Figure 14.18 Reversibility of EMT Although cells at the invasive edge of a primary carcinoma often give evidence of an EMT, derived metastases may exhibit a histology typical of the center of the primary tumor, suggesting a reversion programmed by a mesenchymal–epithelial transition (MET) program. (A) Release of degradative enzymes, notably matrix metalloproteinases (MMPs), is one of the many manifestations of the EMT. These cells in a primary colorectal carcinoma show expression of both cytokeratin 18 (*red*) and a basement membrane protein (*green*). However, at the invasive edge of this tumor, the cells have undergone a partial EMT, in that they have degraded the adjacent basement membranes while still expressing cytokeratin 18, a key epithelial marker. In a subsequently arising metastasis in this patient, which presumably descended from

cells that underwent an EMT and acquired invasiveness en route to metastatic dissemination, the cancer cells form a growth having, once again, the histological appearance of cells in the heart of the primary tumor, suggesting reversibility of the EMT. (B) These dynamics are supported by studies of disseminated cancer cells. Green fluorescent protein (GFP)-expressing cancer cells were prepared from mammary tumors of MMTV-PyMT transgenic mice in which the MMTV promoter drives expression of the polyoma middle T (PyMT) oncogene (established as a transgene in the mouse germline); these mice develop spontaneously metastasizing mammary carcinomas at a high rate. These cell populations were injected into the tail veins of tumor-free host mice and the proportion of GFP^+ cells relative to total cells in the lungs (*blue curve*) was followed over the indicated time intervals (*red curve*). Initially, ~0.1% of all cells in the lungs were GFP^+ carcinoma cells, which declined to ~0.03% a week later and later increased progressively as metastatic colonization and the growth of metastases proceeded. In contrast, the percentage of GFP^+ tumor cells exhibiting a $CD90^+$ $CD24^+$ marker phenotype (representing carcinoma cells with a mesenchymal phenotype; *red curve*) was initially ~1.5%, reflecting the makeup of cells in the primary tumors from which these cells were prepared. This percentage increased almost 20-fold in the first week to over 20%; however, as the individual metastases expanded in size, this percentage decreased back to ~1.8%, almost precisely the level in the initially inoculated cells. Hence, mesenchymal-like carcinoma cells are favored initially to found and establish metastatic colonies, but as colonization proceeds, the representation of mesenchymal/stem-like cells decreases to that seen in the primary tumor. (C) The inducible expression of the Twist1 EMT-TF was used to gauge its effects on metastatic colonization. As indicated, when this EMT-TF was shut down after dissemination (*right bar*), 12 of 14 mice developed metastases, whereas if this EMT-TF continued to be expressed following metastatic dissemination (*left bar*), a far smaller proportion of the mice developed metastatic colonies. This result indicated that the continued high-level expression of this EMT-TF, and thus tumor cell residence in a more mesenchymal state, was counterproductive for metastatic colonization. (D) These observations can be explained by a model in which epithelial cancer cells at the edge of a primary carcinoma (*pink/brown cells*) undergo an EMT as they invade the stroma and become more mesenchymal (*red cells*). This change seems to be triggered by signals that these carcinoma cells receive from the nearby tumor-associated reactive stroma (see Figure 14.17), which is composed of a variety of inflammatory cells that accumulate during the long course of primary tumor formation. The newly acquired mesenchymal state enables the carcinoma cells to invade locally and intravasate, and subsequently to extravasate into the parenchyma of a distant, ostensibly normal tissue. Following extravasation, however, these cancer cells find themselves in a fully normal stroma that lacks the inflammatory cells and therefore does not release EMT-inducing signals. This

allows these cells and their descendants to lapse back to an epithelial phenotype (*pink/brown cells*) via a mesenchymal–epithelial transition (MET). (The regeneration of a basement membrane, which occurs as one consequence of an MET, is not illustrated here.) (A, courtesy of T. Brabletz. B, from I. Malanchi et al., *Nature* 481:85–89, 2012. With permission from Nature. C, from J.H. Tsai, J.L. Donaher, D.A. Murphy et al., *Cancer Cell* 22:725–736, 2012. With permission from Elsevier. D, adapted from J.P. Thiery, *Nat. Rev. Cancer* 2:442–454, 2002. With permission from Nature.)

The above experiments indicate a strong *correlation* between robust outgrowth of metastatic colonies and residence in an epithelial state. Even more compelling are experiments that demonstrate *causality*, specifically that the continued residence in a more mesenchymal phenotypic state is counterproductive for the formation of robustly growing metastatic colonies (Figure 14.18C). All this can be reconciled with a scheme (Figure 14.18D) in which the EMT program participates in the physical dissemination of carcinoma cells from primary tumors, but its continued expression in the majority of cells within derived metastatic colonies actually hinders the robust outgrowth of metastatic colonies, necessitating a reversal of the EMT program, that is, a mesenchymal–epithelial transition (MET) occurring during the process of metastatic colonization.

The reasons why such METs are needed for optimal metastatic colonization and the eruption of macroscopic metastases remain unclear. In fact, cells that have entered into a more mesenchymal state because of the actions of an EMT program proliferate less rapidly than their epithelial counterparts, but this difference is relatively minor and cannot explain the METs observed in recently seeded metastases. More plausible, however, is a mechanism in which the epithelial subpopulations of carcinoma cells within a metastatic colony actively contribute to the robust outgrowth of the colony as a whole, doing so as part of a hierarchy of cells of the sort depicted in Figure 11.20B.

After leaving the primary tumor and entering into the vasculature, additional EMT-inducing signals may be released by the platelets that adsorb to tumor cells in the lumina of vessels (**Supplementary Sidebar 14.5**), reinforcing the previously acquired quasi-mesenchymal state of these cells that drove their intravasation. However, following extravasation of carcinoma cells at sites of metastatic dissemination, the initially encountered stroma is likely to be fully normal and therefore not capable of releasing signals that previously enabled the “reactive stroma” of the primary tumor to actively promote and sustain an EMT program; in the absence of these EMT-promoting signals, recently arrived cells may revert via an MET to the more-epithelial state of their ancestors in the heart of the primary tumor. Later on, if the initially formed micrometastases succeed in colonizing a distant tissue (thereby forming an

actively growing macroscopic tumor), a reactive stroma may eventually be recruited to the resulting metastatic tumor colony, echoing the changes that occurred previously in the primary tumor and inducing, once again, an EMT in the carcinoma cells forming this colony.

Also, as our discussions of the EMT progress, on occasion they will embrace a subtle change in wording: rather than describing a single unitary EMT program, they will refer to EMT *programs* that share a number of core elements but differ from one another in certain details. The existence of multiple alternative EMT programs is dictated by the diverse factors that shape these programs, including the identities of the somatically mutated alleles borne by cancer cells, the differentiation programs of the normal cells-of-origin that spawned various types of neoplastic cells, the nature of the stromal cells that are releasing EMT-inducing heterotypic signals, and the varying extents to which cells have advanced through these programs (see Figure 14.12).

Finally, the phenomena described in this section, when taken together, hold major implications for our thinking about cancer cell biology. Thus, the realization that EMT programs are induced by contextual signals released by other cells indicates that the expression of these programs does not derive directly from mutant alleles carried in the genomes of cancer cells. Hence, the EMT program is an example of an epigenetic rather than a genetically encoded process. In addition, the fact that EMT programs are multifaceted and affect a wide range of cell-biological phenotypes (see Table 14.2), suggests that a significant proportion, possibly the majority, of the distinctive phenotypes of aggressive carcinoma cells are not traceable directly back to somatically mutated alleles of genes (such as the oncogenes and tumor suppressor genes described in earlier chapters) but instead are manifestations of this multifaceted cellular program. This realization moves our thinking away from the notion that cancer cell biology can be understood as a cell-autonomous process, in which study of the genome borne by a neoplastic cell—in its wild-type or mutant configuration—can be used, on its own, to predict the biological phenotypes of this cell (as was implied in Figure 11.12).

OceanofPDF.com

Glossary

metastable
: State of a cell or process that appears over a period of time to be stable and unchanging but can in fact be changed by various signals or perturbants.

reactive stroma
: The stroma of a highly progressed tumor that has recruited a number of cell types that are typically associated with inflammation and wound healing, including prominently activated fibroblasts and myofibroblasts. *See also* **stroma**.

set point
: A state to which a complex regulatory system naturally reverts in the absence of strong external perturbants; set points are often maintained through homeostatic regulatory mechanisms. *See* **homeostasis.**

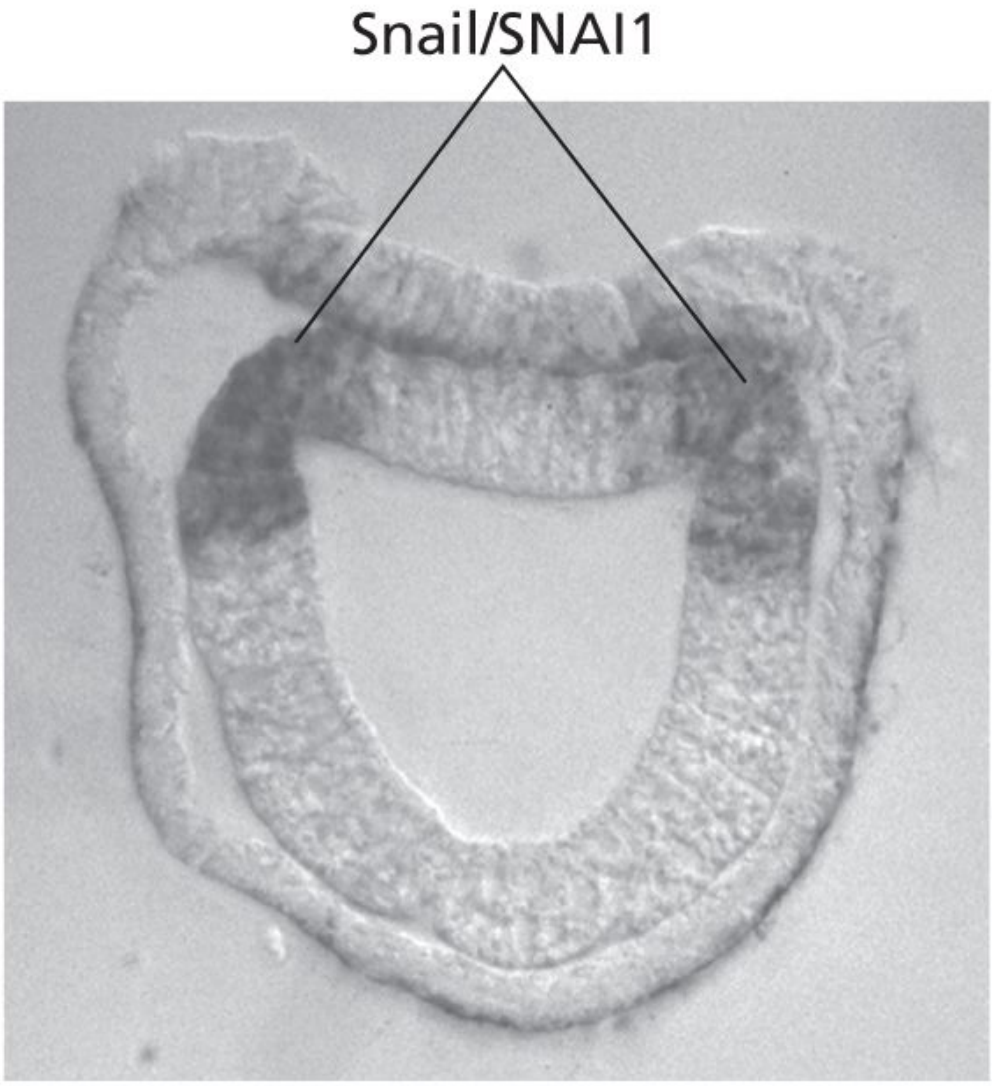
14.4 EMTs are programmed by transcription factors that orchestrate key steps of embryogenesis

Execution of an EMT program depends on coordinated changes in the expression of hundreds of distinct genes as well as complex mechanisms of post-transcriptional regulatory controls. These changes affect many aspects of cell biology, not all of which have been enumerated here. The changes include the organization of a cell's intermediate filament cytoskeleton, its motility, its sensitivity to apoptosis, its association with neighboring cells, its release of proteases, and even its display of cell surface integrins and growth factor receptors (see Table 14.2). While extensive evidence, some of it detailed above, implicates stromal signals as key elements in triggering the EMT of carcinoma cells, none of this evidence, on its own, reveals precisely how the complex EMT program is actually coordinated and executed *within* the responding epithelial cells.

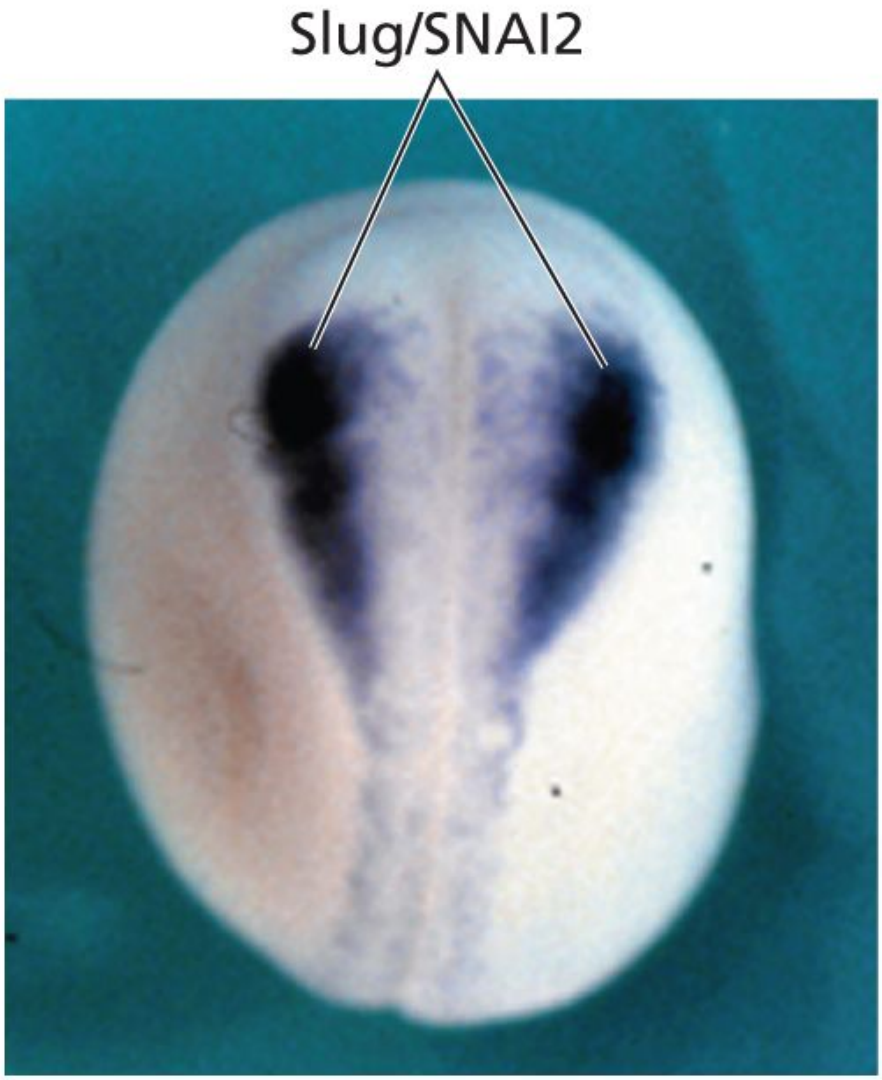
The genetics of the early development of a variety of model organisms has provided many of the answers to this question. Like many complex cell-biological programs, EMTs are orchestrated by a small number of pleiotropically acting transcription factors (TFs). A number of genes specifying these EMT-inducing TFs (EMT-TFs) have been identified (**Figure 14.19**), many initially uncovered in the embryos of the fruit fly, *Drosophila melanogaster*. These genes and the TFs that they encode are conserved in all chordates and in most metazoa and have been found to control key steps in early embryogenesis in various metazoan embryos; these steps involve various versions of the EMT program. (The strong evolutionary conservation of these EMT-TFs indicates that the EMT and key steps of early embryogenesis were developed early in metazoan evolution, long before the radiation of the various metazoan phyla which seems to have occurred before the Cambrian era 550 million years ago.) By activating expression of these TFs, cancer cells gain access to the complex, multifaceted EMT programs that they orchestrate. Implicit in what follows is the following scheme: heterotypic signals from the stroma induce expression of EMT-TFs in carcinoma cells; these TFs, in turn, orchestrate EMT programs within these cells.



Amphioxus

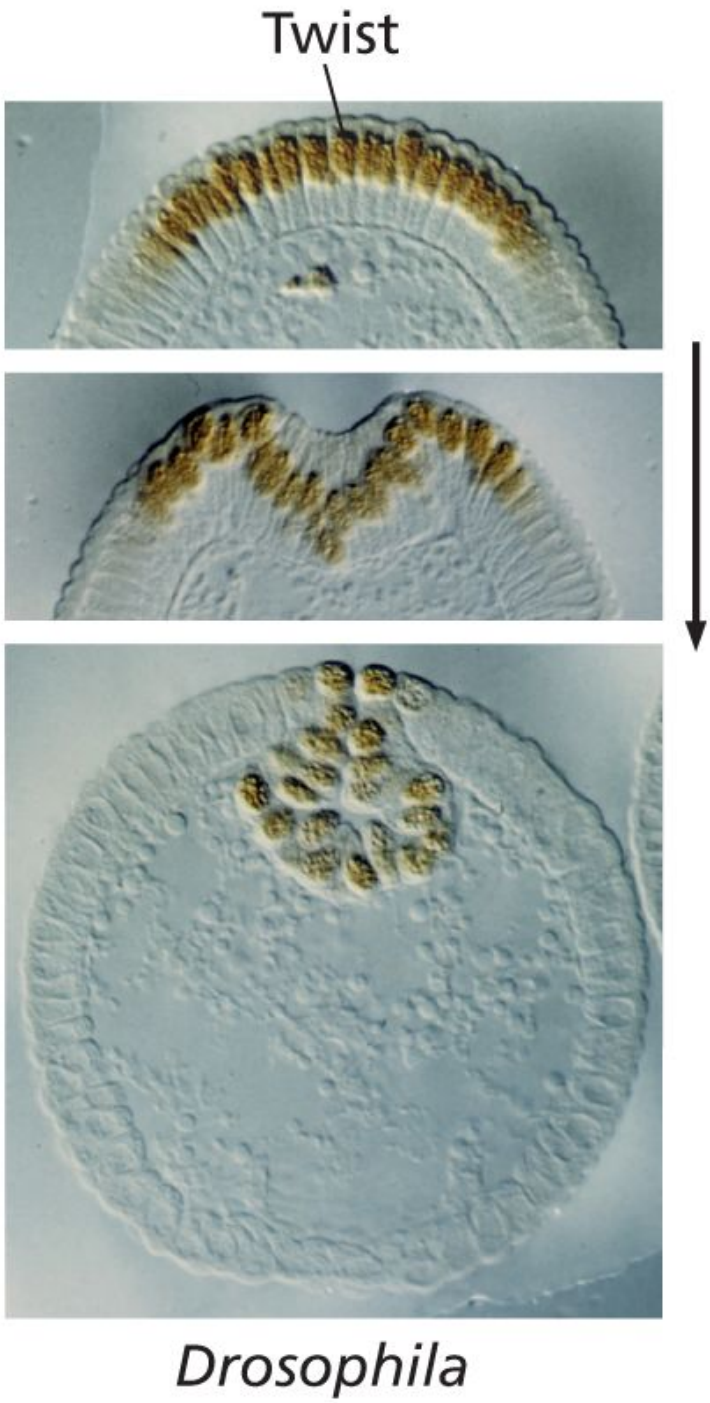
Snail slash S N A I 1 is shown being expressed as two dark spots in an embryo of Amphioxus, a marine species resembling a miniature lamprey.

(A)



Slug slash S N A I 2 is shown being expressed as two dark spots in an embryo of Xenopus laevis, the African clawed frog.

(B)

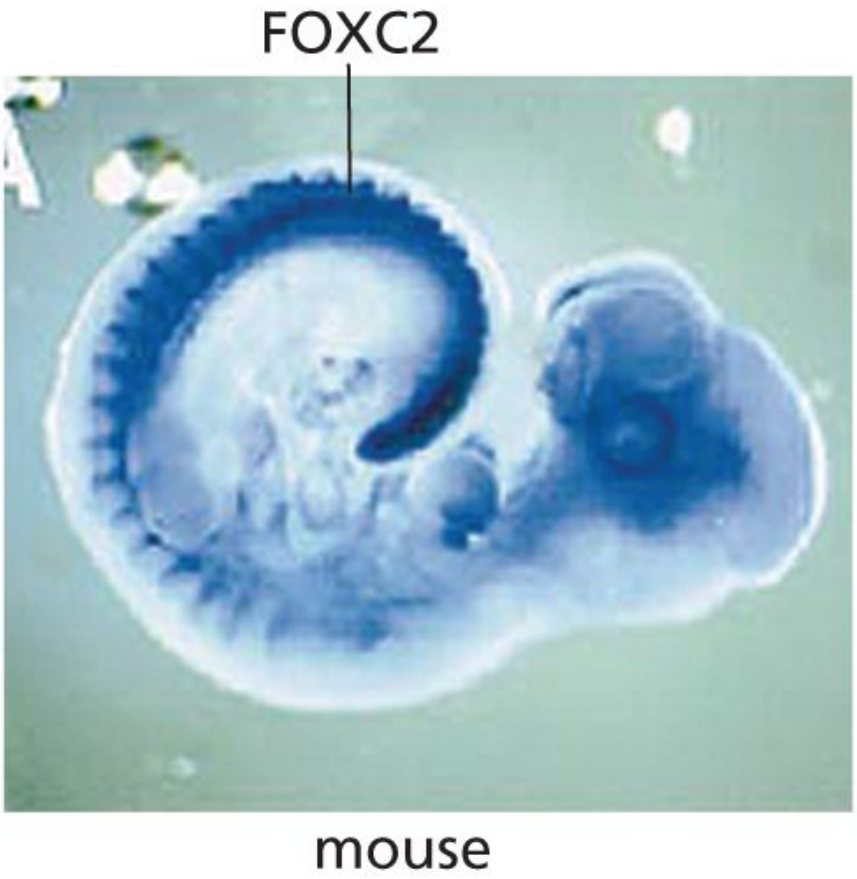


Twist is shown being expressed in a gastrulating blastula of Drosophila, the fruit fly. A patch of cells along the surface forms an indentation and then reshapes into a cluster of cells that extend into the embryo’s interior.

(C)

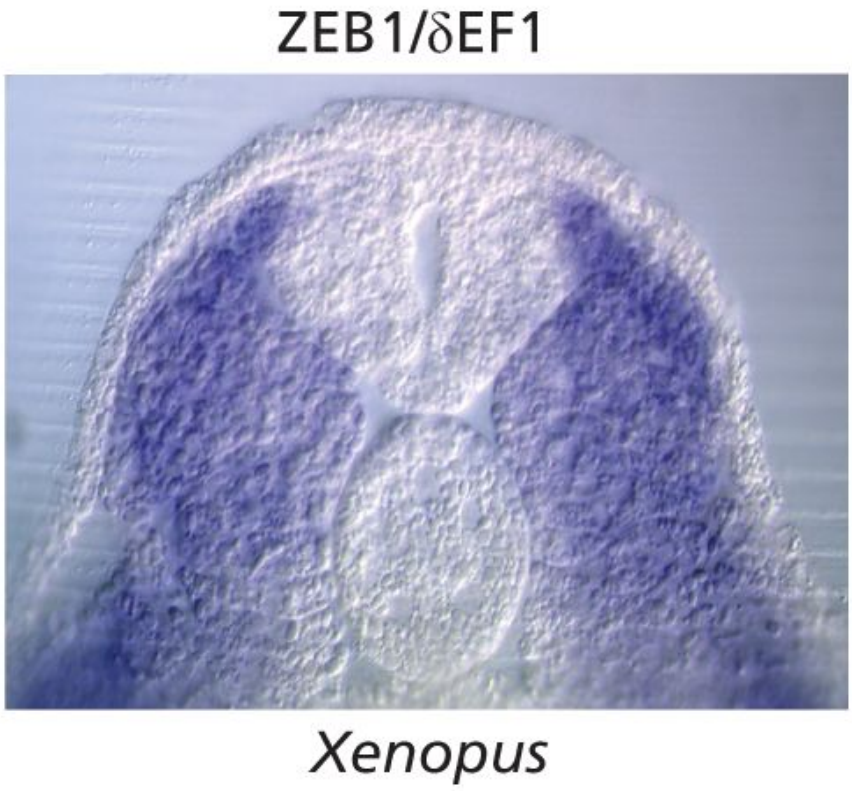
Goosecoid is shown being expressed as a dark spot in a gastrulating Amphioxus blastula.

(D)



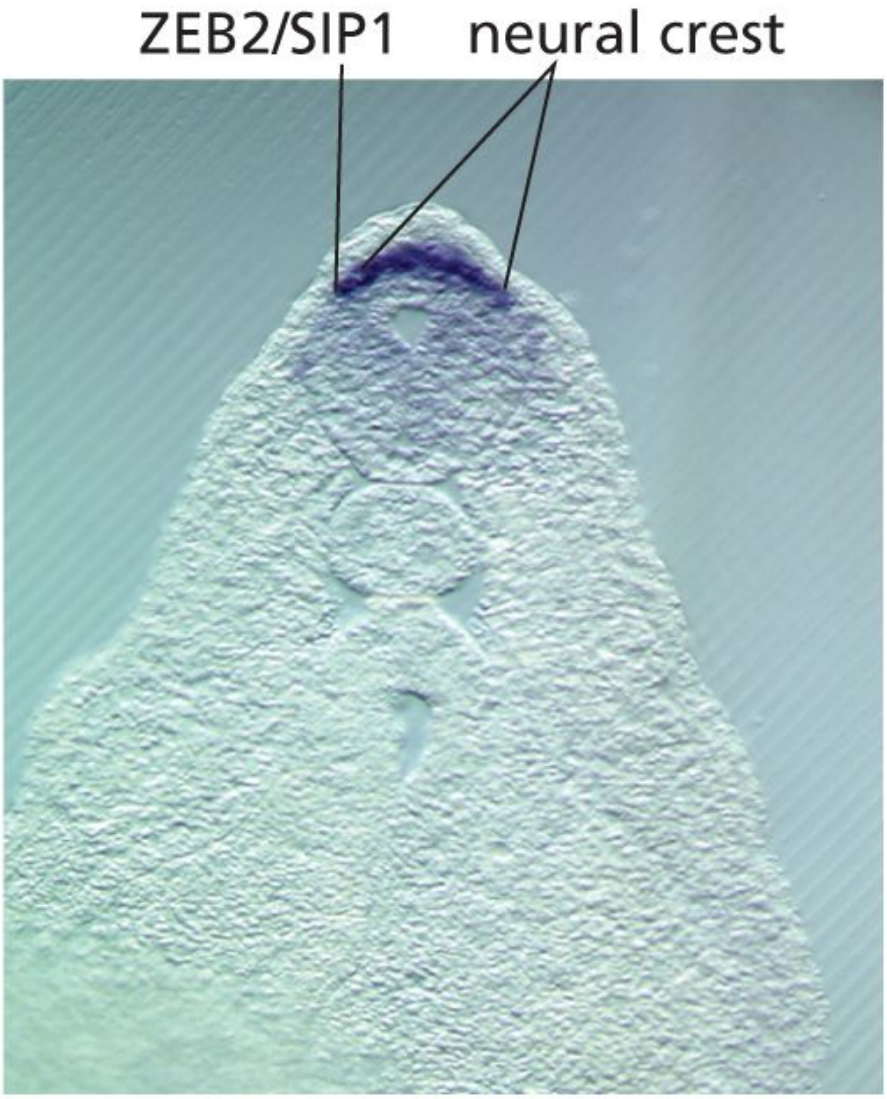
FOX C 2 is shown being expressed as the long, curved bottom part of the developing spine in a mouse embryo.

(E)



Z E B1 slash delta E F 1 is shown being expressed in a Xenopus embryo as two dark areas on either side of the developing spine.

(F)

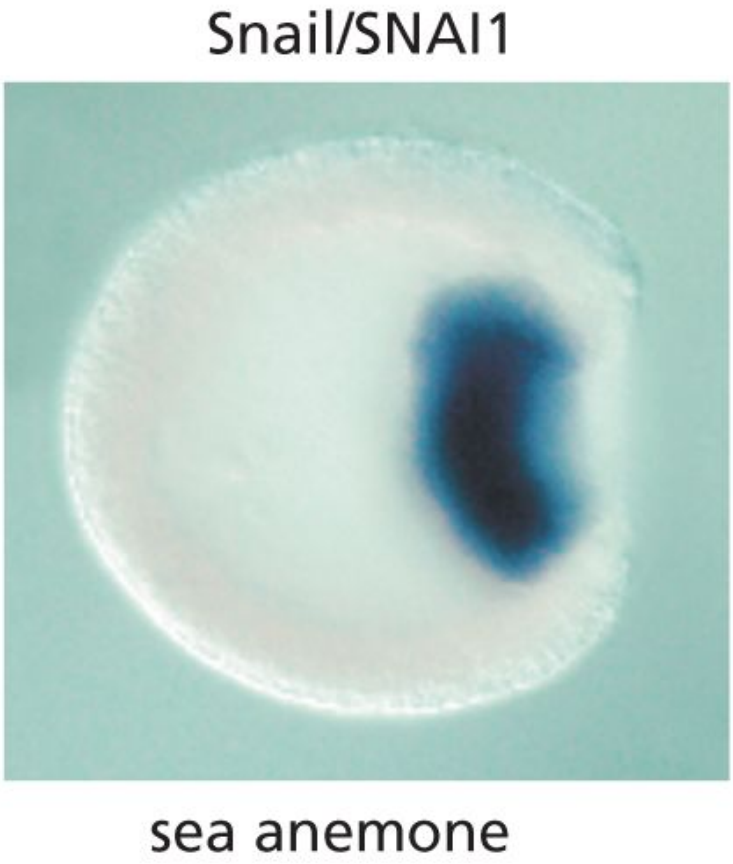


Z E B 2 slash S I P 1 is shown being expressed in a Xenopus embryo as a dark, curved neural crest.

(G)

P r r x1 is shown being expressed in a zebrafish embryo as dark spots along the edges.

(H)



Snail slash S N A I 1 is shown being expressed as a dark spot in a sea anemone blastula.

(I)

Figure 14.19 Embryonic transcription factors programming epithelial–mesenchymal transitions A variety of EMT-inducing transcription factors (EMT-TFs) can induce this program in various stages of embryogenesis, and their expression has been documented in a wide range of organisms. (A) Snail (also known as SNAI1) is shown being expressed in cells of a primitive chordate, specifically in cells (*dark areas*) whose counterparts in higher chordates form the neural crest. (B) The Slug TF (SNAI2), a close relative of Snail, is expressed in *Amphioxus* (*dark blue*) in the embryonic neural crest, here in an embryo of *Xenopus laevis*, the African clawed toad. (C) Twist is shown here in an early *Drosophila* embryo, in which it programs an EMT at the site of gastrulation (*brown*). (D) The Goosecoid TF is expressed at the blastopore lip in gastrulating chordate embryos. Here its expression, which is inducible by the TGF-β signaling pathway, is adjacent to the blastopore 8 hours after fertilization of an *Amphioxus* egg. (E) The FOXC2 TF is expressed in important mesodermal structures in this day 9.5 mouse embryo, including the mesoderm around the developing spinal

column as well as in somites, which are precursors to many of the body's muscles. (F) The ZEB1 (δEF1) TF is expressed in the paraxial mesoderm of an early *Xenopus* embryo, where it may play a role in programming the toad's development from axial stem cells. (G) In the same embryo at this stage, expression of the related ZEB2 (SIP1) TF occurs in a complementary pattern, being highest in the neural crest and neural tube, where it appears to be responsible for the cell movements that lead to closure of the neural tube and emigration of cells from the neural crest to other parts of the body. (H) Expression of the PRXX1 EMT-TF at the 22-somite stage of a zebrafish embryo. (I) The antiquity of these TFs is illustrated by the expression of Snail in the blastula stage of the starlet sea anemone embryo, *Nematostella vectensis.* Its ancestors diverged from those of the chordates >600 million years ago, before the evolution of bilateral animals with three cell layers. It contrasts with *Amphioxus*—clearly a chordate with many features of vertebrate ancestors—which diverged ∼525 million years ago from our own lineage. (A, from J. Langeland et al., *Dev. Genes Evol*. 208:569-577, 1998. With permission from Springer. B, from C. LaBonne et al., J. *Neurobiol*. 36:175-189, 1999. With permission from John Wiley & Sons. C, courtesy of M. Leptin. D, from A.H. Neidert, G. Panopoulou and J.A. Langeland, *Evol. Dev*. 2:303–310, 2000. With permission from John Wiley & Sons. E, from T. Furumoto et al., *Dev. Biol*. 210:15–29, 1999. With permission from Elsevier. F, from L.A. van Grunsven et al., *Dev. Dyn*. 235:1491–1500, 2006. With permission from John Wiley & Sons. G, courtesy of E.J. Bellefroid. H, from O.H. Ocaña, R. Corcoles, A. Fabra I et al., *Cancer Cell* 22:709–724, 2012. With permission from Elsevier. I, from M.Q. Martindale, K. Pang and J.R. Finnerty, *Development* 131:2463–2474, 2004. With permission from The Company of Biologists.)

More than half a dozen EMT-TFs have been described, each capable of inducing an EMT when ectopically expressed in certain epithelial cells (**Table 14.4**). For example, Snail is an EMT-TF that was first described in *Drosophila* and has since been discovered in a wide range of metazoa, including vertebrates, insects, worms, and molluscs. In early vertebrate embryos, Snail is first expressed in the portion of the ectoderm that is destined to become mesoderm following gastrulation. During embryogenesis, Snail, working together with two other EMT-TFs—Slug, and Twist—convert epithelial cells into the migratory mesenchymal cells that form the mesoderm. Snail and its relative Slug are involved in yet other embryonic steps in which one type of tissue is transformed into another. The truly ancient origins of these TFs are illustrated dramatically by Figure 14.19I, in which the embryo of a very primitive organism—a sea anemone, which lacks bilateral symmetry and three germ layers—expresses the Snail EMT-TF at the site of its future embryonic blastopore.

Table 14.4 Transcription factors orchestrating an EMT

Name	Where first identified	Type of transcription factor	Cancer association
Snail (SNAI1)	mesoderm induction in *Drosophila*; neural crest migration in vertebrates	C2H2-type zinc finger	invasive ductal carcinoma
Slug (SNAI2)	delamination of the neural crest and early mesoderm in chicken	C2H2-type zinc finger	breast cancer cell lines, melanoma
Twist	mesoderm induction in *Drosophila*; emigration from neural crest	bHLH	various carcinomas, high-grade melanoma, neuroblastoma
Goosecoid	gastrulation in frog	paired homeodomain	various carcinomas
FOXC2	mesenchyme formation	winged helix/forkhead	basal-like breast cancer
ZEB1 (δEF1)	postgastrulation mesodermal tissue formation	2-handed zinc finger/homeodomain	wide variety of cancers
ZEB2 (SIP1)	neurogenesis	2-handed zinc finger/homeodomain	ovarian, breast, liver carcinomas
E12/E47 (Tcf3)[a]	associated with E-cadherin promoter	bHLH	gastric cancer

Name	Where first identified	Type of transcription factor	Cancer association
Prrx 1	chick mesoderm formation	paired homeobox	various carcinomas

Some of these TFs are expressed transiently in adult tissues during the tissue remodeling that underlies wound healing. This is illustrated nicely by the behavior of confluent monolayers of normal epithelial cells in culture that are wounded experimentally by scraping away a swath of these cells as was seen in Figure 14.15. Slug expression is induced in the surviving epithelial cells sitting at the edge of the wound, which appeared to enable these cells to acquire motility and migrate into the wound site. This pattern of expression helps to explain how epithelial cells at the edges of wounds undergo a transient EMT in order to reassemble epithelial cell sheets (see also Figure 13.15A). Observations like these broaden our perspective on the normal biological roles of these EMT-TFs: in addition to programming key steps in early embryogenesis, the expression of some of these TFs is resurrected transiently in adults in order to help reconstruct damaged epithelial tissues.

Snail and Slug (sometimes called SNAI1 and SNAI2) are members of the C2H2-type family. These two TFs seem to operate largely as repressors of transcription. Thus, both have been found to be able to repress transcription of the gene encoding E-cadherin, which serves as the keystone of the epithelial cell state. (As we read earlier, the loss of E-cadherin expression can, on its own, cause epithelial cells to assume many of the phenotypic changes associated with an EMT.)

The Snail TF has been found to be expressed in the invasive fronts of chemically induced mouse skin carcinomas, and its expression is associated with the degree of lymph node metastasis of human breast cancers. Moreover, embryonic expression of Snail, its cousin Slug, and Goosecoid is induced by contextual signals, such as TGF-β and Wnts, that are known to be responsible for inducing the EMT conversion of mouse tumor cells. Twist is expressed during the gastrulation of *Drosophila* embryos (see Figure 14.19C) and the out-migration of neuroepithelial cells from the neural crest of chordate embryos. Its expression is also induced by exposure to TGF-β.

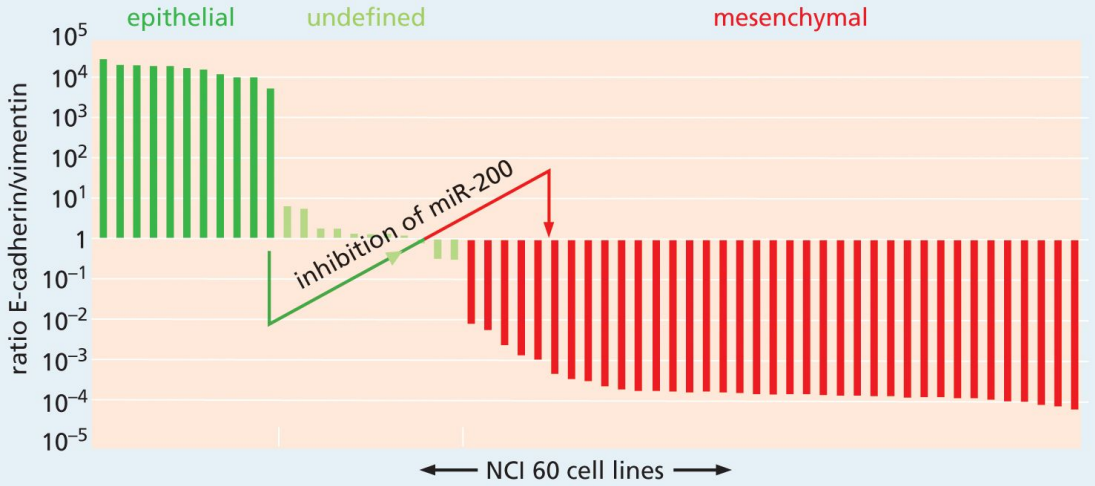
Although the micrographs of Figure 14.19 give the impression that these and other EMT-TFs are involved largely in early embryonic morphogenetic steps, in fact they continue to play roles throughout the entire process of embryonic development and postnatal tissue homeostasis (see **Supplementary Sidebar 14.1**). The multiplicity of these TFs, along with their expression in various combinations in human cancers,

helps to further explain the nomenclature cited earlier, namely that the term “EMT” actually refers to a group of cell-biological programs rather than a single, uniformly expressed program.

Some of the EMT-TFs participate in unusually interesting modes of regulation. For example, the EMT was portrayed as generating a succession of phenotypic states arrayed along a spectrum between highly epithelial and highly mesenchymal (see Figure 14.12). This was cited as an example of how and why the EMT does not operate as a simple binary switch that shuttles cells between two alternative phenotypic states, that is, one fully epithelial, the other fully mesenchymal. Nevertheless, certain binary controls appear to contribute to the regulation of EMT expression. One was seen in the behavior of *ras*-transformed cells that have been triggered by TGF-β exposure to enter into a more mesenchymal, EMT-induced state (see Figure 14.13); the resulting cell state causes them to produce their own, endogenously synthesized TGF-β, which operates, in turn, in an autocrine manner, driving a self-sustaining positive-feedback (sometimes termed “feed-forward”) signaling loop. Such controls can yield phenotypic states that are stably maintained and expressed over many cell generations and operate in a binary fashion, that is, either they are or are not activated. Another manifestation of binary controls operates in the case of the Zeb1 and Zeb2 EMT-TFs, which are important, if not dominant EMT-TFs in imposing a more mesenchymal state on cancer cells (**Sidebar 14.2**). Somehow, these binary switching mechanisms must be integrated into the well-documented notion that EMT programs produce a spectrum of phenotypic states (rather than just two) arrayed along the E to M axis.

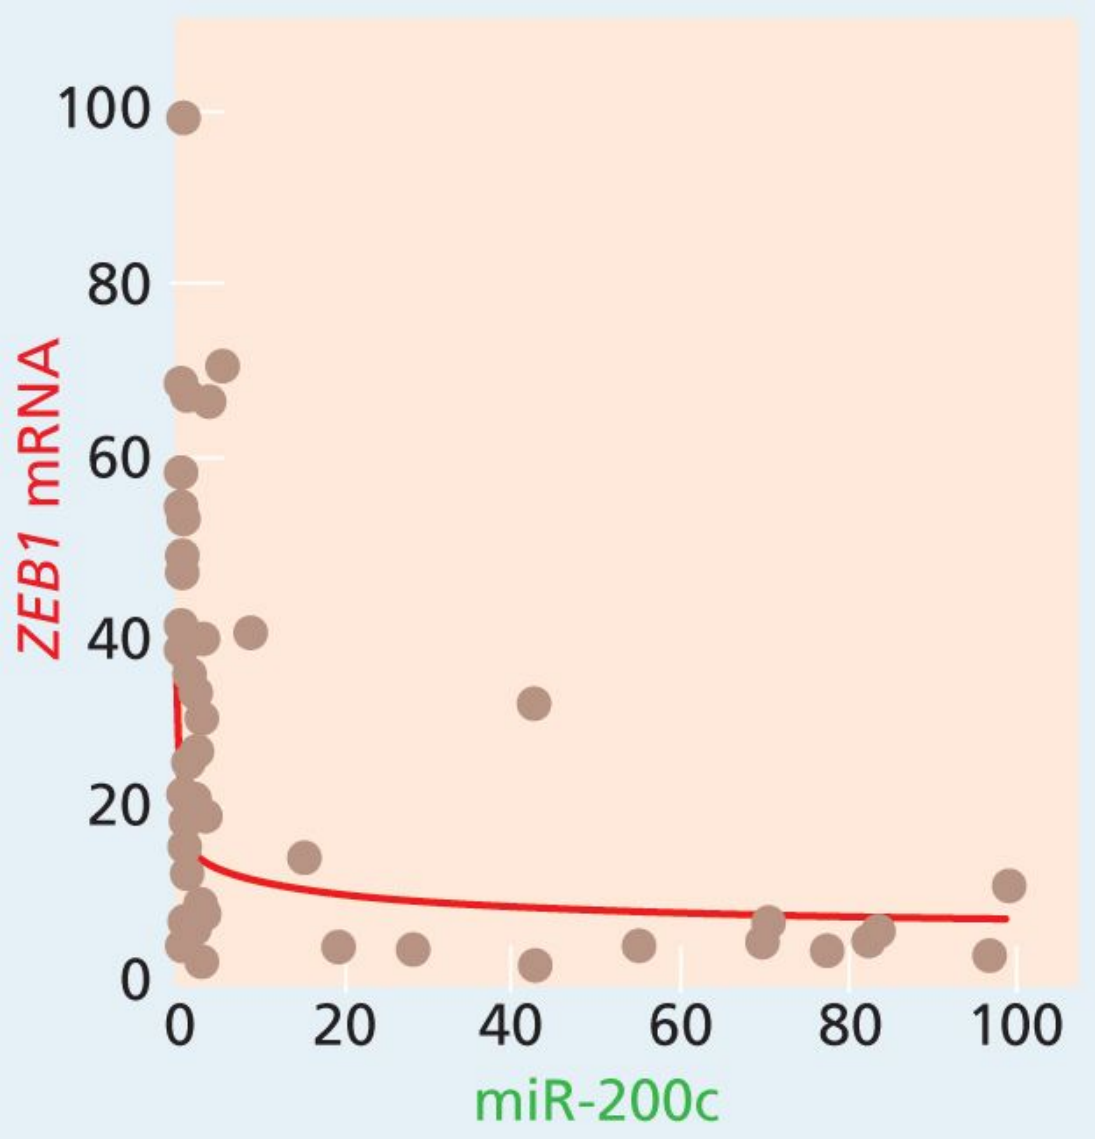
Sidebar 14.2 Binary switches may operate in cells that sit in a diverse set of phenotypic states

A major unresolved puzzle comes from the observation that carcinoma cells seem to reside in a number of distinct alternative phenotypic states arrayed continuously across the epithelial-to-mesenchymal spectrum of phenotypes while, at the same time, some of the controls regulating their phenotypic states operate as binary switches, shunting cells into either an epithelial or a mesenchymal state but not intermediate states (**Figure 14.20**). Related to this quandary is the unresolved question of how precisely the phenotypic states of carcinoma cells are stabilized at various stopping points along the E-to-M spectrum rather than being subjected to continual interconversions between these states.



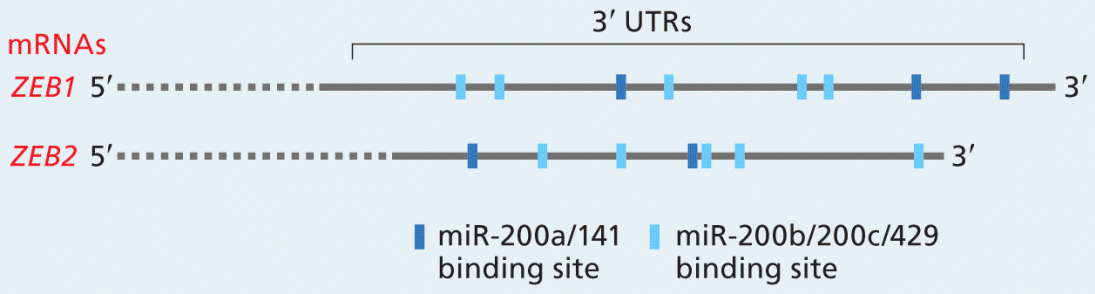
A graphic depicting the ratio of E-cadherin to vimentin in each of the N C I 60 cell lines. The first 11 lines are clearly epithelial, with more than 1000 times as much E-cadherin as vimentin. The next 11 lines are undefined, with E-cadherin to vimentin ratios between 10 and 0.1. The remaining lines are mesenchymal, all with more than 100 times as much vimentin as E-cadherin, and in a few cases 10,000 time as much. One epithelial line is shown undergoing conversion to mesenchymal through inhibition of m i R-200.

(A)



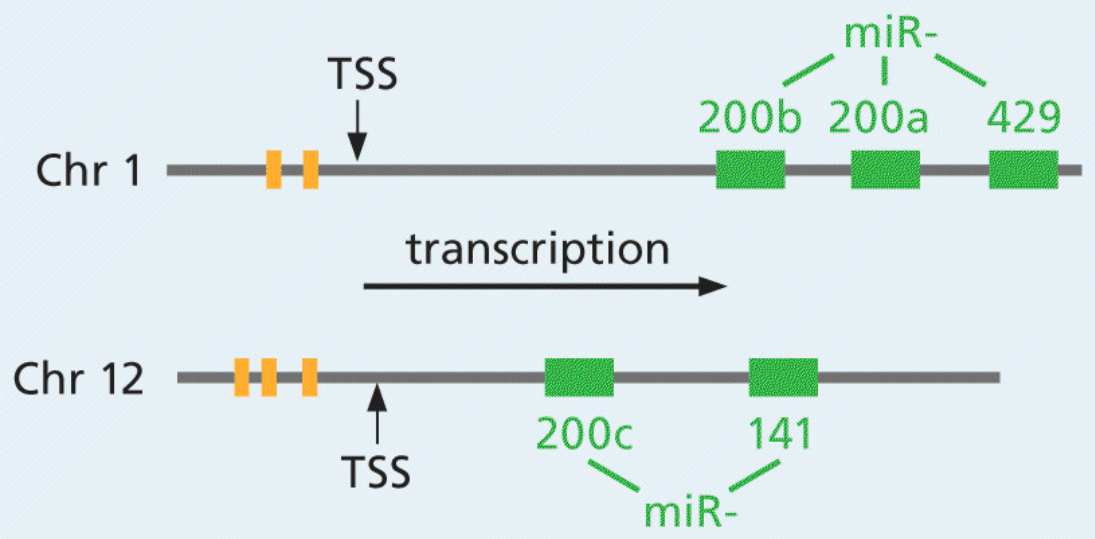
A scatter plot with m i R-200c expression on the horizontal axis and ZEB1 m R N A expression on the vertical axis. Each dot represents one cell line. The dot pattern indicates a mostly one-or-the-other relationship: only one cell line expresses both genes to a significant degree.

(B)



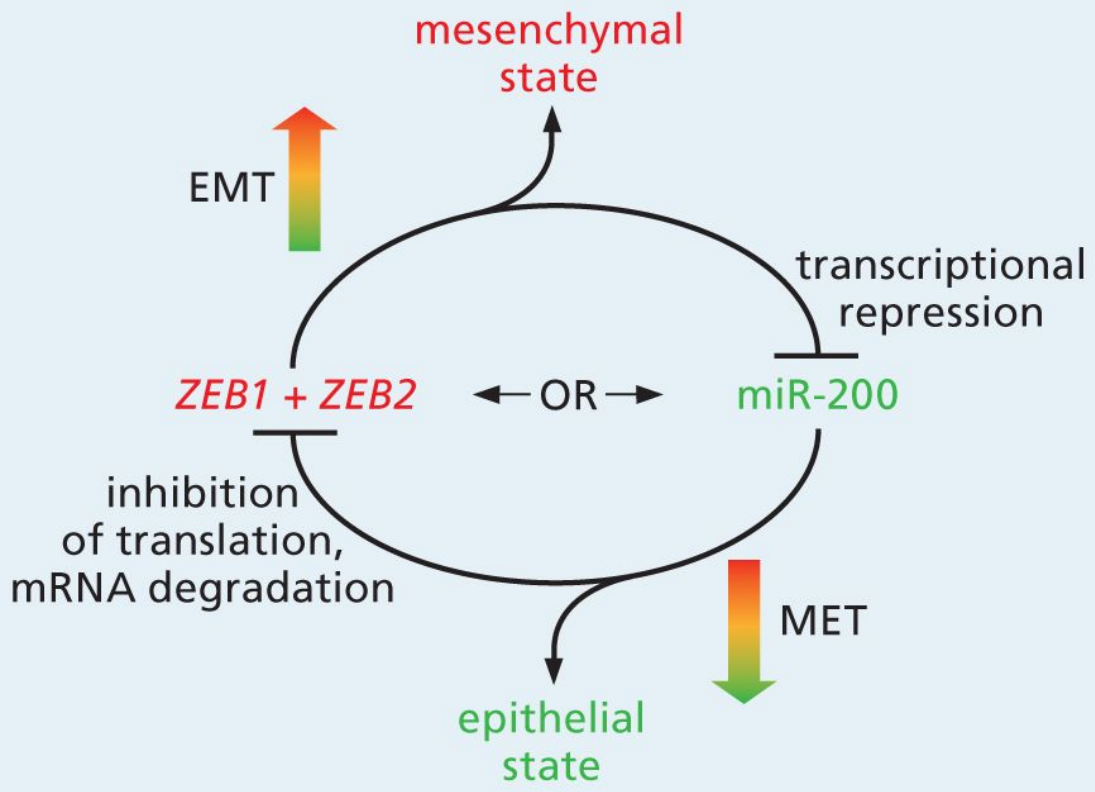
A schematic illustrating the sequencing of m R N Ayze ZEB 1 and ZEB 2, revealing multiple m i R-200a slash 141 and m i R-200b slash 200c slash 429 binding sites on each.

(C)



The C h r 1 gene with a transcription start site on the left and transcription proceeding rightward, with specification points for m i R 200b, 200a, and finally 429. Also, the C h r 12 gene with a transcription start site on the left and transcription proceeding rightward, with specification points for m i R 200c and then 141.

(D)



A diagram of a mutually inhibitory relationship between the epithelial and mesenchymal states. In a cell that has undergone E M T and is mesenchymal, ZEB1 and ZEB2 exert transcriptional repression of m i R-200. On the other hand, in a cell that has undergone M E T and is epithelial, m i R-200 exerts inhibition of translation and m R N A degradation of ZEB1 and ZEB2.

(E)

Figure 14.20 Alternation between the epithelial and mesenchymal states
Although carcinoma cells growing *in vivo* apparently can switch reversibly between epithelial and mesenchymal states, the cells of many cancer cell lines, when propagated *in vitro*, appear to reside stably in one or the other of these states, being controlled seemingly by a governor that functions as a bistable switch. (A) The levels of E-cadherin and vimentin, representative markers of the epithelial and mesenchymal states, respectively, were measured by immunoblotting of lysates of the 60 distinct cancer cell lines that constitute the collection termed the NCI 60 cell lines. The ratio of E-cadherin vs. vimentin (i.e., epithelial vs. mesenchymal) is indicated on the ordinate. As is apparent, almost all of the NCI 60 cells resided either in the epithelial (*green bars*) or mesenchymal (*red bars*) state when propagated in culture. The arrow indicates the shift of one of these cell lines after it was induced experimentally to undergo an EMT as described in panel C. (B) Examination of a series of microRNAs (see Section 1.9)

expressed in either the epithelial or the mesenchymal state revealed that several of these belonging to the miR-200 family of microRNAs were expressed in a fashion that was mutually exclusive with the ZEB1 and ZEB2 EMT-TFs. Shown (in arbitrary units) are the expression levels of ZEB1 mRNA and of miR-200c in ∼60 cell lines, with each point representing a single cell line; regulation of ZEB2 mRNA behaved in an essentially identical fashion (*not shown*). (C) Sequencing of the mRNAs encoding ZEB1 and ZEB2 revealed multiple sites in the 3′ UTRs (3′ untranslated regions; *light and dark blue boxes*) that could be targeted by miR-200 family members, resulting in inhibition of translation or degradation of these mRNAs. Alteration of these target sequences by site-directed mutagenesis rendered these mRNAs resistant to the inhibitory actions of miR-200 microRNAs. Moreover, experimental inhibition in epithelial cells of endogenously expressed miR-200 microRNAs, achieved by transfection of an antisense locked nucleic acid (LNA) construct, allowed accumulation of ZEB1 and ZEB2 and loss of epithelial gene expression. (D) Each of the two genes encoding miR-200 microRNAs specifies multiple miRNAs (*green boxes*) in its primary transcript (*not shown*), which is then cleaved post-transcriptionally to generate several mature microRNAs. The promoters of both genes contain evolutionarily conserved binding sites for ZEB1 and ZEB2 (*orange boxes*), which bind a sequence in these promoters and proceed to repress transcription of these genes. Transcription is from left to right (*horizontal arrow*) and the diagram is not drawn to scale. TSS, transcription start site. (E) The observations in panels C and D, when taken together, indicate the existence of mutually antagonistic interactions that operate as a bistable switch, thereby ensuring the metastable residence of a cell in either the mesenchymal or the epithelial state. Once one group of regulatory molecules gets the upper hand (i.e., either ZEB1/2 or miR-200 microRNAs), it shuts down the other and thereby ensures long-term residence in either the mesenchymal or the epithelial state. In principle, each group of regulators can act on yet other genes and mRNAs; e.g., ZEB1/2 can repress E-cadherin and other epithelial genes. The actions of the miR-200 microRNAs, however, seem to be focused more narrowly on suppressing just *ZEB1/2* expression. (A–C, from S.-M. Park et al., *Genes Dev*. 22:894–907, 2008. 14.5 Signals released by an array of stromal cell types contribute to the induction of invasiveness and intravasation

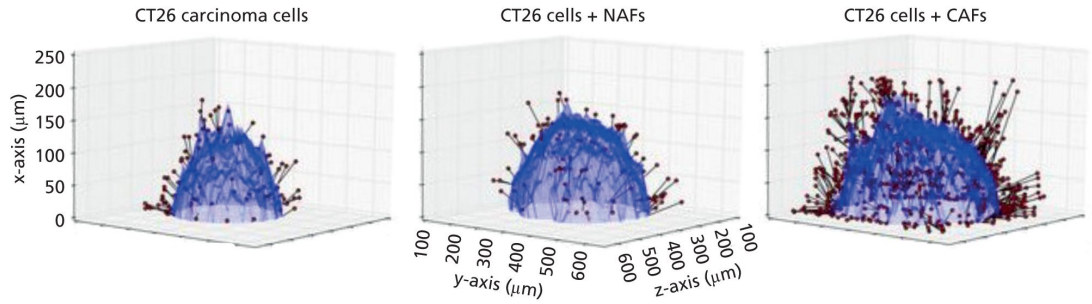
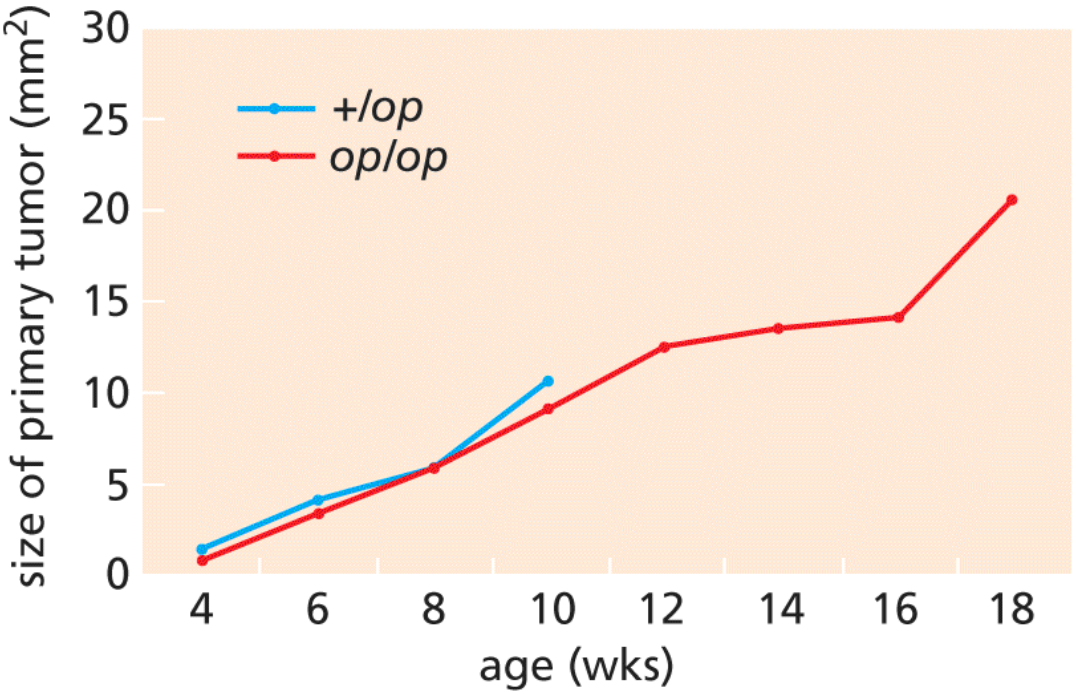
The diversity of the EMT-inducing signals described above (see Table 14.3 and Figure 14.17) draws attention to the stromal cells that are the sources of these signals. The most prominent cells in the stroma of a high-grade tumor are the carcinoma-associated fibroblasts (CAFs), which form the reactive stroma of the tumor and typically resemble myofibroblasts, releasing among other paracrine signals large amounts of TGF-β. As seen in **Figure 14.21A**, when clusters of murine colorectal carcinoma (CRC) cells, sometimes termed spheroids, are introduced into a three-dimensional collagen matrix, small numbers of CRC cells invade the nearby matrix; the same behavior is noted when the CRC cell spheroids are propagated in a collagen matrix containing normal fibroblasts adjacent to an excised tumor. However, when fibroblasts are prepared instead from the tumor-associated stroma (and may be termed CAFs, carcinoma-associated fibroblasts), there is a dramatic increase in invasiveness, ostensibly echoing the behavior of carcinoma cells in a highly progressed primary tumor.



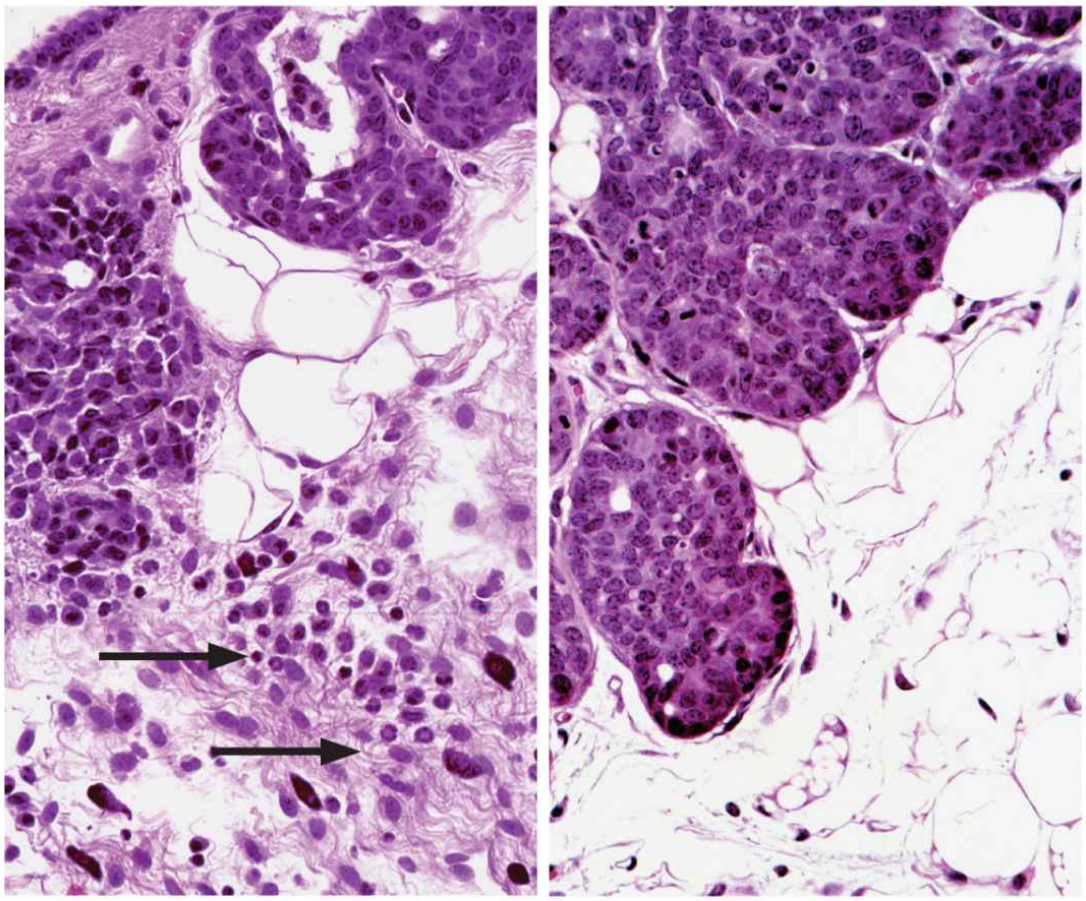
Three three-dimensional visualizations of invasiveness, each showing a round blue core surrounded by dark red dots some distance away. In the visualizations for C T 26 carcinoma cells and for C T 26 carcinoma cells plus N A Effs, the number of red dots is comparable. In the visualization for C T 26 carcinoma cells plus C A Effs, there are far more red dots and their arrangement is less orderly.

(A)



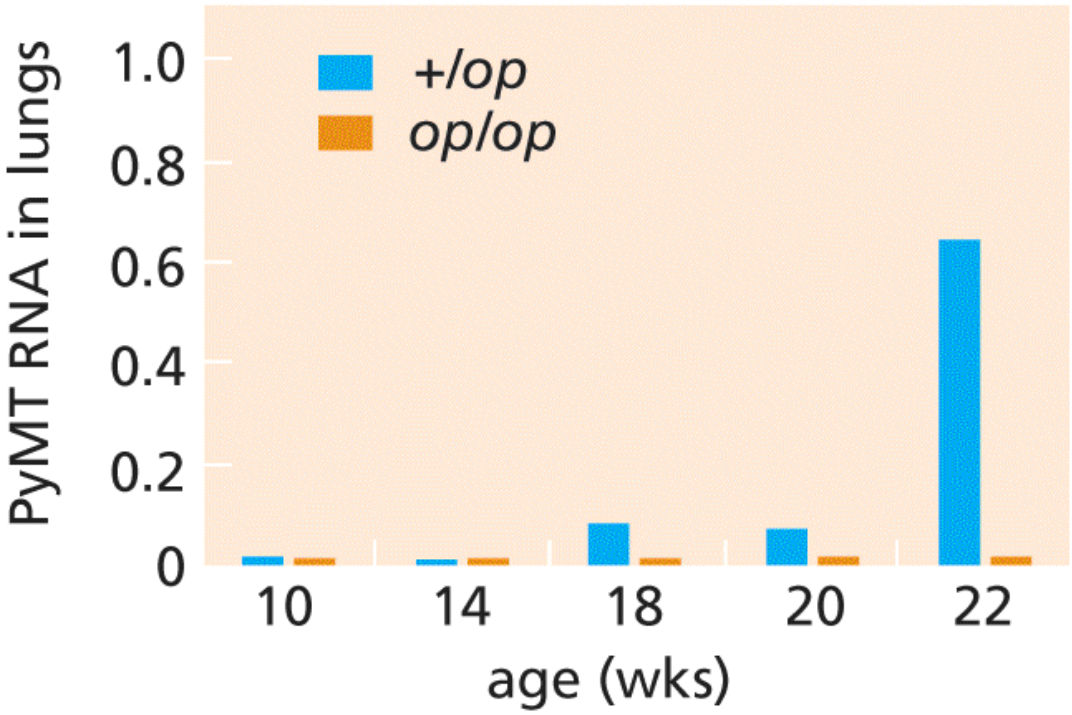
A line graph describing the size of the primary tumor as a function of time for two types of mice. In both plus slash o p and double o p mice, the tumor grows to about 10 square millimeters in 10 weeks. The line for double o p mice continues out to about 20 square millimeters in 18 weeks.

(B)



A pair of histology stain images. In the one for plus slash o p, the middle and lower parts of the image are thick with disordered nuclei. In the image for double o p, the corresponding areas are almost entirely free of nuclei.

(C)



A bar graph that gives P y M T R N A in lungs for two types of mice over time. The bars for plus slash o p are short at 10 weeks and 14 weeks, raised to 0.1 at 18 and 20 weeks, and significantky raised tot 0.6 at 22 weeks. The bars for double o p are short at all times.

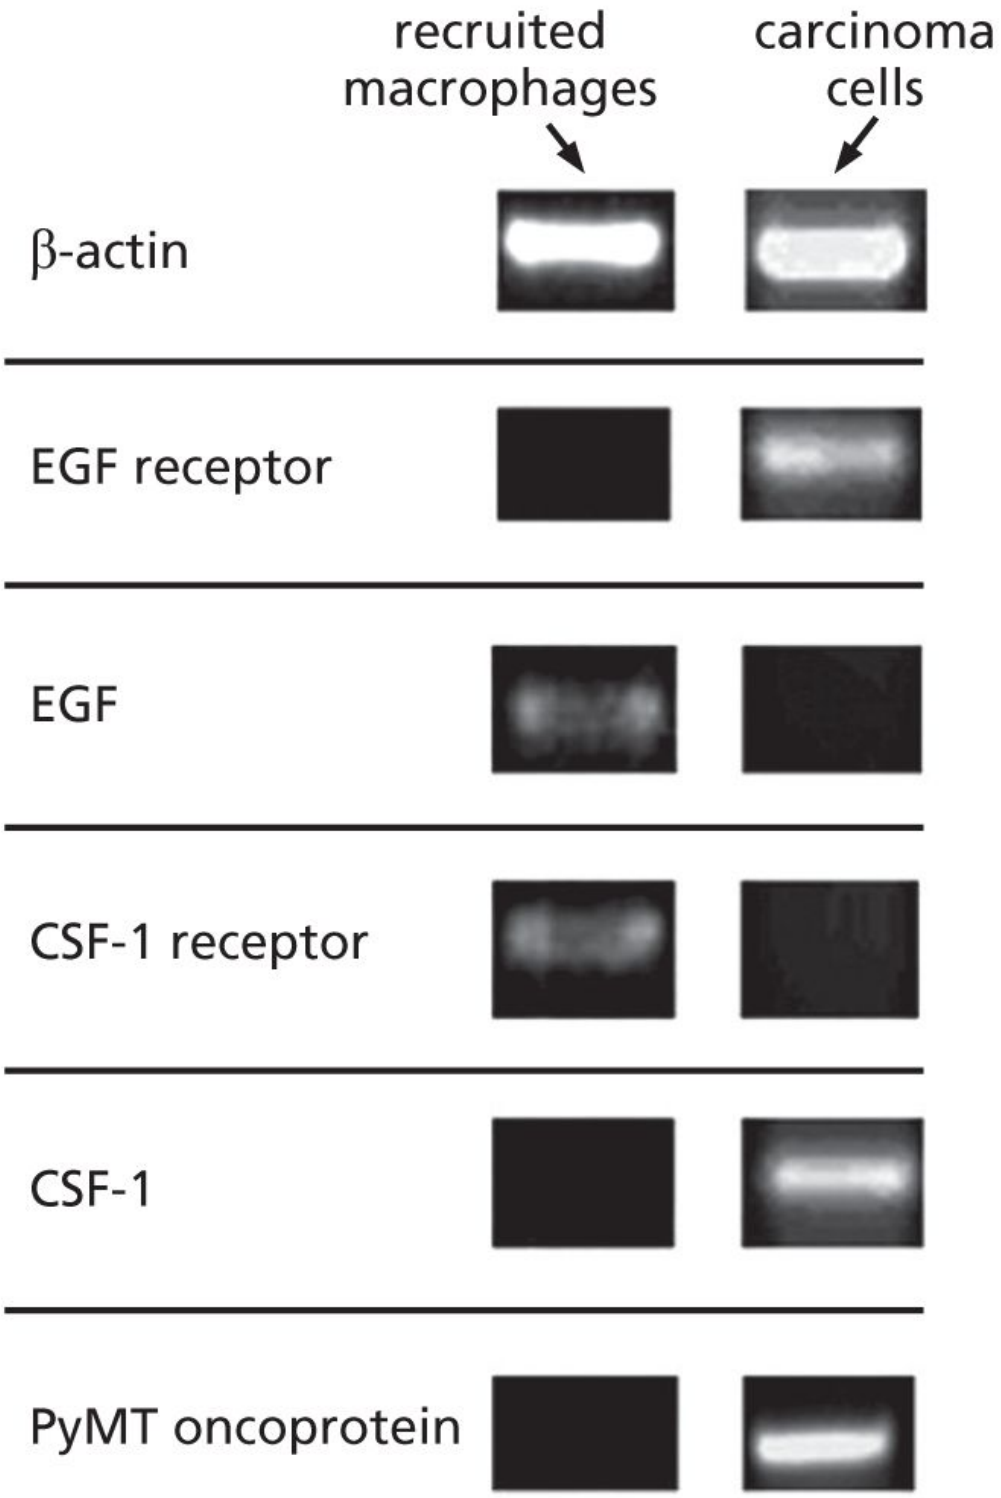
(D)

Figure 14.21 Effects of fibroblasts and macrophages on invasion and metastasis Both cancer-associated fibroblasts (CAFs) and macrophages can have strong effects on the biology of nearby carcinoma cells. (A) In an *in vitro* model of invasiveness, clusters of CT26 murine colorectal carcinoma (CRC) cells were embedded in a 3-dimensional collagen I matrix on their own (*purple, left panel*), in the presence of normal fibroblasts (NAFs) adjacent to a CRC tumor excised at surgery from a patient (*middle panel*), or carcinoma-associated fibroblasts (CAFs) prepared from the stroma of the excised human CRC tumor (*right panel*). The fibroblast populations were mixed into the collagen matrix. After 3 days, the nuclei of the invasive cells were visualized (*dark red dots*) by image-processing software. (B) The PyMT transgene (see Figure 14.18B) has been introduced, through breeding, into mice that can ($Csf^{+/op}$) or cannot ($Csf^{op+/op}$) make colony-stimulating factor-1 (CSF-1), which is needed to recruit macrophages into tumors (see Figure 13.25). The presence (in $Csf^{+/op}$ mice) or absence (in $Csf^{op+/op}$ mice) of recruited tumor-associated macrophages (TAMs) has no effect on the ability of the primary breast tumors to grow in these transgenic mice. (C) Such mammary

tumors arising in *Csf*$^{+/op}$ mice (whose tumors contain many TAMs, *not shown*) develop a highly invasive phenotype, in which individual carcinoma cells invade the nearby stroma in large numbers (*left panel*, *arrows*). However, if tumors develop in *Csf*$^{op+/op}$ mice, in which macrophages cannot be recruited into the tumor-associated stroma (*right panel*), the tumor cells do not break through the basement membrane and the tumor as a whole remains encapsulated and benign, indicating that the macrophages contribute in essential ways to tumor invasiveness. (D) In the *Csf*$^{+/op}$ mice, metastases in the lungs begin to appear at 18 weeks of age and increase progressively thereafter (*blue bars*), as gauged by the amount of polyomavirus middle T RNA (expressed exclusively in tumor cells) present in the lungs (*ordinate*). However, in the *Csf*$^{op+/op}$ TAM-negative mice (*orange bars*), lung metastases are virtually absent. (A, from Y. Attieh, A.G. Clark, C. Grass et al., *J. Cell Biol*. 216:3509–3520, 2017. With permission from Elsevier. B–D, from E.Y. Lin et al., *J. Exp. Med*. 193:727–740, 2001. With permission from Rockefeller University Press.)

The roles played by macrophages in the tumor-associated stroma were already cited briefly earlier. Their influence on the invasive and metastatic behavior of primary cancer cells can be demonstrated by studying genetically altered mice that lack the ability to make colony-stimulating factor-1 (CSF-1). As was discussed in the last chapter (Section 13.3), mammary carcinomas arising in cancer-prone transgenic mice usually recruit large numbers of tumor-associated macrophages (TAMs). However, when the tumor cells in such mice lack the ability to make CSF-1, TAMs are virtually absent (see Figure 13.25). The absence of CSF-1 and TAMs has no effect on primary tumor growth (Figure 14.21B), but such tumors show a benign, noninvasive behavior, in contrast to tumors that succeed in recruiting TAMs (Figure 14.21C). The influence of these macrophages on metastatic behavior is striking: primary mammary tumors usually succeed in seeding large numbers of metastases in the lungs, but without recruited TAMs in their stroma, they fail entirely to seed detectable lung metastases (Figure 14.21D).

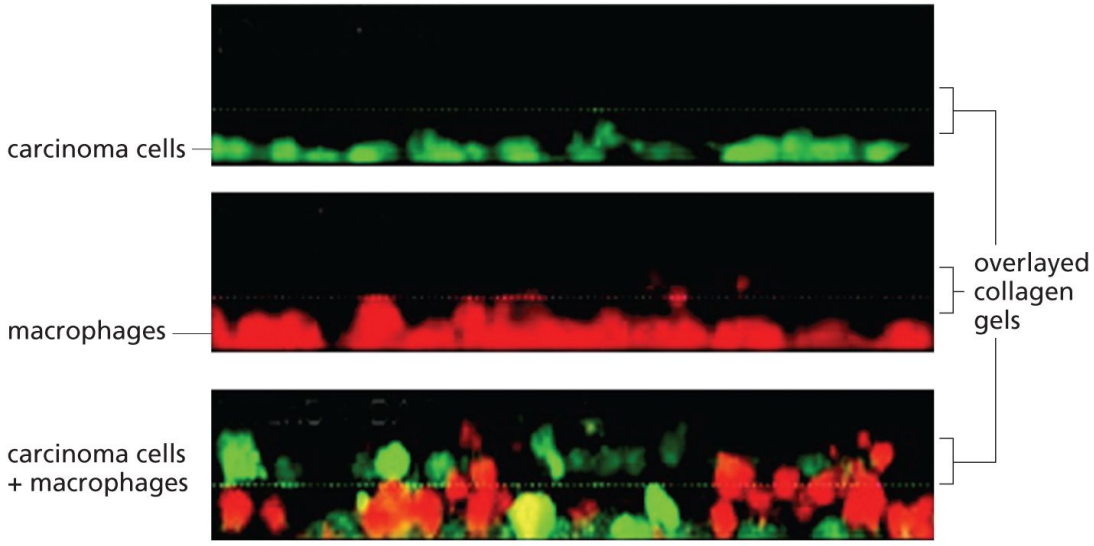
These experiments (Figure 14.21B–D) provide compelling evidence that the invasive and metastatic behavior of mouse breast carcinoma cells can be strongly influenced by the actions of stromal cells, in this case specific heterotypic signals released by macrophages. They fail, however, to reveal the precise nature of these signals. Macrophage-derived TNF-α, as argued earlier, is likely to contribute to induction of the EMT by cancer cells, and therefore to the invasive and metastatic behavior described in **Figure 14.22**.



A table of gel electrophoresis results for six different proteins, in each case showing a result for recruited macrophages and one for carcinoma cells. Both results are strongly positive for Beta-actin. For E G F receptor, C S F-1, and P y M T oncoprotein, the results are negative for recruited macrophages and

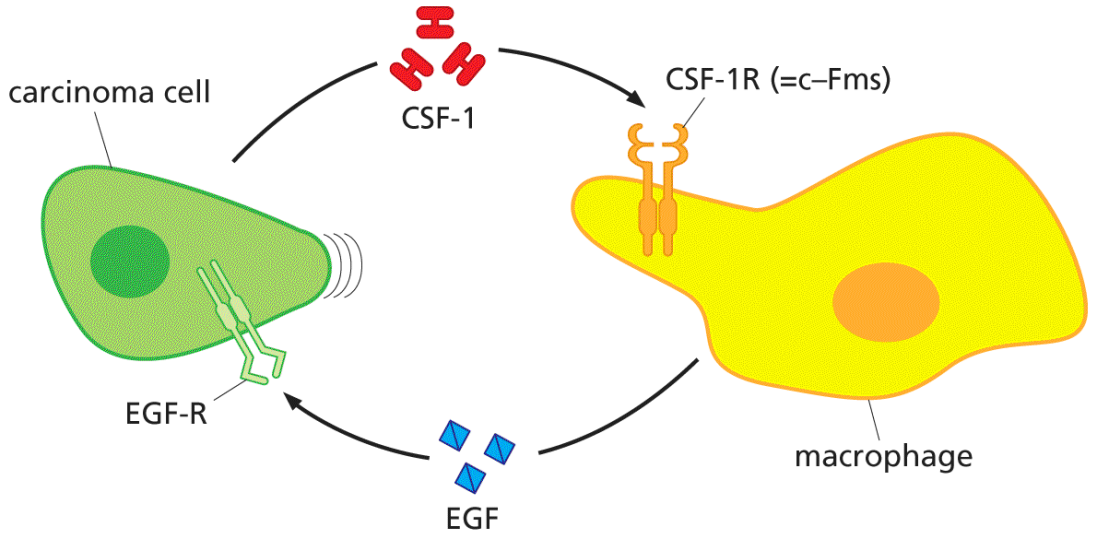
positive for carcinoma cells. For E G F and C S F-1 receptor, the reverse is true.

(A)



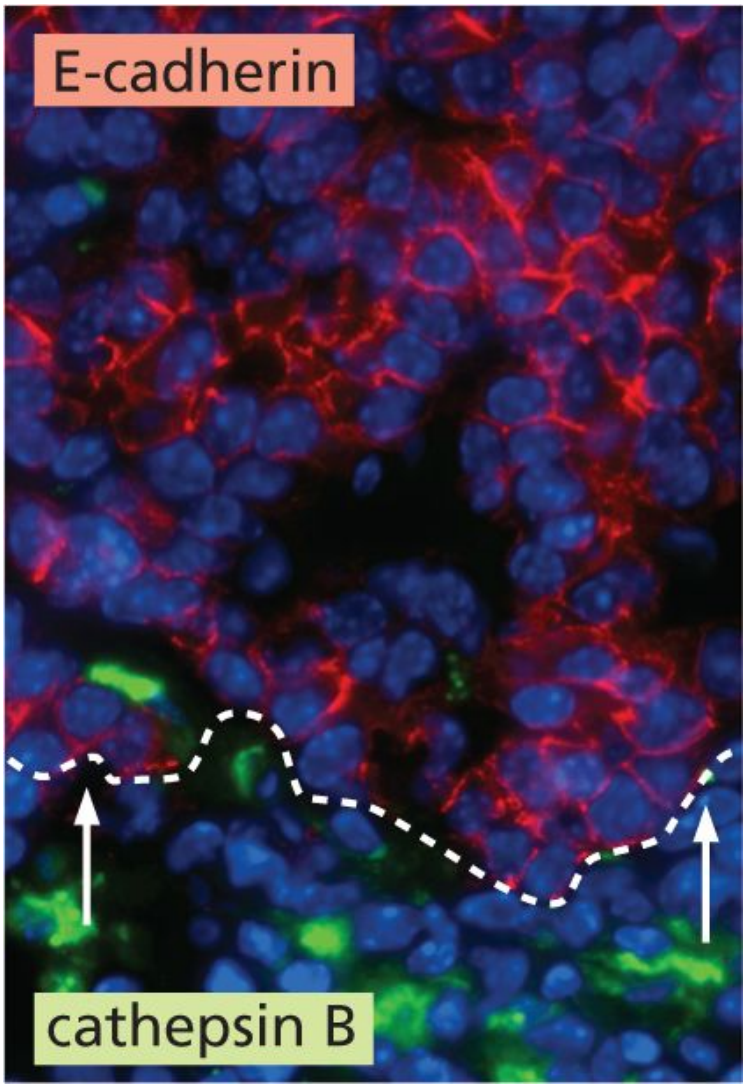
Three fluorescence microscopy images, each showing a petri dish in cross section with a layer of cells across the bottom and a layer of overlayed collagen gel on top. The top image shows carcinoma cells in green. They do not penetrate upward into the collagen gel layer. The middle image shows macrophages in red. They do not penetrate into the collagen gel layer, either. The bottom image shows green carcinoma cells and red macrophages together. They do penetrate into the collagen gel layer.

(B)



A schematic showing the interaction between a carcinoma cell and a macrophage. The carcinoma cell produces C S F-1, which binds to the C S F 1 receptor on the macrophage. The macrophage, in turn, produces E G F, which binds to the E G F receptor on the carcinoma cell.

(C)



A fluorescence microscopy image in which blue nuclei are surrounded by red E-cadherin above a white dashed line and by green cathepsin B below the dashed line.

(D)

Figure 14.22 Reciprocal stimulation by breast cancer cells and macrophages
A variety of experiments indicate that macrophages are the major source of EGF

in breast cancers. EGF is known to be able to stimulate epithelial cancer cells to proliferate and invade through extracellular matrix. In addition, EGF exposure causes breast cancer cells to release CSF-1, which allows them to recruit macrophages and stimulates production by the macrophages of more EGF, resulting in a positive-feedback loop between these two cell types. (A) Using PCR analysis, the mRNA levels of these two growth factors and their receptors are found to be reciprocally expressed in mammary carcinoma cells arising in PyMT tumor-prone transgenic mice (see Figure 14.18B) and in recruited stromal macrophages. (B) Breast cancer cells (labeled here with green fluorescent protein, GFP; *green*) were placed at the bottom of a Petri dish (seen here in side view) below a layer of collagen gel (*top image*), where they remained. Similarly, macrophages (*red*) also remained where they were initially placed at the bottom of the Petri dish below a collagen gel (*middle image*). However, when the two populations were co-cultured at this location, the breast cancer cells (*green*) were now induced to move upward and invade the overlying collagen gel (*lower image*).(C) The reciprocal paracrine interactions between carcinoma cells and macrophages operates by the release of EGF by the macrophages, which stimulates the carcinoma cells, which proceed to release CSF-1, which recruits macrophages. (D) The possibility that macrophages can contribute directly to triggering an EMT program in carcinoma cells is indicated by studies of macrophages that have been recruited to the invasive edge (*dashed line, arrows*) of a pancreatic islet cell tumor (*above*) in the Rip-Tag transgenic mouse model (see Figure 13.35). As seen here, the cathepsin B secreted protease (*green*) produced by the recruited macrophages causes the carcinoma cells to lose expression of E-cadherin (*red*). The resulting carcinoma cells (*below dashed line*) are revealed here only by their DAPI-stained nuclei (*blue*). (Inactivation of cathepsin B production by the macrophages permitted the carcinoma cells to regain their E-cadherin expression and caused them to lose invasiveness; *not shown*. Cathepsin B is also responsible for activating a number of distinct matrix metalloproteinases, whose activation leads to amplification of the cathepsin B-mediated proteolysis.) (A, from J. Wyckoff et al., *Cancer Res*. 64:7022–7029, 2004. B, from S. Goswami et al., *Cancer Res*. 65:5278–5283, 2005. Both with permission from American Association for Cancer Research. D, courtesy of V. Gocheva and J.A. Joyce; see also V. Gocheva et al., *Genes Dev*. 20:543– 556, 2006.)

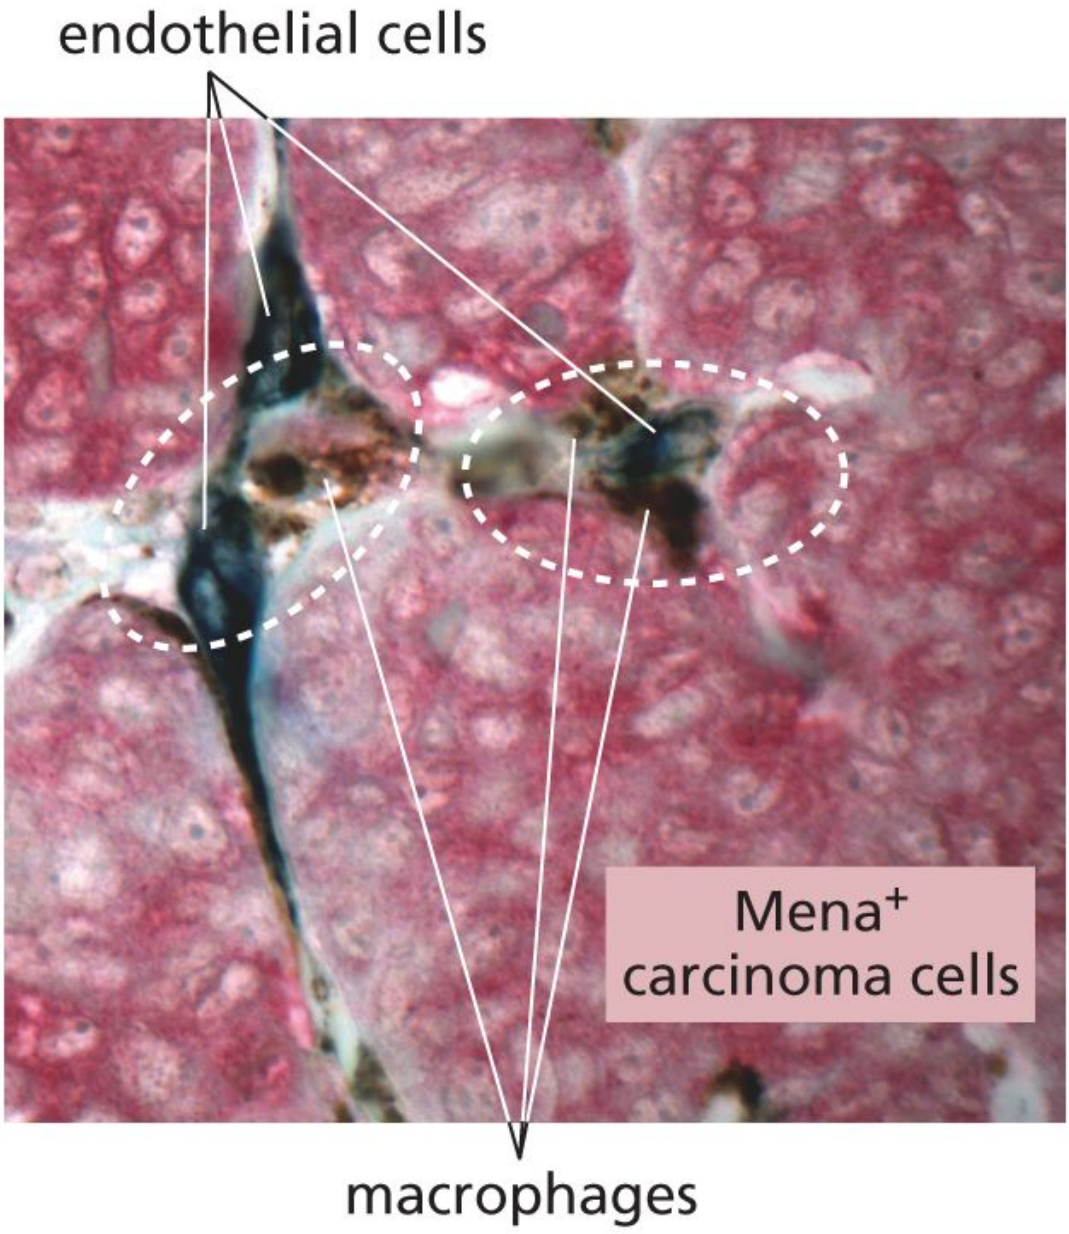
Another key macrophage-derived signal is conveyed by EGF, as mentioned earlier. Some of the evidence favoring EGF as a key inducer of cancer cell invasiveness comes from studies of mouse breast cancer cells both *in vivo* and *in vitro*. Like most epithelial cells, these carcinoma cells express the EGF receptor, and activation of this receptor by EGF causes them to acquire both motility and invasiveness (to be discussed later in

Supplementary Sidebar 14.9) and to secrete CSF-1, a key attractant and stimulant of macrophages. Macrophages respond reciprocally to CSF-1 by proliferating and releasing EGF, which activates the cancer cells. These effects all proceed through paracrine rather than autocrine signaling, as demonstrated by the fact that the breast cancer cells do not express the CSF-1 receptor and the macrophages do not express the EGF receptor (see Figure 14.22A). Hence, these two cell types collaborate by reciprocally stimulating one another, yielding another type of positive-feedback loop (see Figure 14.22C).

Importantly, the behaviors depicted in Figures 14.7 and 14.22B suggest that macrophages actually play critical roles in two stages of the invasion–metastasis cascade—initial invasiveness and intravasation. Although cancer cell motility and invasiveness are clearly demonstrated in such experiments, the induction of an EMT program in the cancer cells can only be inferred from their acquisition of motile, invasive behavior. More direct evidence comes, however, from the Rip-Tag tumor model (see Figure 13.35), in which the secretion by recruited macrophages of the cathepsin B protease is correlated with the loss—ostensibly through proteolytic degradation—of E-cadherin expression from the cell surface of carcinoma cells; such loss, on its own, can serve as a trigger for initiating an EMT (see Figure 14.22D).

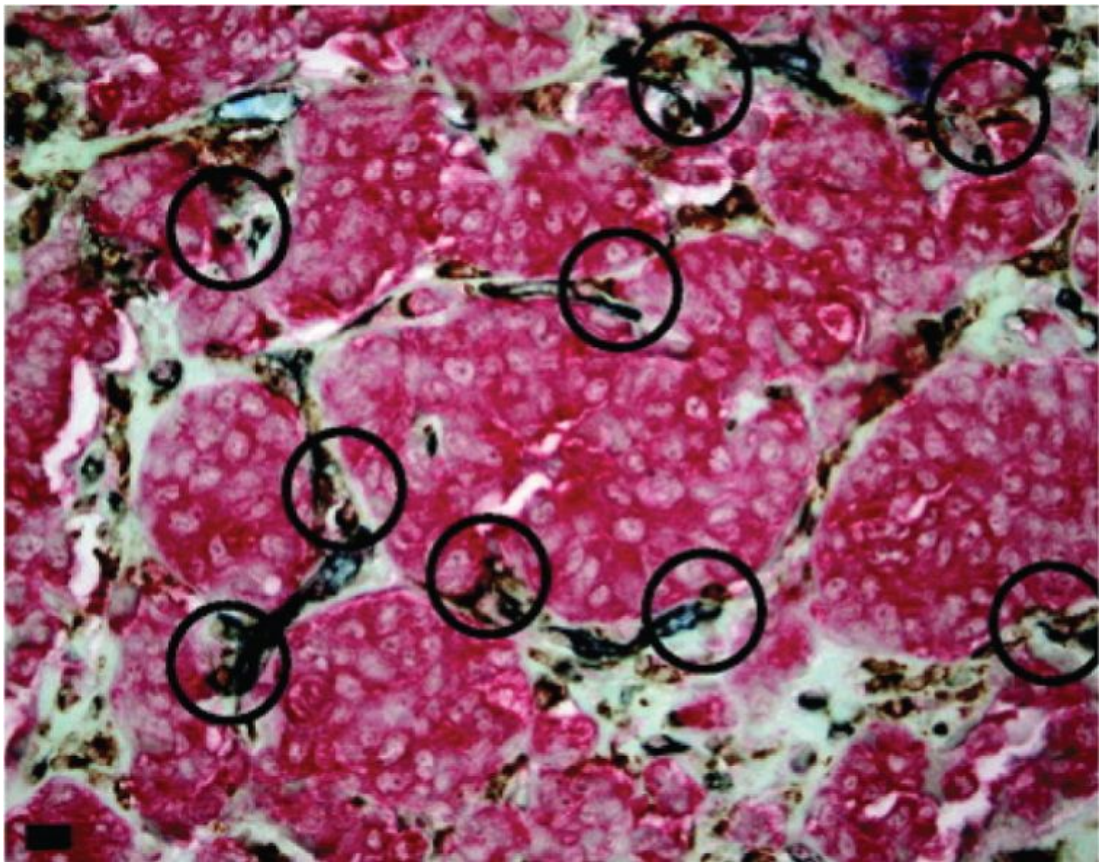
These bidirectional interactions seem to play a critical role in a poorly studied step of the invasion–metastasis cascade, the process of intravasation. As cited earlier, the invasiveness of primary tumor cells leads, with a certain probability, to intravasation, that is, entrance into the lumina of blood and lymphatic vessels. Many had assumed that intravasation is nothing more than an accidental, undirected by-product of invasion. However, recent studies have pointed to more specificity and organization of this process.

These studies indicate that in many breast cancers, and likely in other carcinomas as well, a triad of three distinct cell types—carcinoma cells, macrophages, and endothelial cells—assembles to enable the cancer cells to intravasate (**Figure 14.23**). The macrophages in these multicellular clusters appear to be responsible for creating “doorways” in the endothelial walls of microvessels that allow invasive carcinoma cells to enter the lumina of these vessels. In more detail, the macrophages appear to deploy the VEGF-A angiogenic growth factor to induce retraction of the endothelial cells from one another. These opened doorways therefore represent discrete sites of greatly increased permeability in the vascular endothelial wall and are formed where macrophage-induced endothelial cell retraction creates significant gaps in the otherwise-intact endothelial lining of microvessels (see Figure 14.23D).



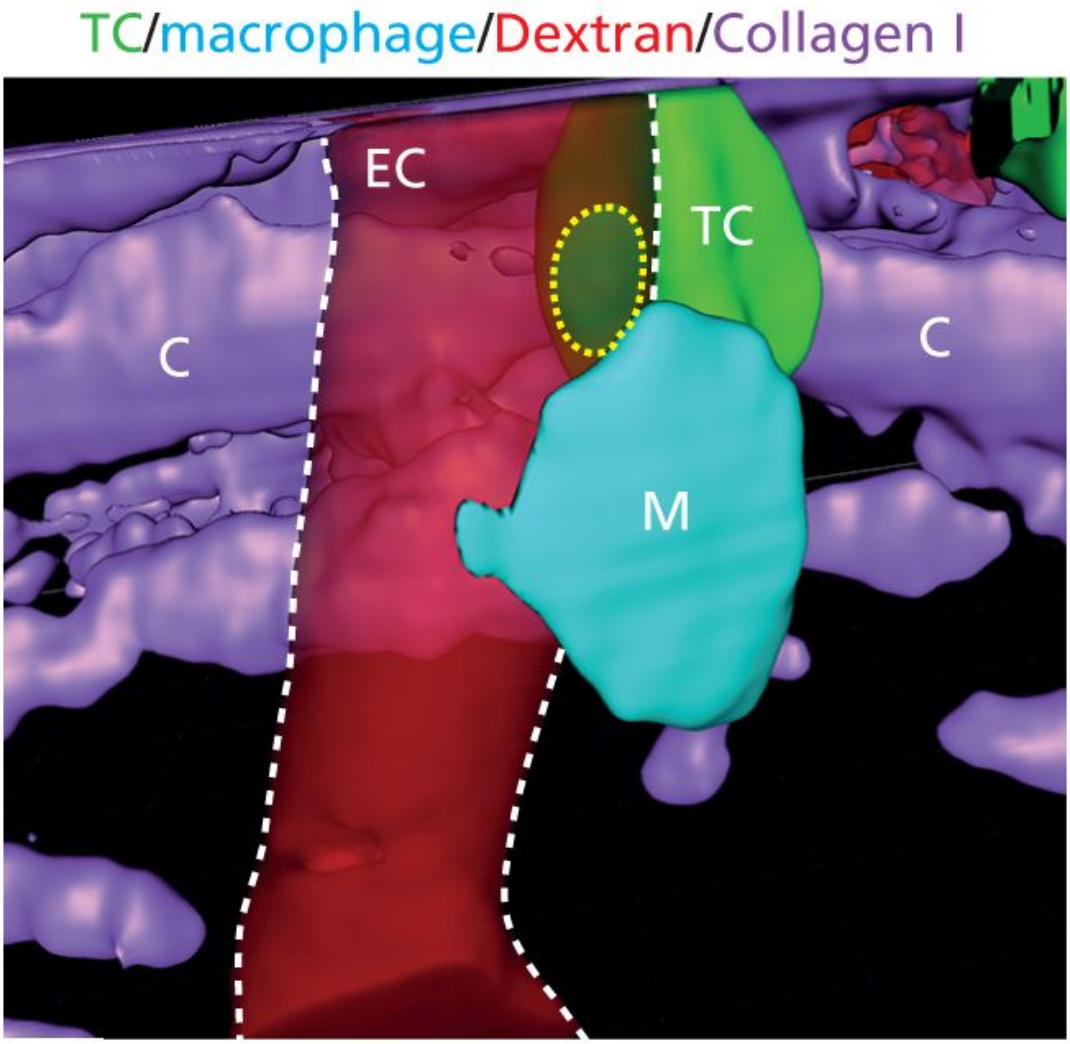
A micrograph of three brown macrophages and three dark endothelial cells clustered together and surrounded by red-pink Mena plus carcinoma cells. Two ovals mark locations where all three cell types are present.

(A)



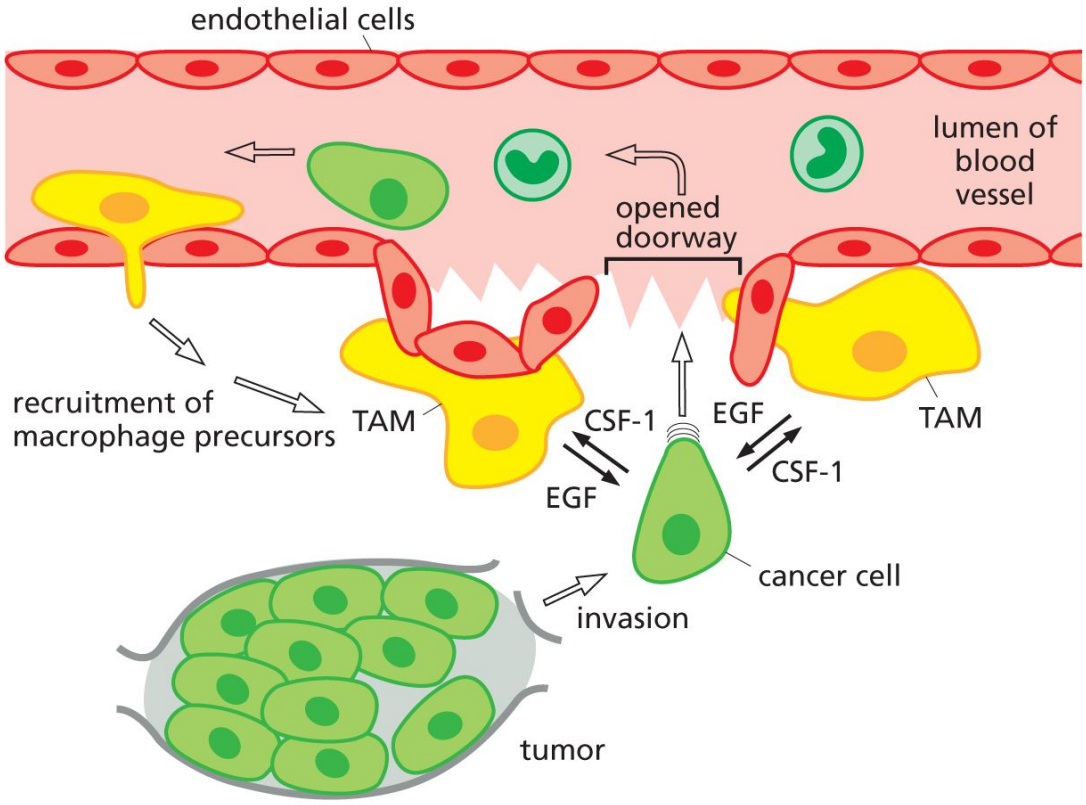
A zoomed out version of Part A, with black circles indicating nine different macrophage-endothelial-carcinoma cell triads.

(B)



A false-color reconstruction of tissue in which a microvessel, labeled E C and outlined with a white dashed line, has attached to its right side a green cell labeled T C and a blue cell labeled M. Part of the green cell is shown to have penetrated into the microvessel. This structure is surrounded by a purple matrix labeled C.

(C)



A schematic depiction of how a tumor places cells into the bloodstream. The recruitment of macrophage precursors from within the lumen of a microvessel leads to a configuration in which cancer cells released by the tumor act with C S F 1 on tumor associated macrophages. In turn, the tumor associated macrophages are acted on by E G F from the macrophages. The macrophages tear open a doorway that provides access to the lumen of the vessel. The cancer cells then pass through the doorway.

(D)

Figure 14.23 Intravasation Like local invasion, the process of intravasation by carcinoma cells often—and perhaps always—requires help from stromal cells, in this case macrophages. (A) Detailed investigation of carcinomas, in both laboratory animal models and human tumors, reveals triads (*ovals*) of carcinoma cells, macrophages, and endothelial cells (sometimes termed TMEM, for tumor microenvironment of metastasis). The macrophages help the carcinoma cells to intravasate through the capillary wall formed by the endothelial cells. A triad is registered only if all three cellular components are directly apposed and if the carcinoma cells express significant levels of the Mena actin-cytoskeleton–regulating protein that is associated with cell motility, seen here as a *red* stain. (B) Although two human carcinomas may have a very similar histopathological

appearance, the counting of the density of TMEM triads (*circles*) within sections of these tumors generates a highly useful prognostic marker of metastasis. (C) A 3-dimensional reconstruction of real-time intravital imaging showing collagen I fibers (C, *purple*) behind a doorway in the wall of a microvessel composed of a tripartite cell complex involving a tumor cell (TC, *green*), a macrophage (M, *cyan*), and an endothelial cell (EC). The endothelial cells were not labeled in this image but form a thin 1- to 2-micron thick cell layer (*dashed white lines*) around the intraluminal space of a microvessel, which is defined by fluorescently labeled dextran (*red*) that was intravascularly injected. The carcinoma cell has partially intravasated into the lumen of the micro vessel with the *yellow dotted line* separating its intraluminal portion (*oval dotted line*) from its portion that remains outside of the vascular lumen. (D) The reciprocal interactions between breast cancer cells and macrophages are illustrated schematically here. Because macrophages are often found in close proximity to microvessels, the stimulation by tumor-associated macrophages (TAMs) of breast cancer cell motility and invasiveness may also contribute to cancer cell intravasation, as suggested by the observations of Figure 14.7 and depicted here in more mechanistic detail. (A, B, from B.D. Robinson et al., *Clin. Cancer Res*. 15:2433–2441, 2009. With permission from American Association for Cancer Research. C, courtesy of D. Entenberg, A.S. Harney, P. Guo, and J. Condeelis. D, from W. Wang et al., *Trends Cell Biol.* 15: 138–145, 2005. With permission from Elsevier.)

Importantly, the density of these microscopically visualized tripartite cell clusters (see Figure 14.23C) represents a strong predictor of eventual systemic metastatic dissemination in breast cancer patients. Thus, in women bearing estrogen receptor-positive, HER2-negative primary breast cancers (which in aggregate constitute ∼60% of all breast tumors), the third of the women whose tumors exhibited the highest density of these triads exhibited a 2.7 times higher risk of developing distant metastases than the third of patients whose tumors carried the lowest density of these triads. In fact, this measurement of triad density was found to be a more accurate indicator of future metastatic risk than was the overall histopathological grade of the primary tumor.

To summarize, these diverse lines of evidence indicate that the acquisition of malignant traits by carcinoma cells, involving notably induction of an EMT, is not governed solely by the genomes of these cells. Instead, these profound shifts in cell phenotype are often initiated by a collaboration between specific mutant alleles harbored in cancer cell genomes (for example, mutant *ras* or *p53* genes) and the signals that these cancer cells receive in certain tissue microenvironments, specifically at the boundaries between islands of tumor cells and reactive stroma. In many tumors, these contextual signals are conveyed by certain factors, such as TGF-β, Wnts, PGE_2,

and TNF-α, that are released by cells in the reactive stroma. Yet other stromal signals, such as those carried by EGF and HGF, may also help to elicit many of the changes that we associate with cancer cell invasiveness and the EMT. Importantly, these descriptions likely apply to the biology of all carcinomas, which together account for ∼80% of life-threatening human tumors; there is also evidence that neuroectodermal tumors of the brain also exhibit EMT-like behavior, possibly testifying to their formation in a tissue derived from an epithelium—the neuroectoderm—present in the early embryo. However, the relevance of our discussions in this chapter to the other main classes of human tumors—mesenchymal tumors (that is, sarcomas) and hematopoietic cancers—remains unclear.

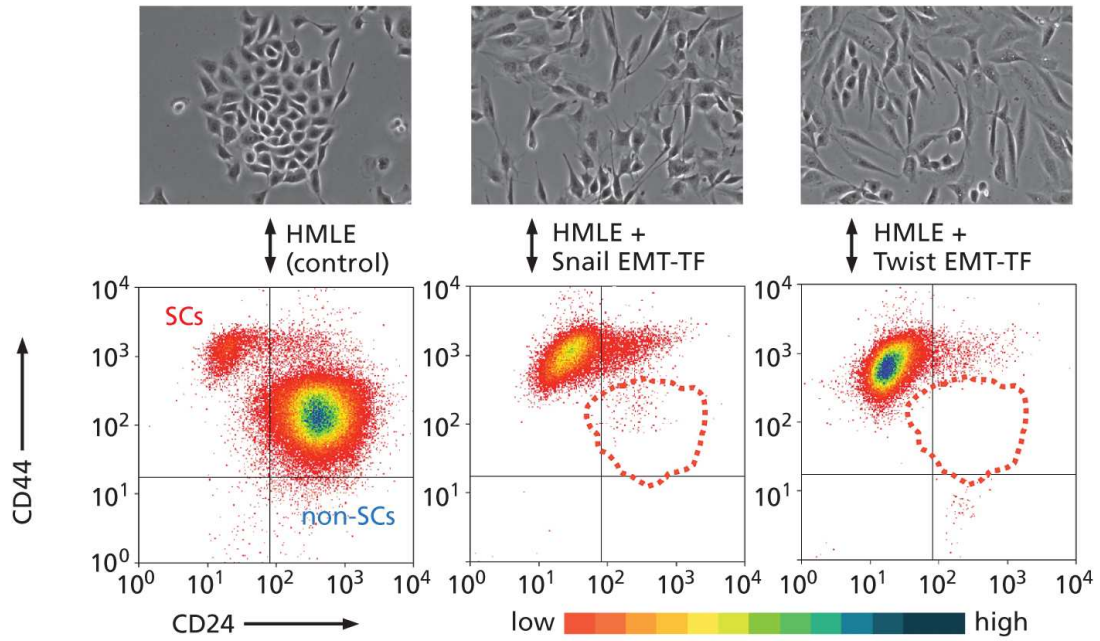
14.6 EMT-inducing transcription factors may enable entrance into the stem cell state

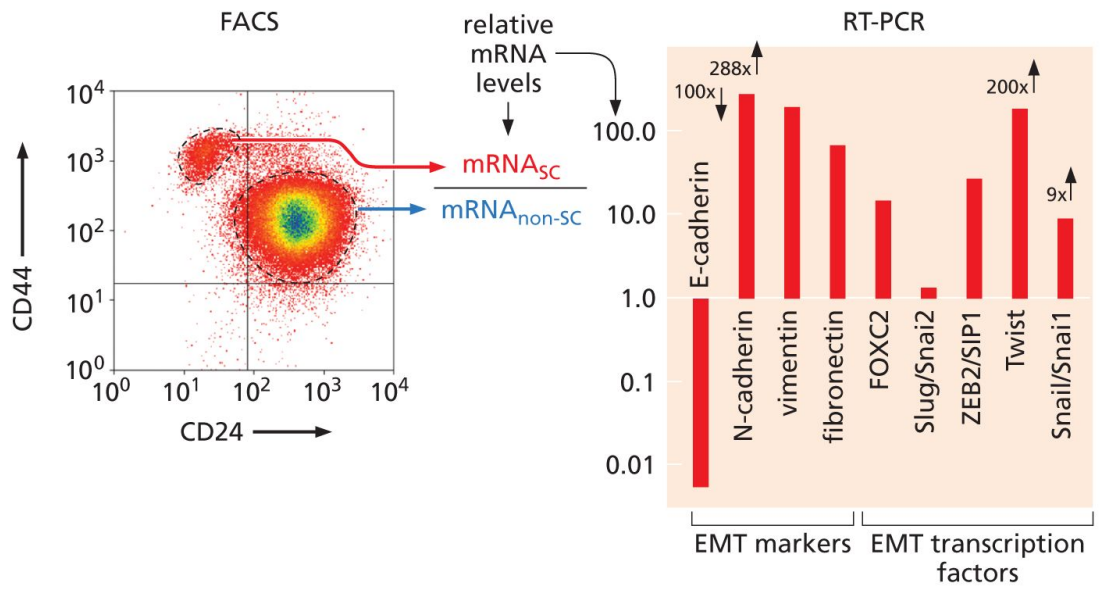
The cellular traits that are induced by the actions of one or another EMT-TF suggest that these master regulators can orchestrate many of the steps of the invasion–metastasis cascade. There is, however, one trait that is critical for metastasis that has not yet been considered here: in order for a disseminated cancer cell to seed a metastasis, it must possess the tumor-initiating ability that we previously ascribed to cancer stem cells (CSCs; see Section 11.7). Recall that these cells are defined operationally through their ability to seed new tumors following experimental implantation into suitable hosts. In principle, the seeding of a metastatic colony, when it occurs as a consequence of primary tumor progression, represents a very similar process: in both cases, small numbers of cells—sometimes just a single cell—are able to spawn the large cell populations that form macroscopic tumors, including the secondary growths that we term metastases.

The trait of self-renewal that is so central to the stem cell state would seem to be far removed mechanistically from the aggressive cell-biological traits programmed by EMT transcription factors. Evidence first reported in 2008, however, indicates otherwise: this work revealed that immortalized human mammary epithelial cells (MECs) that are forced to pass through an EMT acquire many of the attributes of stem cells (**Figure 14.24**). Related studies later extended this work in two directions by showing that mammary carcinoma cells that have undergone an EMT exhibit vastly increased tumor-initiating capacity; similar dynamics apply to normal MECs and their stem cell-like behavior (**Figure 14.25**).



Three pairings of a micrographic image of cells with a two-dimensional differentiation of the cells, with C D 24 level on the horizontal axis and C D 44 level on vertical axis. The left pairing, labeled H M L E control, shows a micrograph of cells in a cobblestone pattern and below a differentiation that shows that most of these cells are non-stem cells with high C D 24 expression and low C D 44 expression, but with a minority of stem cells with low C D 24 expression and high C D 44 expression. In both the middle pairing, labeled H M L E control plus Snail E M T-T F, and the right pairing, labeled H M L E control plus Twist E M T-T F, the micrograph shows a more dispersed spatial distribution, and in the 2 D differentiation, the non-stem cell grouping has disappeared while the stem cell grouping has grown denser.

(A)



A comparison of various m R N A levels in stem cells and non-stem cells from the H M L E control group. The E M T marker E-cadherin was much more strongly expressed, by a factor of over 100, in non-stem cells. The E M T transcription factor Slug slash S n a i2 was about equally expressed in both cell types. The E M T markers N-cadherin, vimentin, and fibronectin were all more strongly expressed in stem cells, as were the E M T transcription factors FOX C2, ZEB2 slash SIP1, Twist, and Snail slash S n a i 1.

(B)

Figure 14.24 EMT-inducing transcription factors confer stem cell properties on epithelial cells Epithelial cells acquire certain properties associated with stem cells (SCs) following activation of EMT programs. (A) When experimentally immortalized human mammary epithelial cells, termed HMLE, are viewed in monolayer culture by phase microscopy (*left*, *above*), they exhibit the cobblestone morphology that is typical of epithelial cells. These cells can be fractionated using fluorescence-activated cell sorting (FACS) into a minority subpopulation that has a $CD44^{hi}$ $CD24^{lo}$ cell surface antigen profile and a majority subpopulation that has the opposite antigen profile—$CD44^{lo}$ $CD24^{hi}$ (*left*, *below*). The minority population, although not homogeneous, is greatly enriched for stem cells (SCs), which are absent from the majority population; this appears to be true for normal, immortalized, and neoplastically transformed human mammary epithelial cells. When these cells were then forced to express either the Snail (*middle column*) or the Twist (*right column*) EMT-inducing transcription factor (EMT-TF), their morphology changed in monolayer culture to the dispersed elongated phenotype typical of mesenchymal cells such as fibroblasts (*below*). In addition, virtually all the cells that were previously in the $CD44^{lo}$ $CD24^{hi}$ non-SC state were converted

to the $CD44^{hi}$ $CD24^{lo}$ population, which is greatly enriched in mammary SCs. (B) The relative levels of mRNAs expressed in each of the two populations in (A) (*left*) were quantified using RT-PCR analysis; the results are shown in the histogram (*right*). The mRNA encoding E-cadherin, the key epithelial marker, was expressed at ~1/100 the level per cell in the $CD44^{hi}$ $CD24^{lo}$ cells, whereas N-cadherin, vimentin, and fibronectin mRNAs (all encoding mesenchymal proteins) were expressed at levels ranging from ~65- to ~280-fold more abundantly in these cells. Of greater interest, cells that resided in the $CD44^{hi}$ $CD24^{lo}$ state naturally expressed levels of mRNAs specifying four EMT-TFs (FOXC2, ZEB2, Twist, and Snail) that were between 9- and 200-fold higher per cell than the $CD44^{lo}$ $CD24^{hi}$ cells. (A, B, from S.A. Mani et al., *Cell* 133:704–715, 2008. With permission from Elsevier.)

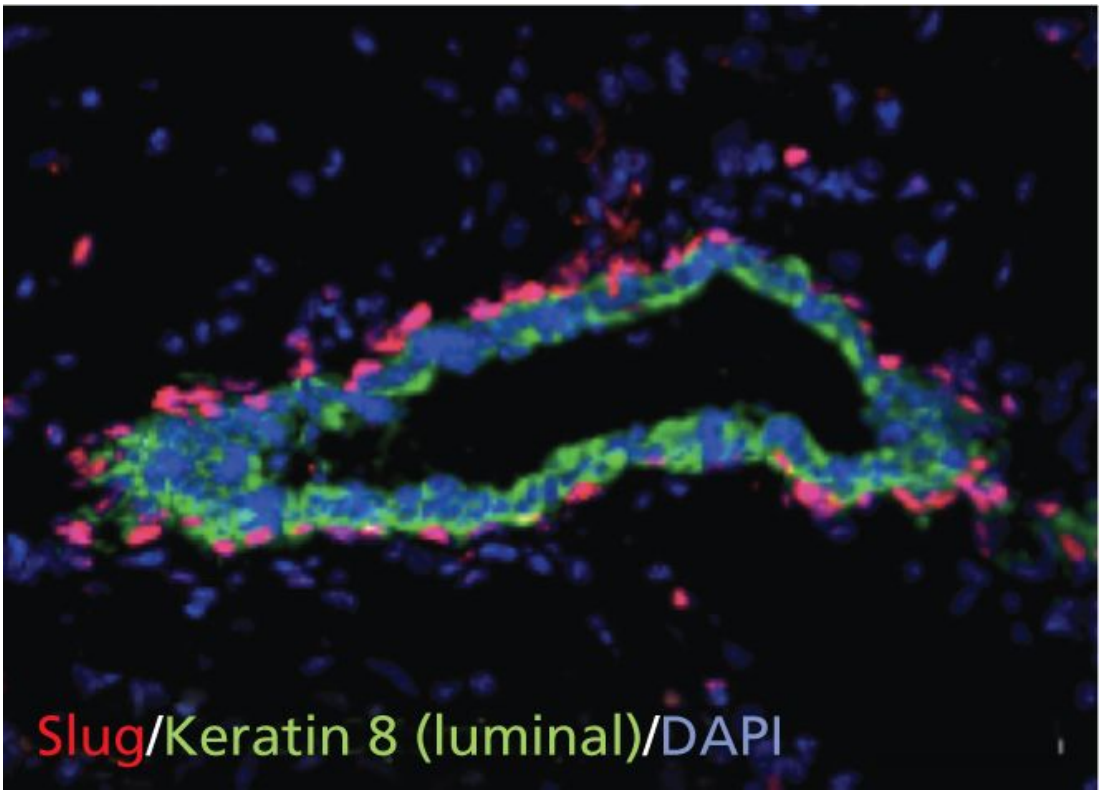
frequency of TICs in subpopulations of mammary carcinoma cells

number of implanted cells	1×10^5	1×10^4	1×10^3	1×10^2	estimated TIC frequency (95% confidence interval)
Snail-YFP^{hi} $EpCAM^{lo}$	6/6	6/6	6/6	3/6	1/143 (1/428~1/47)
Snail-YFP^{lo} $EpCAM^{hi}$	5/6	2/6	0/6	0/6	1/46,014 (1/111,052~1/19,065)

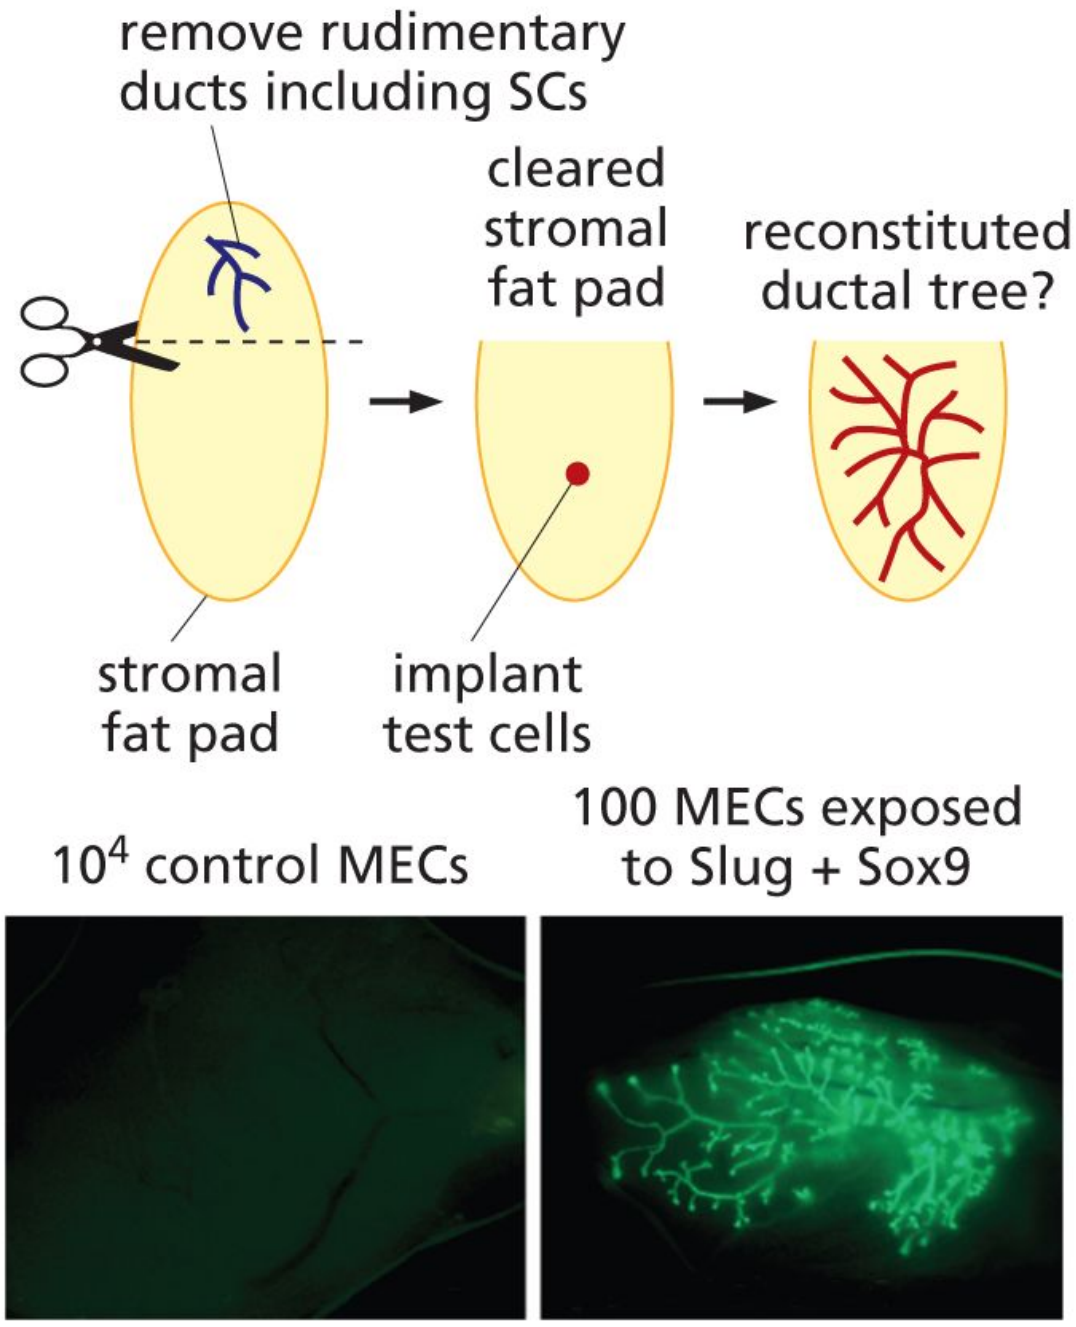
A table listing the frequency of T I Sees in subpopulations of two types of mammary carcinoma cells. One type is given as Snail-Y F P high Ep C A M low. In this type, the estimated T I C frequency is 1 in 143, with 95 percent confidence that the value lies between 1 in 428 and 1 in 47. The other type is given as Snail-Y F P low Ep C A M high. In this type, the estimated T I C frequency is 1 in 46,014, with 95 percent confidence that the value lies between 1 in 111,052 and 1 in 19,065.

(A)



A fluorescence microscopy image of a duct cross section. The duct wall is blue and green, edged with red along the outer perimeter.

(B)



An experiment. A diagram shows remove rudimentary ducts including stem cells being excised from a stromal fat pad, and test cells being implanted in the cleared fat pad. The looked-for result is a reconstituted ductal tree. Fluorescence microscopy images confirm that this is what happens, but only when the implanted cells were exposed to Slug and Sox9.

(C)

Figure 14.25 Contributions of EMT-TFs to mammary carcinoma and normal mammary gland formation (A) Implantation of populations of cancer cells, performed here in syngeneic host mice and at different concentrations, makes it possible, using the algorithm of limiting dilution analysis (LDA), to estimate the representation of tumor-initiating cells (TICs) in the undiluted cancer cell population. As is apparent, when gauging the percentage of TICs/CSCs within these tumors, among the cells expressing high levels of the Snail EMT-TF (Snail-$YFP^{hi}EpCAM^{lo}$) 1 in 143 can be registered as a TIC, whereas among cells that express much lower levels of Snail (Snail-$YFP^{lo}EpCAM^{hi}$) only 1 in 46,014 cells was calculated to be a TIC. In these tumors, the latter class of cells expressed significant levels of the Slug EMT-TF. (B) In this cross section of a duct of the normal mouse mammary gland, abluminal (situated away from the lumen) cells in a location known to contain both myoepithelial and stem cells are seen to express the Slug EMT-TF protein at significant levels (*pinkish red*), in contrast to the luminal epithelial cells, which express cytokeratin 8 (*green*). Nuclei are stained *blue* with DAPI. (C) A rigorous test of stemness comes from implanting as few as one mouse mammary epithelial SC into a mammary stromal fat pad that lacks its own endogenous MECs (*above*). Success in mammary gland reconstitution demonstrates the presence of SCs among the implanted cells. In this test, 10,000 control mouse MECs were implanted in a cleared fat pad (*below, left*), resulting in no reconstituted mammary ductal tree. However, If the Slug EMT-TF and a second collaborating TF, termed Sox9, were transiently co-expressed in mouse MECs, as few as 100 of these cells (*below, right*) were able to reconstitute a mammary ductal tree. (A, from X. Ye, W.L. Tam, T. Shibue et al., *Nature* 525:256–260, 2015. With permission from Nature. B and C (bottom), from W. Guo, Z. Keckesova, J.L. Donaher et al., *Cell* 148:1015–1028, 2012. With permission from Elsevier. C (top), adapted from L. Hennighausen and G.W. Robinson, *Nat. Rev. Mol. Cell Biol*. 6:715–725, 2005.)

In the analysis provided in Figure 14.24A, a population of experimentally immortalized human MECs could be fractionated, as judged by FACS analysis, into a minority and a majority subpopulation, with cells in the minority subpopulation exhibiting cell surface markers of the stem cell-like state; we encountered the same fractionation procedure previously in Figures 11.19 and 11.20, where it was used to resolve tumor-initiating cells (TICs) from non-TIC subpopulations. Because all the cells in this analysis appeared to share the same genome, this suggested, on its own, that cell populations like this one spontaneously sort themselves into majority and minority subpopulations, doing so via a process that did not require genetic change.

When two EMT-TFs were introduced separately into the cells analyzed in Figure 14.24A, the cells that had previously resided in the majority, non-stem-cell population

migrated into the position in this FACS plot of stem-like cells. This behavior suggested that activation of an EMT program facilitated entrance into a stem-like state, but on its own did not prove this because the cellular products of this conversion were not tested biologically for stemness.

Perhaps more persuasive were the observations of Figure 14.24B, in which mRNA levels were quantified in the cells of these two subpopulations, this analysis being measured in the absence of any experimentally forced expression of EMT-TFs. This analysis made it clear that the cells residing in the position (in the FACS plot) of stem-like cells expressed mesenchymal markers at greatly elevated levels relative to cells in the non-stem-like position. Included among these mesenchymal markers were mRNAs specifying a group of EMT-TFs. Here, the affiliation of EMT-inducing TFs with an SC-enriched state reflected regulation by natural, endogenous transcriptional controls rather than regulation imposed by experimentally introduced genes.

This association could also be extended in two directions with fully neoplastic, transformed mammary carcinoma cells and with non-neoplastic normal mammary stem cells. In one set of experiments, distinct populations of mammary carcinoma cells formed spontaneously in a transgenic model of breast cancer pathogenesis were implanted at different dilutions (diluted in tenfold increments over three orders of magnitude) in the mammary glands of syngeneic mouse hosts. This procedure (see Figure 14.25A) is termed limiting dilution analysis (LDA) and can be employed to quantify the number of tumor-initiating cells (TICs), also termed cancer stem cells (CSCs), that are present in a larger population of cells isolated directly from a tumor.

As can be seen in Figure 14.25A, ∼1 out of 143 tumor cells that expressed high levels of the Snail EMT-TF and resided in a more mesenchymal state could seed a new tumor upon implantation in the mammary glands of syngeneic mouse hosts; in contrast, the carcinoma cells in a cell population that expressed low levels of the Snail EMT-TF and resided in a more epithelial state (as indicated by the high levels of the EpCAM epithelial marker) harbored a far lower representation of TICs, specifically ∼1 in 46,014 cells, that is, a greater than 300-fold difference in the relative concentrations of TICs. When taken together, these experiments showed a *correlation* between EMT-TF expression and concentrations of TICs. Other experiments to be described below relate to the issue of *causation*, that is, by demonstrating directly that an experimentally induced EMT program can actually drive an increase in the formation of CSCs and metastases. (Inevitably, demonstrations of causation are more compelling than those showing only correlation.)

As mentioned earlier, association of an EMT program with stemness could also be found in non-neoplastic mammary epithelial cells (MECs) (see Figure 14.25B). A cross-section of a normal mouse mammary duct reveals its bilayered structure, much like a number of other epithelial tissues throughout the body. The cells in the luminal

layer directly confront the lumen of this duct, whereas those of the basal layer underlie the luminal cells, being one cell layer removed from the lumen. Figure 14.25B reveals that the basal cells, which are known from other work to contain the normal stem cells of the mammary duct, naturally express the Slug EMT-TF. This observation is striking for the following reason: until now, we have depicted EMT-TFs as master regulators that function in embryonic morphogenesis, in wound healing, and in tumor progression. Now one of them is found to be routinely expressed in an adult tissue that is operating in an unperturbed, fully normal fashion.

Once again this observation, on its own, was also correlative because it did not demonstrate directly that the Slug-expressing cells are functional stem cells (and if so, whether Slug was responsible for their stem-like properties). In this instance, functional tests of stemness could be undertaken using mammary gland reconstitution experiments. This procedure gauges the ability of small numbers of implanted normal mammary cells to generate entire mammary ductal trees after their implantation in mammary stromal fat pads (see Figure 14.25C). Here, the presence of stem cells is gauged by their ability to spawn an entire normal mammary gland—a stringent test of stemness. When MECs prepared from a mouse mammary gland that had been forced to transiently express Slug and Sox9 were implanted into a cleared mammary stromal fat pad, their ability to generate a normal mammary ductal tree was increased >100-fold relative to MECs that had not been exposed transiently to these transcription factors. (Sox9 is a second TF that potentiates in this case the actions of the Slug EMT-TF.)

We are only beginning to learn the identities of the stromal cells that cooperate with one another to create both normal and neoplastic stem cell (SC) niches. These signals clearly overlap significantly with the EMT-inducing signals described in Section 14.5 because activation of an EMT program places MECs in a position to advance into the SC state. Interestingly, the macrophages that assist in the intravasation of primary tumor cells, as described in Figure 14.23, are also reported to induce carcinoma cells to enter into the CSC state during the course of this assisted intravasation.

Evidence from numerous sources now indicates that carcinoma cells residing in a hybrid phenotypic state expressing a mixture of epithelial and mesenchymal attributes (see Figure 14.12), which can be annotated as E/M or termed “quasi-mesenchymal,” are placed optimally to function as cancer stem cells. Conversely, transformed cells residing at either end of the E-to-M spectrum of phenotypes, that is, fully epithelial and fully mesenchymal, have far less if any tumor-initiating activity. Moreover, carcinoma cells that lack phenotypic plasticity and have been trapped experimentally in such an E/M phenotypic state (achieved through manipulation of EMT-TF expression) exhibit a high degree of tumor-initiating activity. This indicates that the CSC phenotype exhibited by such E/M cells does not depend on their plasticity, that is, their ability to interconvert to other phenotypic states arrayed along the E-to-M

spectrum. Instead, a specific mixture of epithelial and mesenchymal cell-biological traits exhibited by such cells suffices to empower them to function as tumor-initiating cells (TICs) and thus, quite possibly, as founders of metastatic colonies.

These observations hold important implications for the role of EMT programs in epithelial stemness. Although they were only performed in the context of mammary gland biology, it is likely that similar behaviors will be found in other bilayered epithelial tissues throughout the body, both normal and neoplastic. To enumerate these conclusions: (1) The SC machinery that operates in normal mammary epithelial tissue operates in a similar fashion in mammary carcinoma cells; hence, breast cancers do not seem to invent entirely novel SC programs during tumor formation but instead appropriate versions of an SC program that operates in a normal precursor tissue. (2) Contrary to intuition, the SCs in the basal cell layers of the mammary gland express a series of mesenchymal markers. Accordingly, in bilayered epithelia, to the extent that self-renewing stem cells are associated with basal cells, it seems likely that the luminal epithelial cells are the more differentiated progeny of quasi-mesenchymal, less differentiated SCs. It remains unclear whether this lesson also applies to single-layer epithelia. (3) From the perspective of multi-step tumor progression (see Figure 11.7A), because both fully normal and fully neoplastic cells employ EMT-associated stem cell programs, it is plausible if not likely that each of the distinct cell populations formed at intermediate stages of multi-step tumor formation do so as well, that is, they harbor subpopulations of quasi-mesenchymal SCs (see Figures 11.22 and S11.4). Stated differently, it seems that epithelial cell populations, independent of their state of neoplastic transformation, naturally form their own subpopulations of SCs. The latter, in turn, employ versions of EMT programs to help organize themselves, at least in tumors arising in bilayered epithelial tissues.

Finally, in the context of metastasis formation, the tumor-initiating powers associated with the CSC phenotype hold important implications for the seeding of metastases. Intuition would dictate that the same cell-biological functions required to seed tumors upon experimental implantation (as analyzed in Figure 14.25A), are also critical to the founding of metastatic colonies following spontaneous dissemination of cells from primary tumors. Indeed, deletion from carcinoma cells of an important regulator of stemness—the p53-related p63 protein—while compatible with ongoing growth of established primary tumors, deprives these tumors of the ability to seed metastases, which they would otherwise spawn in large numbers. Still, all this leaves us with a major conceptual puzzle that has never been satisfactorily resolved: Why are the EMT program and epithelial stemness so tightly interconnected in certain tissues?

Glossary

limiting dilution analysis
: Procedure in which the representation or percentage of a given cell type of interest within a larger, often heterogeneous cell population is gauged by diluting the sample of interest and extrapolating from subsequent biological assays the concentration of the cell type of interest in the initial sample being analyzed.

luminal
: Referring to a cavity in a tissue or the cells that line and face a lumen. See also **lumen**.

basal
: (1) Referring to a lower physical location. (2) Referring to cells in an epithelium that are located away from an exposed surface of the epithelium such as its luminal surface. (3) Referring to the surface of an individual epithelial cell that is located away from an exposed surface of the epithelium such as its luminal surface. (4) Referring to a (low) rate of activity or function observed in the absence of any activating stimulus. *See also* **apical**.

14.7EMT-inducing transcription factors help drive malignant progression including metastatic dissemination

Once certain EMT-TFs are expressed in cancer cells, they act in various combinations to induce multiple cellular changes associated with invasion and metastasis. They are invariably expressed in combinations in cancer cells, which suggests that no one of them, acting on its own, is able to organize all of the cell-biological changes associated with passage through an EMT program. Indeed, these master regulators have been found to induce the synthesis of one another, often by the direct binding of one EMT-TF to the transcriptional promoter of another. For example, Twist binds directly to the promoters of the genes encoding Twist, Snail, Slug, and Zeb1, and actually depends on Slug induction in order to activate an EMT program. In addition, expression of Slug, which is frequently co-expressed with Twist in human breast cancers, is lost when Twist expression is shut down in some breast cancer cells. Also, some of these TFs can act in a redundant fashion; for example, Snail, Slug, Zeb1, and Zeb2 can all bind to the promoter of the E-cadherin gene (*CDH1*) and thereby repress E-cadherin expression. Accordingly, Twist may delegate the job of shutting down E-cadherin expression to Slug. Although Snail and its cousin Slug function very similarly, their expression is regulated very differently, giving us clues about the dynamics of EMT induction (**Sidebar 14.3**).

Sidebar 14.3 Snail stands out from its colleagues

Like many other cell-biological processes, the induction of an EMT program depends on increases in EMT-inducing TFs in the cell nucleus. These increases generally depend on the relatively slow processes of inducing the transcription of the genes that encode these EMT-TFs, the processing of the resulting pre-mRNA transcripts, and the translation of the mRNA products into the proteins that thereafter function as TFs in the nucleus; these yield, in turn, mRNAs that, with the passage of time, enable the accumulation of proteins related to the mesenchymal state. Taken together, these steps dictate that EMT-TF proteins and their downstream gene products proteins only respond to inductive signals over periods of several hours, possibly days.

This account describes the regulation of Slug. However, its close cousin, Snail is an outlier: Snail is usually produced at a high rate and is rapidly degraded thereafter, yielding a short lifetime of 25 minutes; this so-called “futile cycle” resembles the cycles governing the levels of the Myc and p53 proteins (see Sections 8.9 and 9.5). If Snail degradation is blocked, the ongoing high rate of Snail synthesis allows for rapid increases in protein levels that can be measured over the course of minutes and the resulting rapid induction of EMT programs.

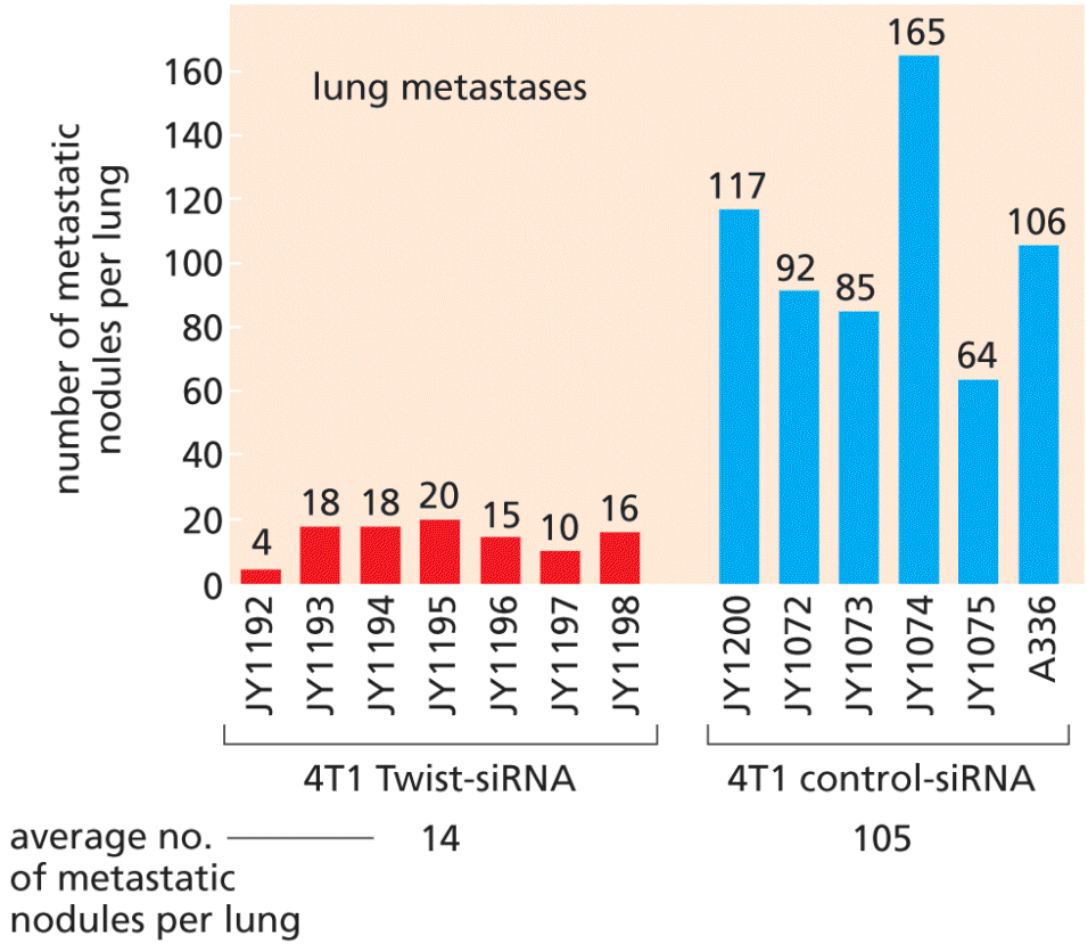
Under conditions of cell quiescence, the GSK-3β kinase phosphorylates recently synthesized Snail, thereby causing it to be tagged (by ubiquitylation) for rapid destruction in proteasomes. Conversely, activation of mitogenic signaling via growth factor ligands and their receptors and resulting activation of the Ras–PI3K–Akt/PKB pathway results in the inactivation of GSK-3β by Akt/PKB, permitting in turn survival and thus accumulation of Snail. (We first encountered GSK-3β in its role in driving β-catenin degradation; see Figure 6.19B.)

These dynamics operate in other situations as well. For example, interactions of cancer cells with macrophages, as described earlier in this chapter, result in, among other things, the release of tumor necrosis factor-α (TNF-α) by these myeloid cells, which in turn helps to initiate an EMT in nearby carcinoma cells. (TNF-α, as we read earlier, is an important player in the process of tumor promotion via inflammation; see Figures 11.35 and 11.36). By activating the NF-κB transcription factor in carcinoma cells, TNF-α causes expression of the CSN2 protein, which associates with and blocks the ubiquitylation of Snail, once again allowing the latter to accumulate rapidly in periods of less than an hour. Finally, we should note that certain aspects of the tumor-promoting effects of inflammatory cells, as described in Section 11.13, can be nicely explained by the EMT-inducing effect of TNF-α.

Although experiments described above related to the connections between EMT programs and the stem-cell state, they did not directly confront the key question of metastasis: Do the EMT-TFs simply confer traits associated with high-grade malignancy on cultured cells, or are their powers also apparent *in vivo*? More importantly, do they actually *cause* metastatic dissemination or merely accompany it? The most direct route for demonstrating their role in causing various steps of invasion and metastasis involves either overexpressing them or shutting down their expression in tumorigenic cells that have been implanted in suitable host mice.

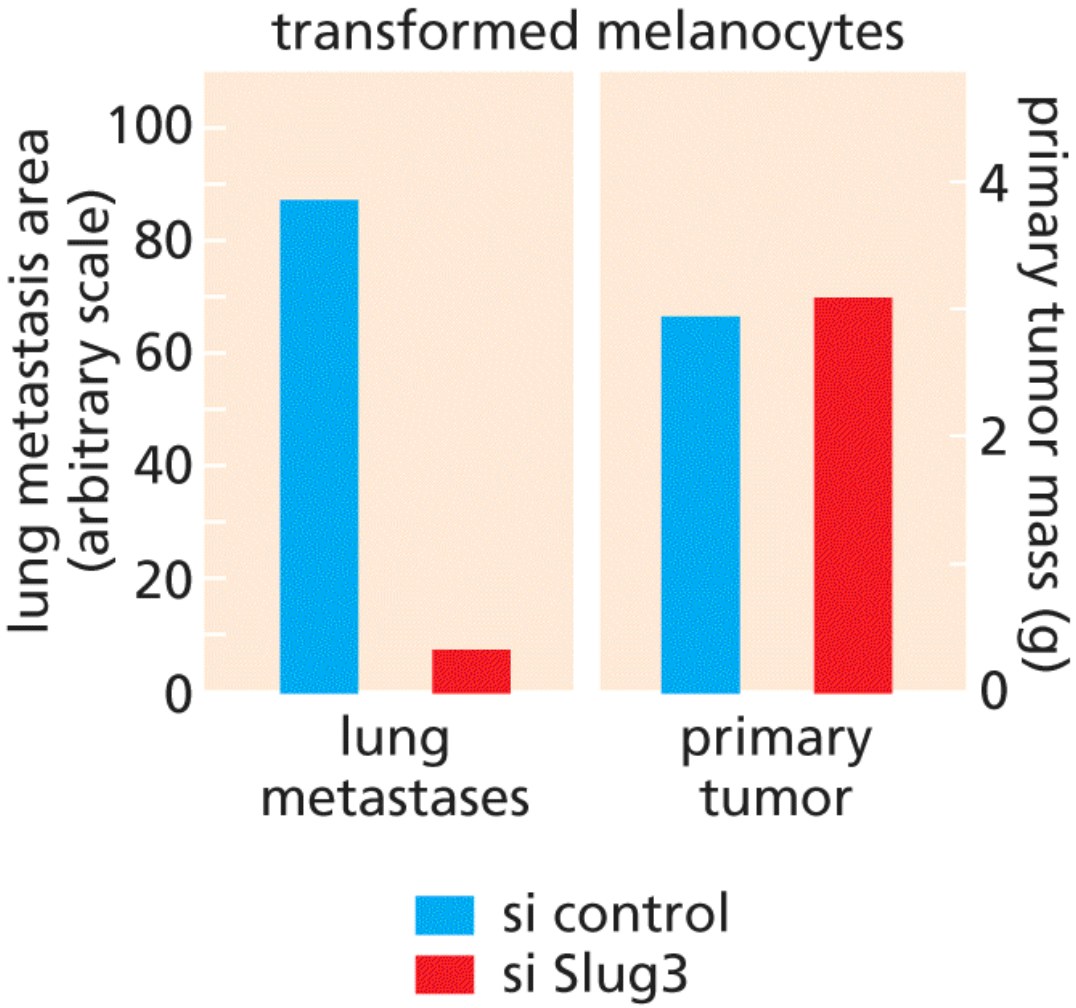
In fact, some research shows that EMT-TF function is *necessary* for efficient metastasis. Thus, in one set of experiments, expression by carcinoma cells of either the Twist1 or the Slug EMT-TF was suppressed through the use of siRNA constructs. As seen in **Figure 14.26A and B**, suppression of Twist1 expression in mammary carcinoma cells or of Slug in melanoma cells resulted, in both cases, in significant

decreases in the lung metastases formed by primary tumors. In the experiment involving Twist (see Figure 14.26A), the few metastases that formed following siRNA-mediated suppression of Twist1 were found to have escaped complete Twist shutdown by the siRNA. These experiments address the necessity of EMT in metastatic dissemination of pulmonary metastases from primary tumor sites. A similar outcome was seen when the Zeb1 EMT-TF was shut down in epithelial cells transformed by a combination of forced expression of a receptor and its ligand (Figure 14.26C).



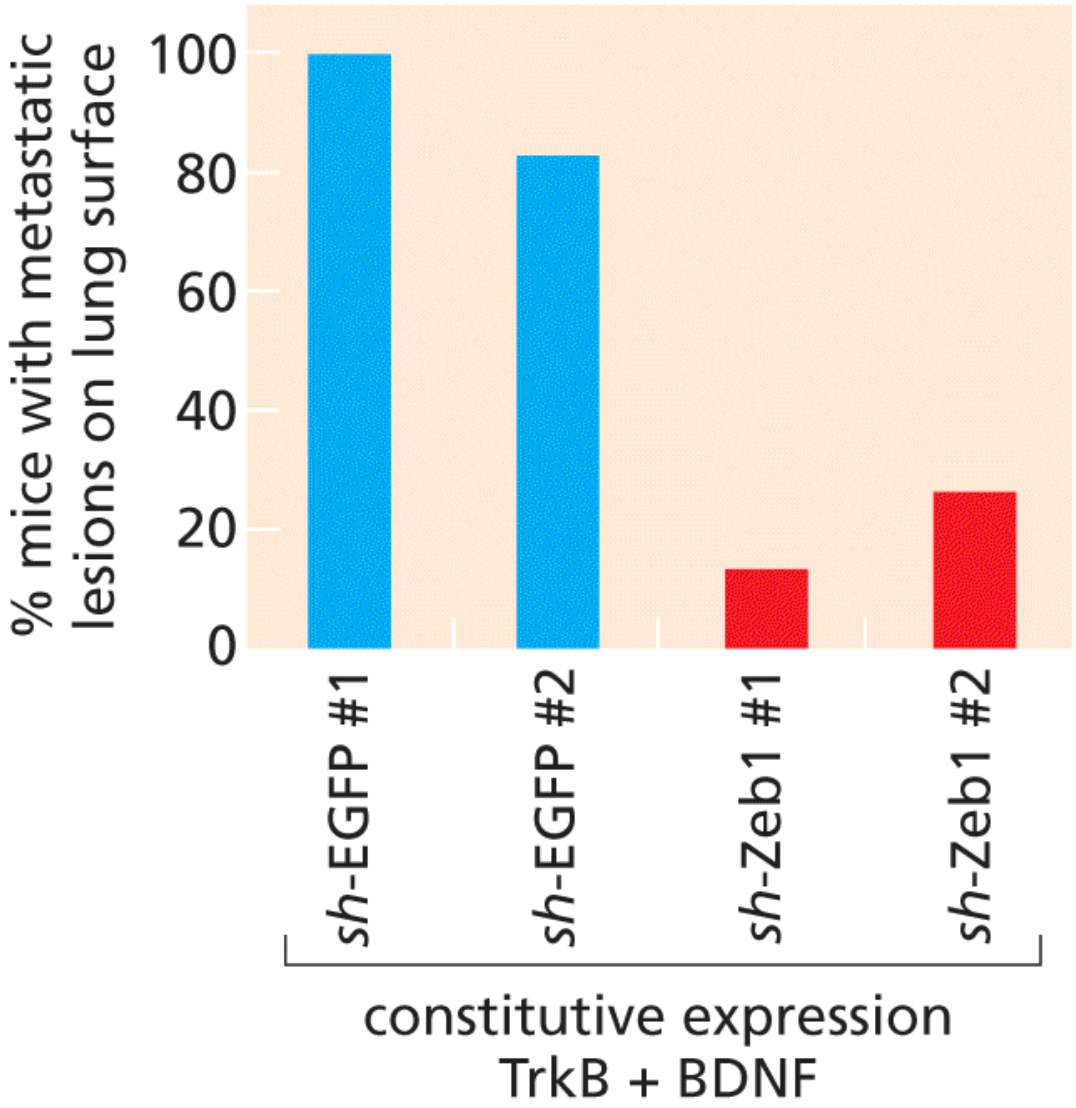
A bar graph that gives the number of metastatic cancer nodules per lung for six 4T1 control-s i R N A cell lines and seven 4T1 Twist-s i R N A cell lines. The average number of nodules was 105 for the control lines and only 14 for the twist lines.

(A)



A bar graph that gives information about two types of transformed melanocytes, namely s i control and s i slug 3. The primary tumor mass was about 3 grams in both cases, but the control cells generated far more metastases into the lungs.

(B)



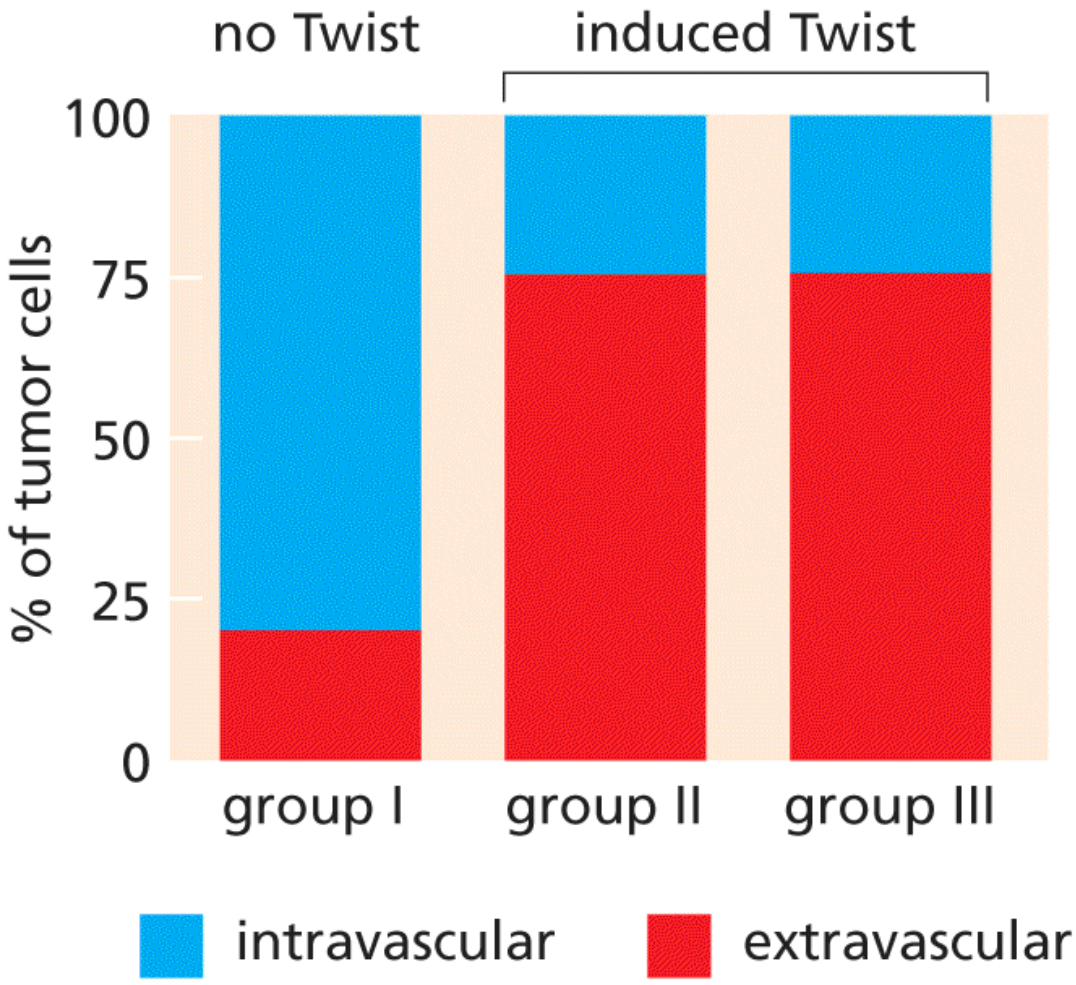
A bar graph that gives the percent of mice with metastatic lesions on lung surface for four different cell lines, all characterized by constitutive expression of T r k B and B D N F. The percentage was 100 percent for s h-E G F P number 1, 80 percent for s h-E G F P number 2, 10 percent for s h-Z e b 1 number 1, and 30 percent for s h-Z e b 1 number 2.

(C)

Figure 14.26 Dependence of metastasis in mouse models on EMT-inducing TFs (A) 4T1 mouse mammary carcinoma cells are usually highly metastatic following implantation in the orthotopic site—the mammary gland (*blue bars*). However, when these cells were infected with a retrovirus vector specifying a potent siRNA directed against the Twist EMT-TF, primary tumors grew as rapidly

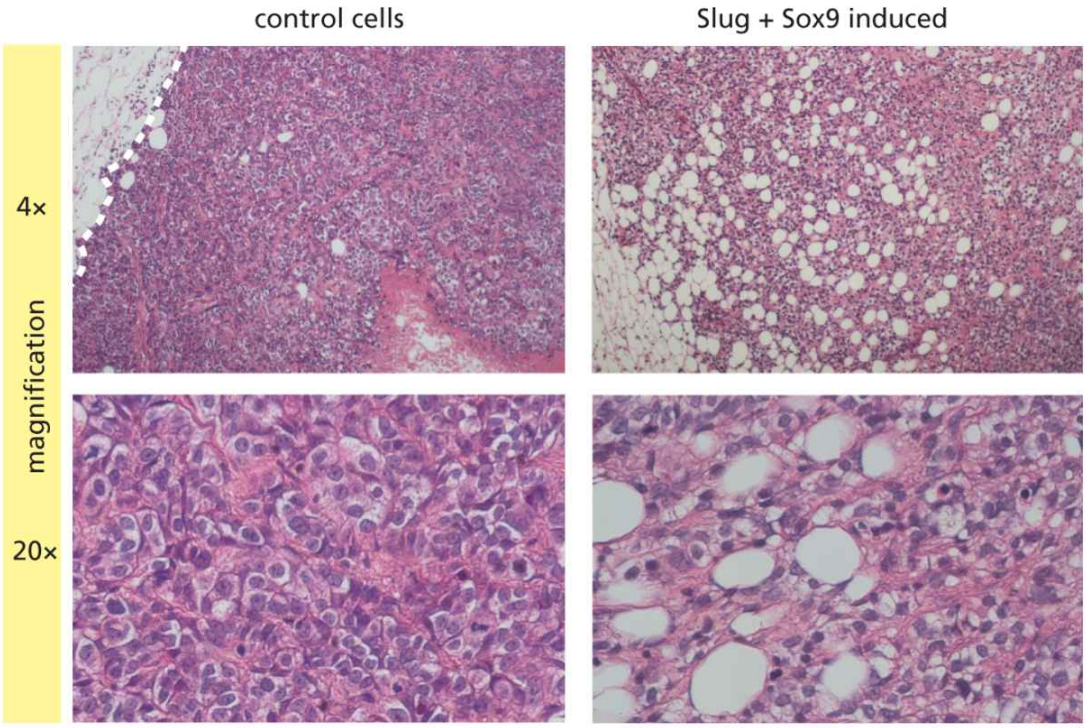
as before, but metastases to the lungs were reduced by ∼85%. The residual metastases expressed significant levels of Twist, indicating that they derived from primary tumor cells in which Twist expression had not been successfully knocked down (*red bars*). (B) Experimentally transformed human melanocytes were found to express high levels of the Slug EMT-inducing TF. When these cells were implanted in a subcutaneous site, they generated large numbers of lung metastases. However, when an siRNA was expressed that reduced Slug mRNA levels by 80%, the number of pulmonary metastases decreased by ∼90%, while the growth of the corresponding primary tumors was hardly affected. (C) Rat epithelial cells were transformed by forced constitutive expression of both TrkB (a tyrosine kinase receptor) and its ligand, BDNF, achieved in both cases by retrovirus vectors. The number of mice bearing subcutaneously implanted TrkB-transformed cells was reduced significantly by anti-ZEB1 shRNA relative to those bearing tumors expressing control (anti-EGFP) shRNAs. (A, from J. Yang et al., *Cell* 117:927–939, 2004. With permission from Elsevier. B, from P.B. Gupta et al., *Nat. Genet*. 37:1047–1054, 2005. C, from M.A. Smit and D.S. Peeper, *Oncogene* 30:3735–3744, 2011. Both with permission from Nature.)

Experiments like those of Figure 14.26 do not address whether expression of EMT-TFs is *sufficient* to trigger the latter steps of the invasion–metastasis cascade. One critical rate-limiting step of metastasis formation is extravasation—escape of cancer cells from microvessels into the parenchyma of nearby tissue (see Figure 14.3). The efficiency of this step can be gauged by injecting cancer cells into the tail vein of a mouse, which results in their rapid trapping in the microvessels of the lungs—the procedure termed “experimental metastasis”. In this instance, extravasation rates can be determined by microscopic examination of lung tissue, specifically by examining whether injected cancer cells remain trapped intraluminally in the microvessels or have escaped into the lung parenchyma. The experiments shown in **Figure 14.27A** reveal that when the tumors cells used in these experiments were injected without any induced EMT-TF, about 20% succeeded in extravasating; however, when expression of the Twist EMT-TF was induced in the tumor cells for a week or more while these cells were still in culture, ∼80% of the subsequently injected cells succeeded in extravasating within 36 hours of tail-vein injection, whether or not Twist expression continued after tail-vein injection. Hence, the process of extravasation, which represents one of the last steps of the invasion-metastasis cascade, is greatly facilitated by the actions of an EMT program.



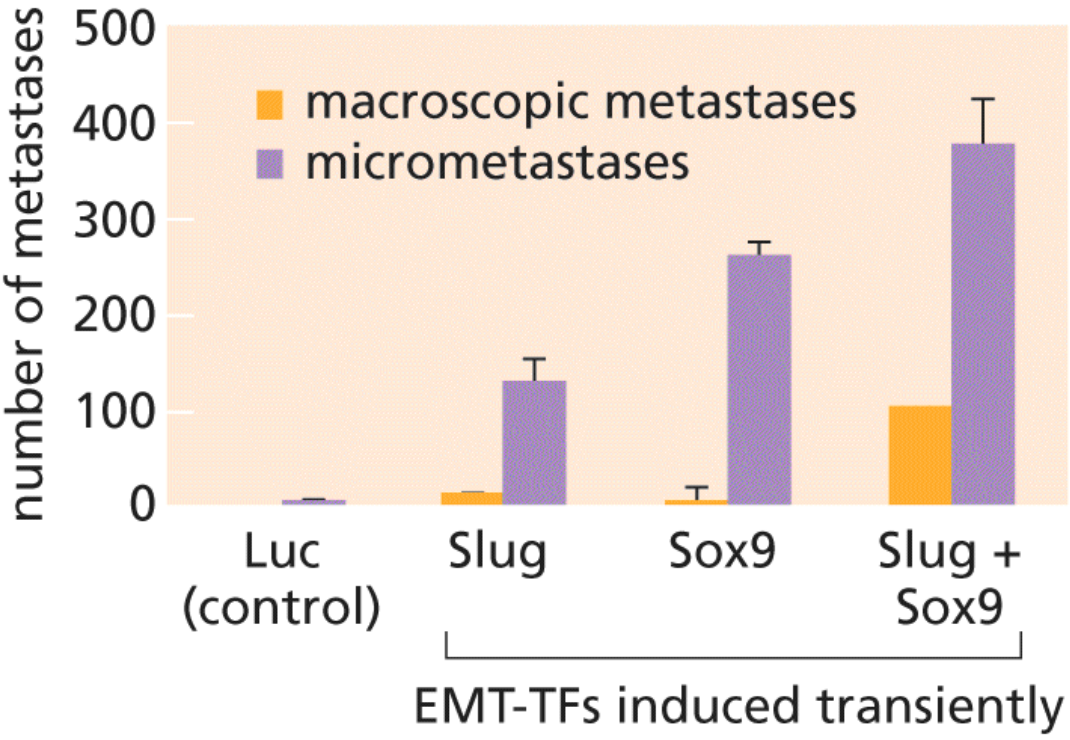
A vertical bar graph that displays the ratio of extravascular to intravascular cells for three different groups of tumor cells. In Group 1, with no twist, less than 20 percent of cells are extravascular. In Groups 2 and 3, both with twist, 75 percent of cells are extravascular.

(A)



Histology stain images of two sets of cancer cells, each at both 4 x and 20 x magnification. On the left, control cells are fairly uniform in texture and have a clear margin where they meet non-cancerous cells. On the right, Slug and Sox9 induced cells have a spongy texture, with many large pores, and a poorly defined margin where they meet non-cancerous cells.

(B)



A vertical bar graph that gives the number of micrometastases and macroscopic metastases for four different cell types, namely Luc (the control), three types with E M T-T Effs induced transiently: Slug, Sox9, and Slug plus Sox9. The number of micrometastases is 0 for Luc, over 100 for Slug, over 250 for Sox9, and over 350 for Slug plus Sox9. The number of macroscopic metastases is low for the first three cell types but jumps to 100 for Slug plus Sox9.

(C)

Figure 14.27 Contributions of EMT-inducing TFs to invasion, extravasation, and metastasis (A) The effects of the Twist EMT-TF specifically on the process of extravasation was tested in a mouse model of cutaneous squamous cell carcinoma. Primary tumor cells were propagated in culture and then injected into the tail vein of a mouse with microscopic monitoring 36 hours later in order to determine whether the carcinoma cells had remained trapped in microvasculature of the lungs or had extravasated into the lung parenchyma. In the absence of any induced Twist expression, ~20% of the cells successfully extravasated (*left bar*). However, if Twist was expressed for a week or more in culture prior to tail-vein injection and was either kept on or shut off after tail-vein injection (achieved through use of an inducible Twist expression construct), ~80% of the carcinoma cells were found to have successfully extravasated (*middle, right bars*). (B) Human breast cancer cells of the MCF7-ras cell line are weakly invasive and

metastatic. Thus 12 weeks after implantation into an immunocompromised mouse host, these cells formed tumors (*left panels*) that had smooth outer margins (*white line, top left panel*) and the absence of histopathological traits that were indicative of invasiveness. In contrast, cells in which the combination of the Slug and Sox9 EMT-TFs was induced for 2 weeks after implantation *in vivo* and then shut down (*right panels*), the tumors that formed 10 weeks later showed invasive margins, indicative of invasion into adjacent adipocyte-rich stromal tissue. Hence, these cells continue to be affected by the actions of the EMT-TFs long after expression of these TFs had been de-induced. (C) Lung metastases were counted 12 weeks after orthotopic implantation of MCF7-ras breast cancer cells. Neither micrometastases nor macroscopic metastases were present in significant numbers in the Luc (control) cells. However, these EMT-TFs, induced either singly or in combination, yielded as many as ∼400 micrometastases and ∼100 macroscopic metastases, demonstrating the powers of the EMT program to drive otherwise-benign primary tumor cells through most of the steps of the invasion–metastasis cascade. (A, from J.H. Tsai, J.L. Donaher, D.A. Murphy et al., *Cancer Cell* 22:725–736, 2012. With permission from Elsevier. B, C, courtesy of Z. Keckesova and J. DeCock.)

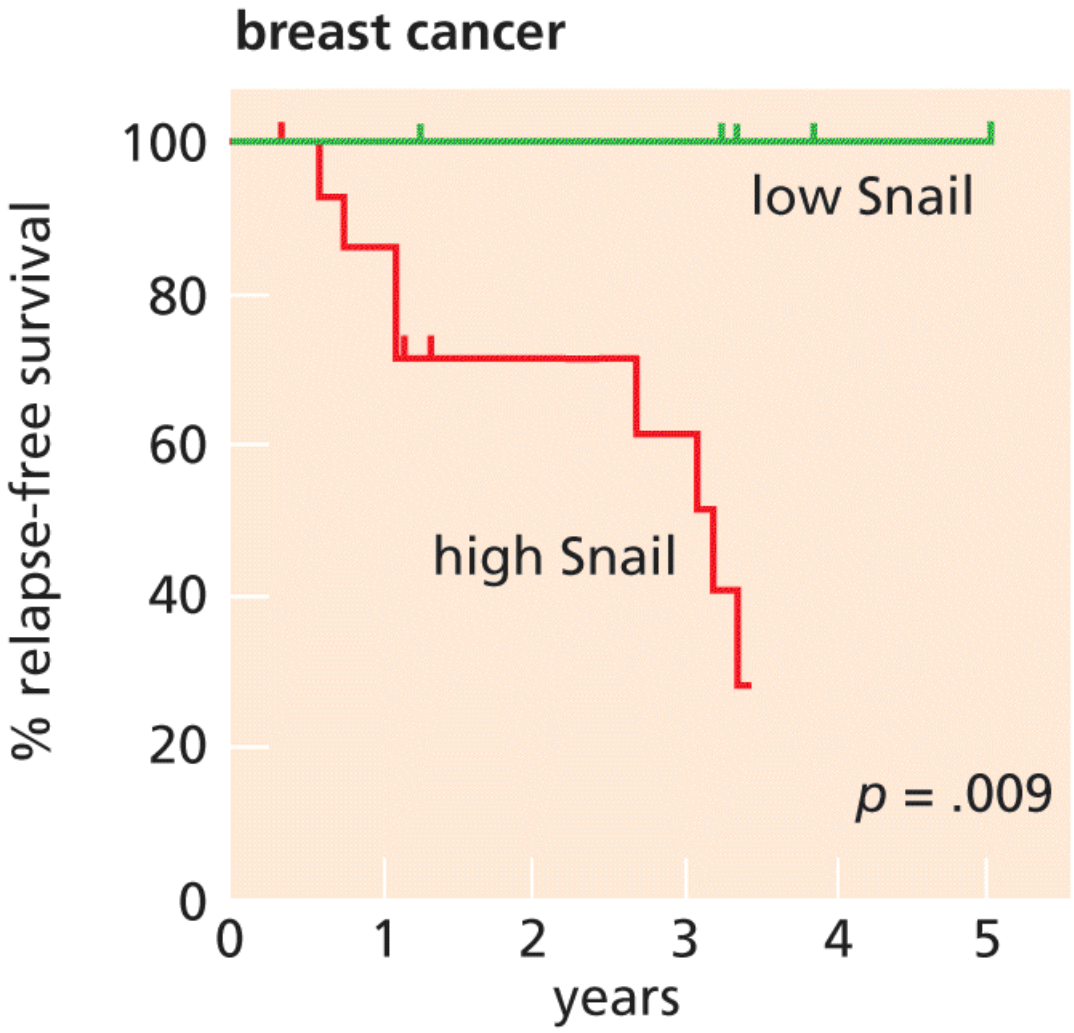
Yet other experiments deal with the larger question of whether expression of EMT-TFs and resulting induction of EMT programs is, on its own, *sufficient* to force otherwise-nonmetastatic human breast cancer cells growing in primary tumors to form metastases and therefore complete most of the steps of the invasion–metastasis cascade. These experiments relied on the reversible induction of the Slug EMT-TF together with a second TF, Sox9; this pair of transcription factors had been previously found to induce stemness of normal mouse mammary epithelial cells, as illustrated in Figure 14.25C. Expression of this pair of TFs was induced in orthotopically implanted tumors (that is, in this case in mammary stromal fat pads) for 2 weeks, after which their expression was shut down and the tumor-bearing mice were observed for another 10 weeks.

Figure 14.27B reveals that control cells (Luciferase), in which expression of the two TFs had not been induced, formed primary tumors at the end of the 12-week experiment that exhibited smooth outer edges, indicative of a lack of invasiveness, as well as harboring cells with more epithelial cell morphologies. In contrast, the tumor cells that had been exposed 10 weeks earlier to the two TFs generated tumors whose outer edges were highly invasive; also, the associated individual carcinoma cells were more mesenchymal in morphology. Hence, once an EMT had been induced in these cells, their descendants “remembered” the effects of the induced EMT-TFs 10 weeks later, even in the absence of ongoing induction of the TFs that had initially triggered the EMT. This result indicated that once an EMT program had been induced, its effects

were transmitted in a cell-heritable fashion to its lineal descendants and maintained during the subsequent long period of cell proliferation and tumor growth, ostensibly under the auspices of self-reinforcing positive-feedback loops such as those driven by autocrine signaling. Of even greater interest were the lung metastases that were spawned by the subcutaneously implanted primary tumor cells. As shown in Figure 14.27C, the parental control cells generated essentially no metastases, while the cells that had experienced transient Slug + Sox9 expression formed almost 400 micrometastases and almost 100 macroscopic metastases.

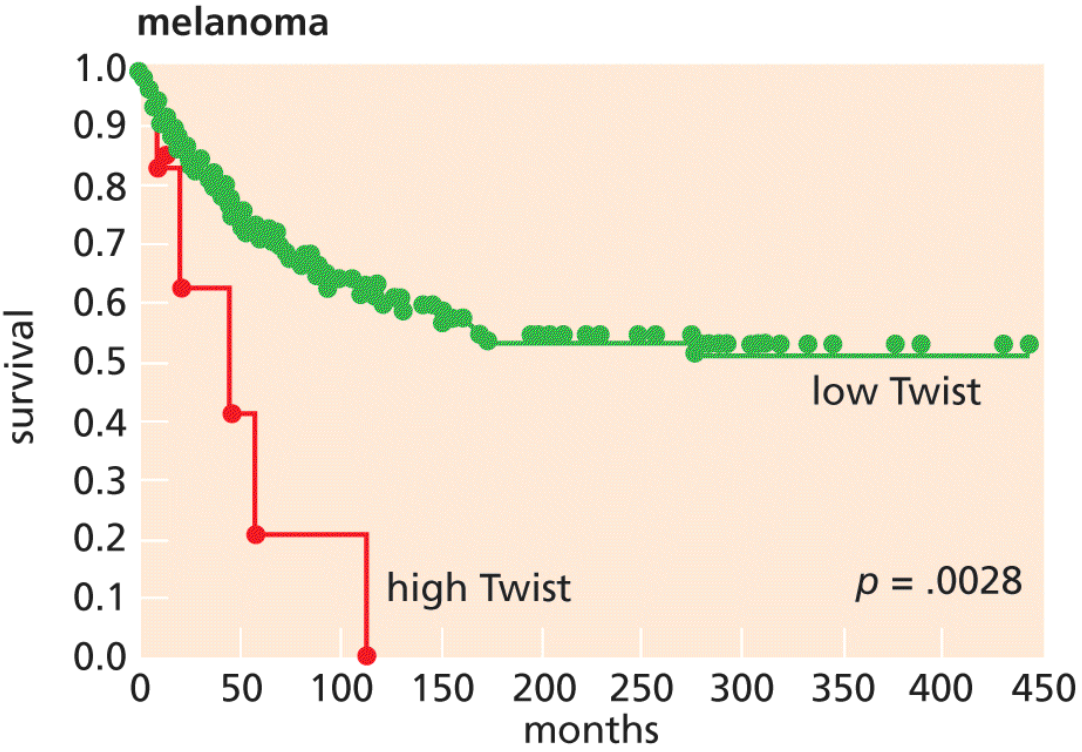
Preclinical studies like these and others not shown here, all of which have been conducted in mice, provide compelling evidence that expression of an EMT program enables primary cancer cells to complete almost all the steps of the invasion–metastasis cascade illustrated in Figure 14.3. Included among these are the steps of localized invasion, the formation of circulating tumors cells (CTCs) that results from intravasation, subsequent extravasation, and the formation of micrometastases. Although the experiments described in Figure 14.27B indicate that macroscopic metastases, which result from the process of colonization, could be accomplished by expression of an EMT program, as discussed further below, execution of this final step of the cascade cannot generally be achieved simply by expression of an EMT program. Nonetheless, these various experiments reveal that, at the very least, EMT programs can physically convey carcinoma cells from the confines of a primary tumor into the parenchyma of a distant tissue; the execution of the last step of the invasion–metastasis cascade (see Figure 14.3), entails unrelated, complex phenotypic shifts that we will encounter later in this chapter.

Reassuringly, the results of the experiments described here have correlates in the observations of human cancer patients occurring in the oncology clinic. As seen in a variety of carcinomas, expression of the Snail, Twist, and Slug EMT-TFs in primary tumors is associated with poor prognoses in at least four types of human carcinomas (**Figure 14.28**). These studies and others like them provide confidence that our discussions in this chapter, focused for historical reasons largely on breast cancer, will eventually prove applicable to a broad range of human carcinomas, possibly all of them. Moreover, the strong effects of EMT, as indicated by the expression of EMT-TFs and EMT phenotype (Figure 14.28D), validate the use of mouse models of carcinoma progression for understanding human cancer pathogenesis.



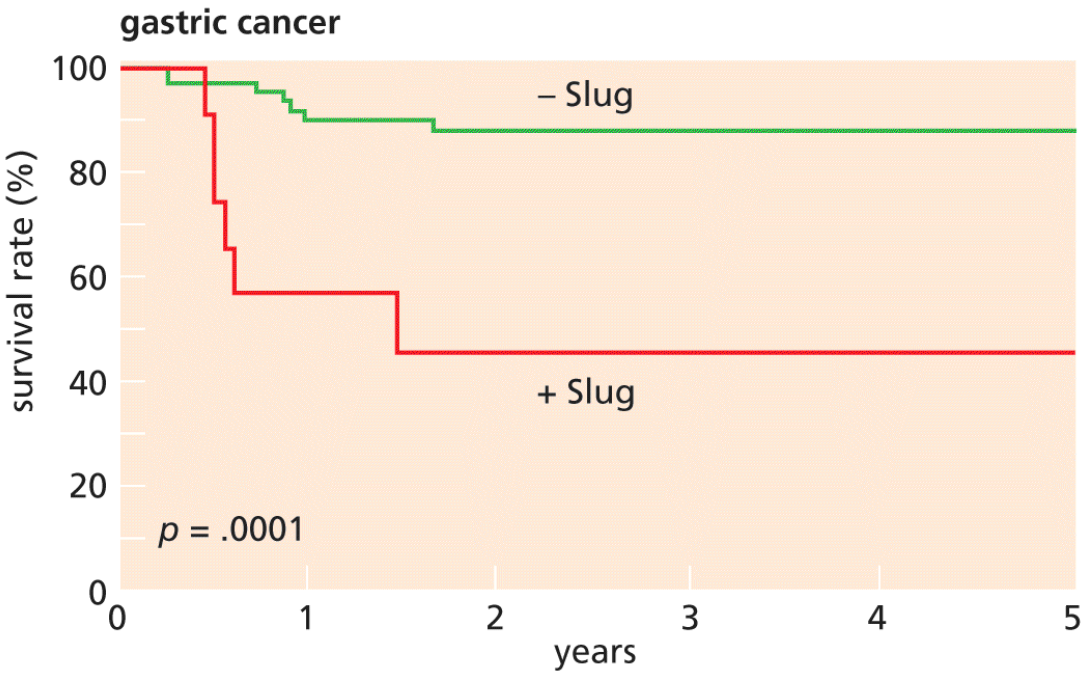
A line graph showing that the percent of relapse-free survival of breast cancer remains at 100 out to 5 years for patients with low Snail, but drops to nearly 20 percent in about 3 years for patients with high Snail.

(A)



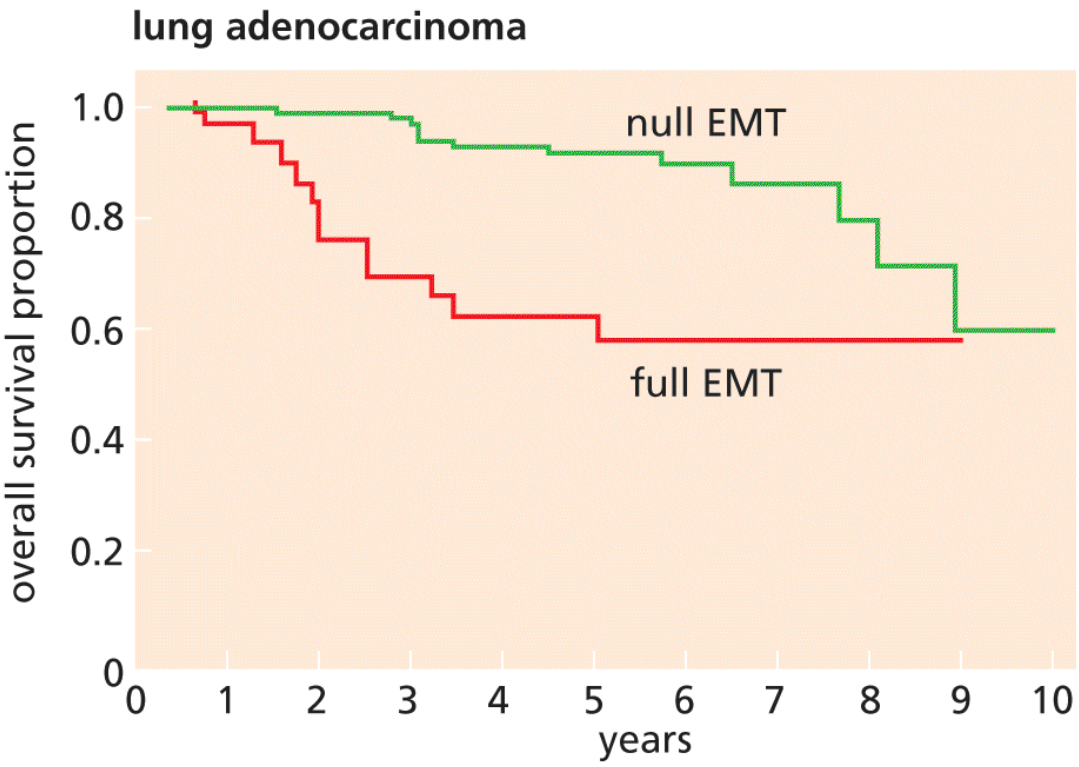
A line graph showing that the percent of relapse-free survival of melanoma in patients with low Twist declines from 100 percent down to about 50 percent ir 300 months and remains there out to 450 months. For patients with high twist, the percent declines sharply from 100 down to 0 within 120 months.

(B)



A line graph showing that the survival rate with gastric cancer remains near 9(percent out to 5 years for Slug negative patients, but drops below 50 percent in less than 2 years for Slug positive patients.

(C)



A line graph showing that the overall survival proportion from lung adenocarcinoma after 6 years is around 90 percent for null E M T patients and around 60 percent for full E M T patients. The proportion at 10 years is 60 percent for both patient types.

(D)

Figure 14.28 Indications of the role of EMT-inducing transcription factors in human tumor progression Increasing evidence correlates the expression of EMT-inducing TFs with the induction of malignant behavior in cancer cells in patients. (A) Among a group of women with locally advanced breast cancers (tumors that appeared histologically to be aggressive without evidence of disseminated disease), those whose tumors expressed either high or low levels of Snail were followed for a period of 5 years after initial surgery. The percentage of women who enjoyed relapse-free survival varied dramatically, depending on whether or not the carcinoma cells in their primary tumors expressed high levels of the Snail EMT-TF protein. (B) Sections of primary melanomas were immunostained for Twist EMT-TF expression and correlated retrospectively with the long-term survival of the patients bearing these tumors. (C) Shown are the postoperative survival rates for stomach cancer patients whose primary tumors retained detectable E-cadherin expression together with or in the absence of Slug EMT-TF expression. (D) The clinical progression of patients suffering from lung

adenocarcinomas was tracked following their initial presentation in the oncology clinic. Patients whose tumors were CD133-negative (a stem cell marker) were classified into two groups: null EMT–E-cadherin-positive, vimentin-negative; or Full EMT (E-cadherin-negative, vimentin-positive.) (A, from S.E. Moody et al., *Cancer Cell* 8:197–209, 2005. With permission from Elsevier. B, from K. Hoek et al., *Cancer Res*. 64:5270–5282, 2004. With permission from American Association for Cancer Research. C, from Y. Uchikado et al., *Gastric Cancer* 14:41–49, 2011. With permission from Springer. D, from T. Sowa, T. Menju, M. Sonobe et al., *Cancer Med*. 4:1853–1862, 2015. With permission from John Wiley & Sons.)

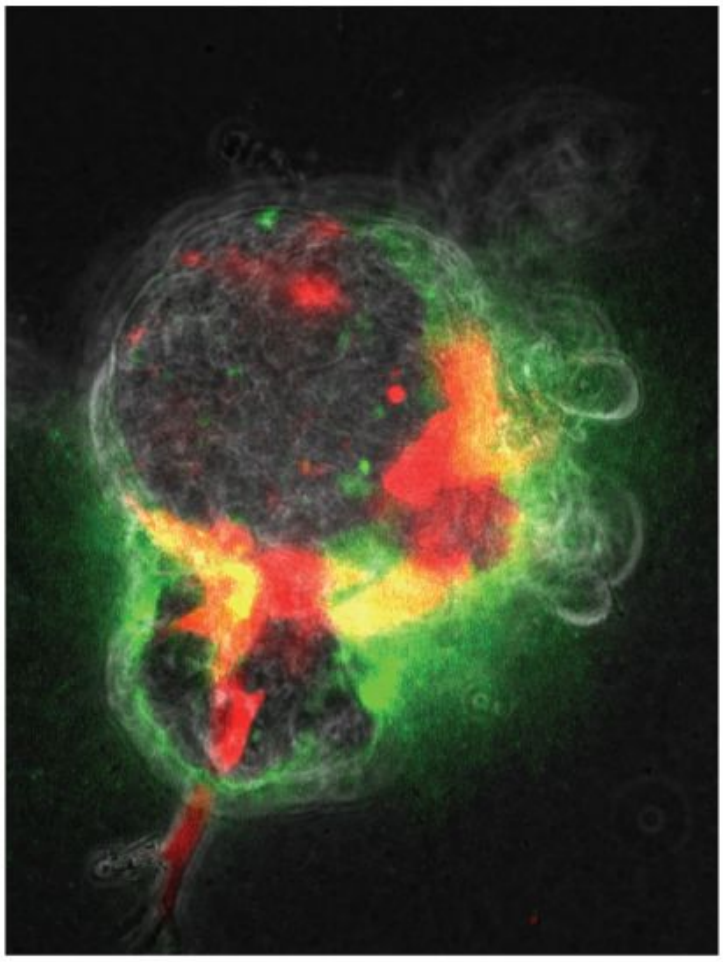
To summarize, the discovery of the EMT-inducing TFs and the mechanisms that control their expression suggest at least three important ideas about malignant progression. First, many malignant cell phenotypes, notably those displayed by carcinoma cells, may be induced by *nongenetic* changes—heterotypic signals of stromal origin—rather than somatically acquired genetic changes occurring within carcinoma cell genomes; hence the cells within primary tumors may already possess the genetic alterations required for dissemination and therefore only require activation of an EMT program in order to spread to distant sites (**Supplementary Sidebar 14.6**). Second, because expression of these TFs and the resulting EMT is often dependent on heterotypic signaling from the reactive stroma of primary tumors, carcinoma cells may revert from a more mesenchymal state to an epithelial state once they have left the primary tumor and encounter the normal stromal microenvironments present in sites of metastasis; by definition, such normal stromata do not release the heterotypic signals that can induce activation of EMT programs in nearby carcinoma cells. Third, cancer cells do not need to cobble together all of the phenotypes associated with highly malignant cells by acquiring multiple mutant genes or activating multiple cell-biological programs; instead, many of the malignancy-associated traits enabling completion of most of the steps of the invasion–metastasis cascade can be acquired concomitantly through the actions of a single cell-biological program—the EMT.

OceanofPDF.com

14.8 The invasiveness of carcinoma cells depends on clearance of obstructing ECM

The discussions of EMT programs and the TFs that induce them have overlooked the individual steps of the invasion–metastasis cascade that yield the final products—fully formed, life-threatening metastases. So, now we backtrack to revisit these steps and revisit how they are manifested in aggressive primary tumors cells. To begin, and as cited on multiple occasions earlier, among the critical consequences of EMT activation are its effects on the invasiveness of carcinoma cells. This invasiveness plays critical roles in enabling islands of primary carcinoma cells to invade the nearby stroma (see Figure 14.5), to intravasate (see Figure 14.23) and, following lymphatic and hematogenous dissemination, to extravasate into the parenchyma of distant tissues (see Figure 14.27A). The observed invasiveness is, in turn, the product of two distinct but closely coordinated cellular processes: the dissolution of extracellular matrix (ECM) that would otherwise obstruct the forward march of invading tumor cells, operating together with the acquisition of motility by these cells, which enables them to enter the spaces created by localized degradation of the ECM. Both processes are critical to the burrowing of cancer cells into adjacent parenchymal tissues.

The most important EMT effectors responsible for excavating space for invading cancer cells are the matrix metalloproteinases (MMPs; see Table 13.1). In carcinomas, the bulk of these proteases are secreted by recruited stromal cells, notably macrophages, mast cells, and fibroblasts, rather than by the neoplastic epithelial cells themselves (**Figure 14.29**). By dissolving the dense thickets of ECM molecules that surround and confine carcinoma cells within tissues (see Figure 14.7A), these secreted MMPs excavate spaces for these cells to advance forward. Included among the ECM components that are cleaved by MMPs are fibronectin, tenascin, laminin, collagens, and proteoglycans. (The loss of metastatic ability observed in the absence of macrophages, as seen in Figure 14.21D, can be ascribed to the absence of the MMPs that are usually essential for metastatic dissemination.) Of note, these MMPs are also critical for nonpathological processes, such as the neoangiogenesis that enables endothelial cells present at the tips of growing capillaries to invade into tissues that require vascularization; similar dynamics seem to apply to the growing extensions of mammary ducts into the mammary stromal fat pad (see Figure 14.25C).



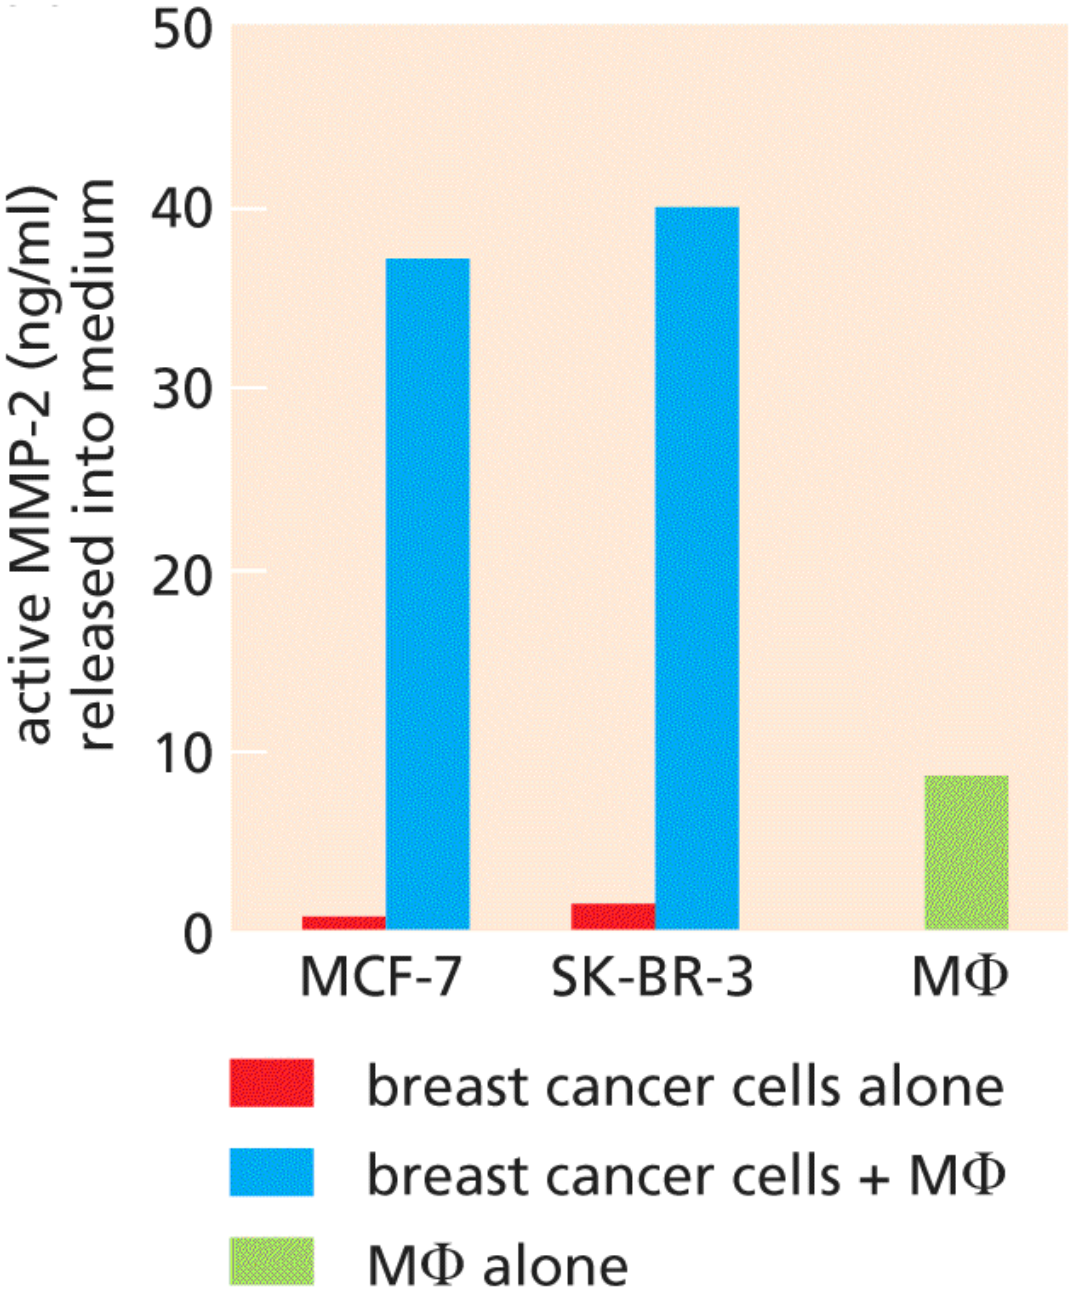
cleaved collagen IV

normal fibroblasts

overlap: fibroblasts
+ cleaved Col IV

A fluorescence microscopy image of a globular tissue clump in which cleaved collagen I V is green, normal fibroblasts are red, and the overlap of the two appears as yellow.

(A)



A bar graph showing the amount of active M M P-2 released into growth medium by five cell colony types or combinations. For M C F-7 and S K-B R-3, the amount of active M M P-2 was very low. For the same two cell lines combined with macrophages, the amount was much higher, around 37 to 40 nanograms per milliliter. For macrophages alone, the amount was moderate, around 9 nanograms per milliliter.

(B)

Figure 14.29 Matrix metalloproteinases produced by tumor-associated stromal cells (A) The ability of tumors to degrade collagen IV, a key component of the basement membrane, can be measured by generating a modified collagen IV substrate that fluoresces *green* upon cleavage. In this experiment, human mammary carcinoma cells (*not seen*) and human mammary fibroblasts (*red*) showed relatively weak ability to degrade the collagen IV substrate when these two cell populations were cultured on their own. However, when these two cell populations were co-cultured, regions of collagen IV cleavage (*green*) were evident, often in areas where fibroblasts were also present (*yellow*: *overlap of green and red*). This cleavage was essentially eliminated in the presence of MMP inhibitors (*not shown*). (B) An even more important source of MMPs is the macrophages (MΦs) that are recruited into the tumor stroma. In this *in vitro* experiment, the presence of MMP-2 was measured in the culture medium of MΦs that were cultured alone (*green*) or together with either of two human breast cancer cell lines—MCF-7 or SK-BR-3. Neither of these cancer cell types released significant levels of MMP-2 on its own (*red*), but in the presence of MΦs (*blue*), the production and release of MMP-2 increased 4- to 5-fold. (The increase could be traced to the induction of MMP-2 mRNA expression by the MΦs, *not shown*.) The released MMP-2 imparted increased invasiveness to these breast cancer cells (*not shown*). (A, from M. Sameni et al., *Mol. Imaging* 2:159–175, 2003. With permission from SAGE. B, from T. Hagemann et al., *Carcinogenesis* 25:1543–1549, 2004. With permission from Oxford University Press.)

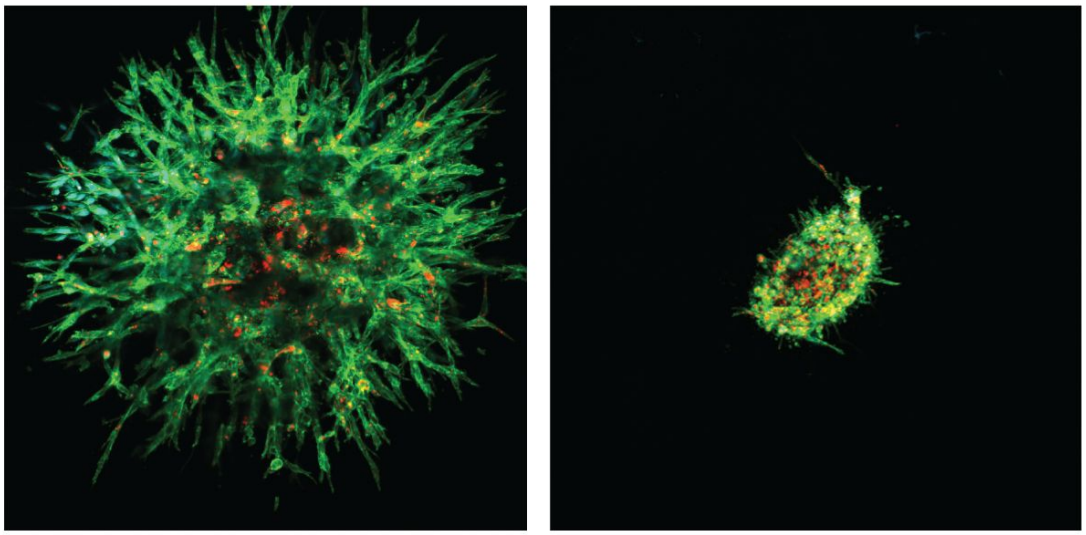
During the course of degrading ECM components, MMPs also mobilize and activate certain growth factors that have been tethered in inactive form to the ECM or to the surfaces of cells. These actions are actually directly intertwined with the control of EMT programs: On the one hand, EMT-induced transcriptomes include mRNAs encoding an array of secreted MMPs, such as MMP-2 and MMP-9. On the other, these MMPs act in the intercellular space to cleave the ectodomains of E-cadherin molecules and to activate previously latent TGF-β; both of these actions stimulate, in turn, the expression of EMT-TFs, creating self-reinforcing, positive-feedback loops that help to sustain expression of EMT programs in cells that have initiated components of these programs.

Complementing these secreted MMPs is a critically important one—MT1-MMP (membrane type-1 MMP)—that remains tethered directly to the plasma membrane surfaces of cancer cells and is wielded by them in order to cleave cell ECM components, cell surface adhesion molecules (for example, cadherins and integrins), as well as growth factor receptors and chemokines. Most importantly, MT1-MMP can also cleave inactive pro-enzymes, such as pro-MMP-2, into enzymatically active MMP isoforms. By activating soluble, diffusible MMPs like MMP-2, MT1-MMP can amplify and extend its proteolytic effects to regions in the pericellular space that are

not immediately adjacent to the cell surface of cancer cells. (MT1-MMP is one of six MMPs that are membrane-anchored and therefore limited to cleaving substrate proteins in the immediate vicinity of the cells that produce them.) Taken together, these properties explain how ectopic expression of MT1-MMP, acting via its downstream MMP effectors, can induce EMTs in cultured epithelial cells.

As we have read, the initial steps of invasion by a carcinoma cell are obstructed by the basement membrane (BM), which may have pores as small as 40 nm in diameter (see Figure 13.10). Although cells can distort their cytoplasms in order to squeeze through small openings, their nuclei are relatively rigid and thus govern the size of the smallest pores through which cells can pass. Cell nuclei are generally in the size range of 3 to 10 μm, about 100 times larger than the pores in the BM; this explains why dissolution of the BM is critical to carcinoma cell invasion (see also Figure 14.4).

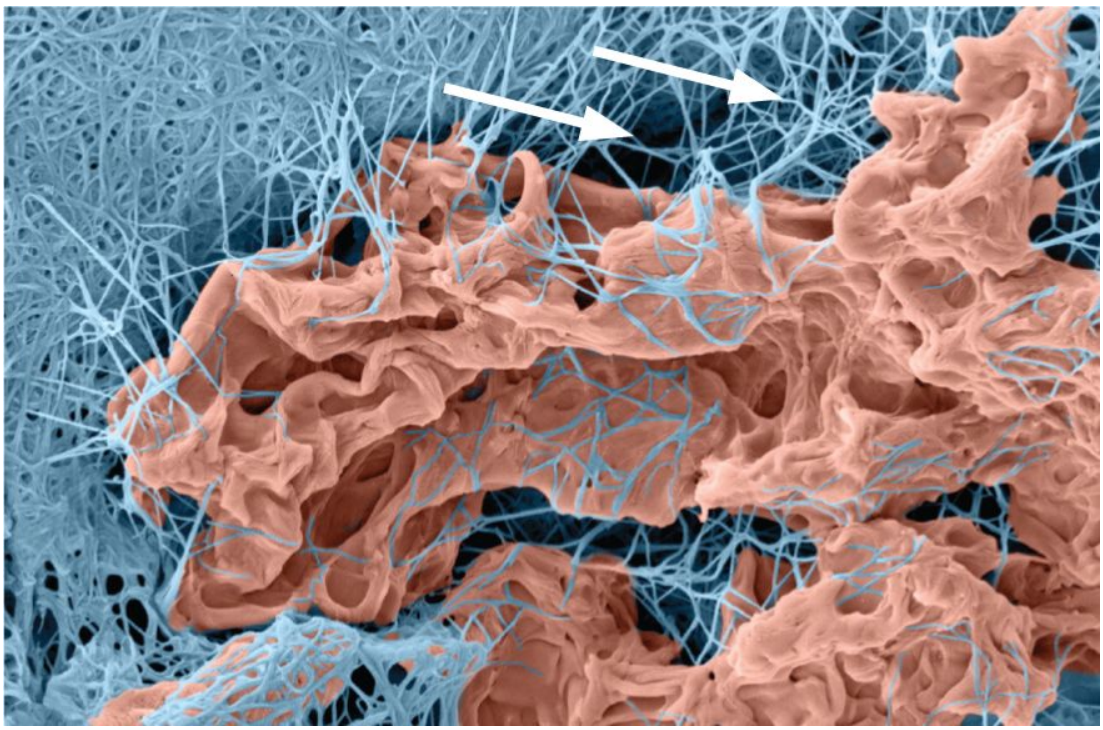
The activities of MT1-MMP, which plays a leading role in BM breakdown, seem to be confined through its concentration at discrete cell surface foci, initially termed **podosomes** but increasingly called invadopodia because of the involvement of these structures in cancer cell invasion (**Figure 14.30**). Early in malignant progression, MT1-MMP displayed on the surface of carcinoma cells can cleave collagen type IV, the collagen that imparts rigidity to the basement membrane (BM; see Figures 2.3 and 13.10). The resulting weakening of the BM allows cancer cells to begin invading the underlying stroma (see Figure 14.4). Once in the stroma, an invading carcinoma cell confronts a dense network of cross-linked collagen type I fibers that obstructs further advance (see Figure 14.30B); here, MT1-MMP once again plays a central role. It initiates collagen I degradation and then recruits an inactive pro-enzyme (pro-MMP-2) of stromal origin, which it activates by cleavage as mentioned above (**Figure 14.31**). The resulting active MMP-2 then operates in the peri-cellular space to further reduce collagen I into lower–molecular-weight fragments. Without these proteolytic steps, the dense networks of collagen I fibers that are present in the stromal ECM totally block cancer cell invasion.



control siRNA anti-MT1-MMP siRNA

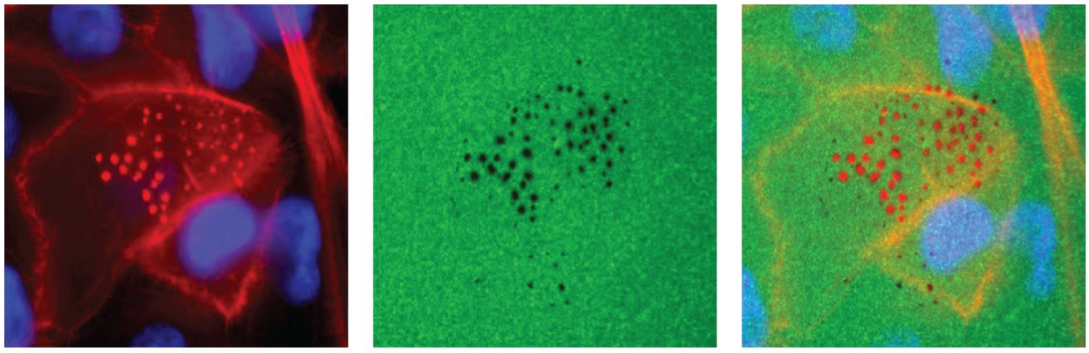
Two fluorescence microscopy images. The first is of a large round burst of green spikes and tendrils, labeled control s i R N A. The second is of a small, concentrated fuzzy green oval shape, labeled anti-M T 1-M M P s i R N A.

(A)



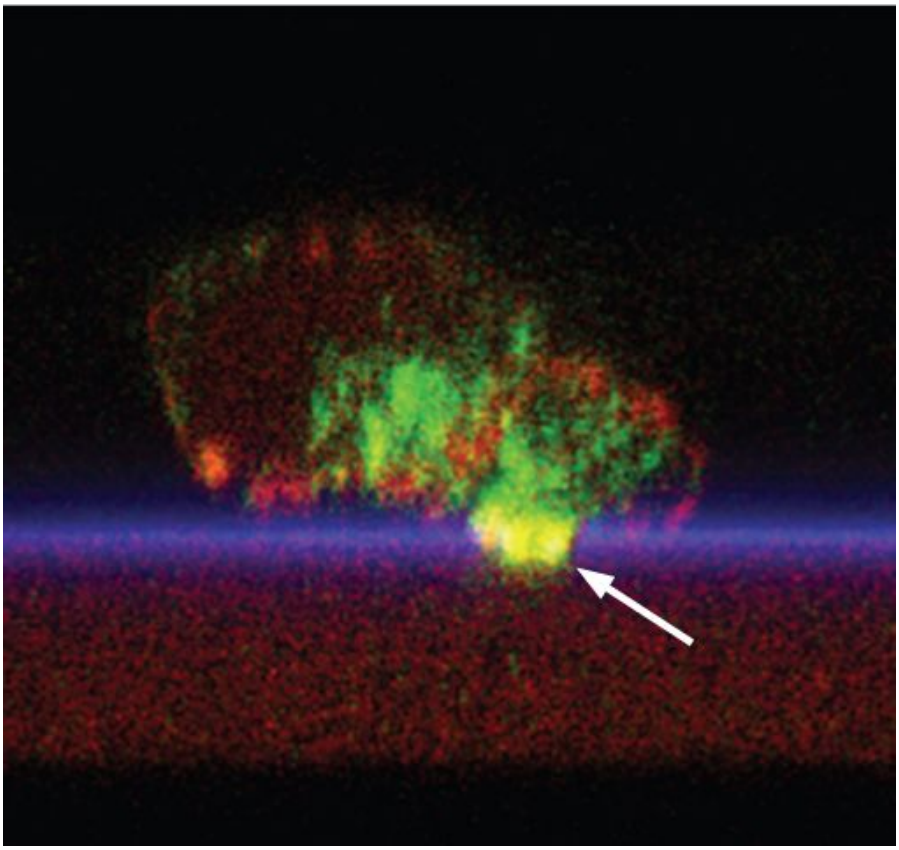
A false-color image of a pink carcinoma enmeshed in a matrix of pale blue collagen fibers, which are denser further away from the carcinoma than where

they touch it.
(B)



Three fluorescence microscopy images. The first, labeled D A P I F actin, shows fibers and dots glowing red amid blue nuclei. The second, labled F I T C gelatin, shows black dots in a field of green. The third image, labled overlap, is a superposition of the first two, showing that the red dots in the first image match the black dots in the second one.

(C)

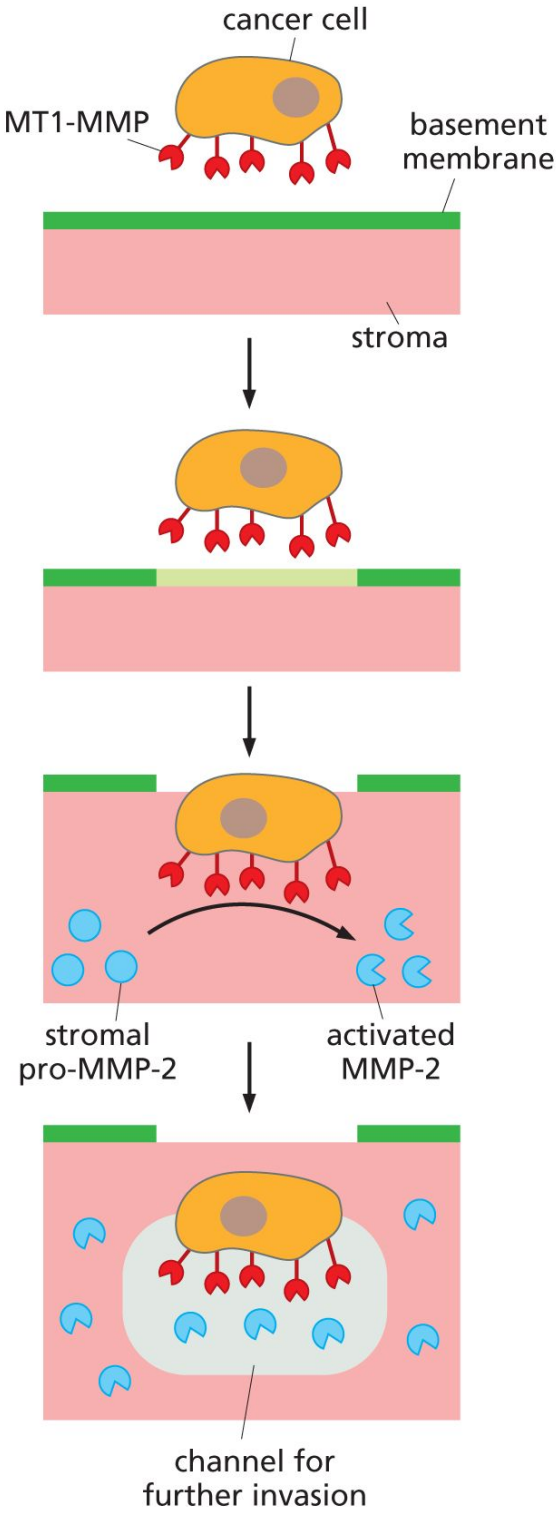


A fluorescence microscopy image in which a yellow and green blob with a fringe of red dots sits mostly above a horizontal blue line that has many tiny red dots below it. A portion of the blob has penetrated down through the blue line.

(D)

Figure 14.30 MT1-MMP, invadopodia, and the degradation of the extracellular matrix Invadopodia, sometimes termed podosomes, are small, focal protrusions from the cell surface that degrade localized areas of extracellular matrix (ECM) in their immediate vicinity. In the case of tumor development, invadopodia are deployed by invasive cancer cells to drive localized, highly controlled degradation of the ECM near the leading edges of these cells. (A) The critical contribution of MT1-MMP, which is tethered to the surface of invadopodia, in cancer cell invasion can be demonstrated *in vitro* through the behavior of HT1080 human fibrosarcoma cells. When these cells, seen here growing as a colony in a 3D matrix of collagen I, were forced to express a control siRNA (*left panel*), they demonstrated a high degree of invasiveness, as indicated by the numerous protruding columns of cancer cells invading the matrix. However, when MT1-MMP production was knocked down through the actions of a specific siRNA, these cells were confined to a small volume surrounding the site at which the founding cell was initially introduced into the matrix. Knockdown of the two secreted metalloproteinases also made by these cells—MMP-1 and MMP-2—had no effect on their invasiveness (*not shown*). Cells were treated with a phalloidin derivative, which labels filamentous actin (*green*), and di-I (3,3-dioctadecyl indocarbocyanine), which stains membranes (*red*). (B) The effects of the proteases produced by the invasive HT1080 cells are seen in fine detail in this scanning electron micrograph in which the collagen I fibers in the ECM have been pseudo-colored *blue* and the fibrosarcoma cells are colorized *pink*. Note that the collagen matrix is dense beyond the immediate vicinity of the fibrosarcoma cells (*top left*), whereas the collagen fibers are sparse in the immediate vicinity of the cells (*arrows, center, right*) from the actions of the proteases, largely and perhaps exclusively the MT1-MMP made by these cells. (C) MT1-MMP is the major protease displayed on invadopodia. These organelles are defined by dense concentrations of filamentous actin, stained here with phalloidin (*red, left panel*) on the ventral surface (i.e., the surface directly apposed to the underlying substrate) of immortalized human mammary epithelial cells; nuclei are labeled with DAPI (*blue*). These immortalized human mammary epithelial cells were plated above a thin matrix of gelatin labeled with FITC dye (*green, middle panel*). The single cell seen in the middle of the left panel has eroded numerous holes (*black dots, middle panel*) in the gelatin (thereby solubilizing FITC) precisely under the focal areas where invadopodia were seen; the overlap between the F-actin foci and the eroded holes in the gelatin is seen here in red (*right panel*).

Formation of these invadopodia was dependent on activation of the Twist EMT-TF as well as expression of the PDGF-Rα that resulted from activation of the EMT program. (D) The invadopodia of a small cluster of cells are visualized from the side (a *z*-axis view) through confocal microscopy. The staining of filamentous actin (*red*) and cortical actin (*green*; see Figure 14.40) overlap in the invadopodia (*yellow*), which are protruding through a layer of the ECM protein fibronectin (*blue*) through which they have eroded an opening (*white arrow*). (A and B, from F. Sabeh et al., *J. Cell Biol*. 185:11–19, 2009. With permission from Rockefeller University Press. C, from M.A. Eckert et al., *Cancer Cell* 19:372–386, 2011. With permission from Elsevier. D, courtesy of S. Vitale and M. Frame; see also S. Vitale et al., *Eur. J. Cell Biol*. 87:569–579, 2008.)



A diagram showing the Collaboration of M T 1-M M P and M M P-2 in carcinoma cell invasion. A cancer cell with numerous M T1-M M P proteases protruding from its underside descends onto a basement membrane. The proteases open a hole in the membrane, through which the cell passes into the underlying stroma.

There, the proteases convert stromal pro-M M P-2 into activated M M P-2. These open up a channel in the stroma for further invasion.

Figure 14.31 Collaboration of MT1-MMP and MMP-2 in carcinoma cell invasion Membrane-tethered proteases, notably MT1-MMP, initially enable carcinoma cells to degrade the basement membrane (*green*) that separates them from the adjacent stroma. Once in direct contact with the stroma (*pink*), MT1-MMP can cleave pro-MMP-2 made by the stromal cells, converting it to an active, soluble protease. MT1-MMP also partially cleaves collagen I, which normally forms a densely interwoven network in the ECM of the stroma; the activated MMP-2 then proceeds to degrade the initially formed collagen I cleavage products to lower–molecular-weight fragments. Dissolving the collagen I network creates a channel immediately in front of the carcinoma cell that allows it to invade more deeply into the stroma.

Membrane-bound and secreted proteases clearly play important roles in normal cell survival and proliferation. After all, each time a cell within a normal tissue goes through a cycle of growth and division, spaces within the ECM must be carved out for its daughters. Once formed, each daughter cell must, in turn, reassemble a new ECM around itself. Hence, the remodeling of the ECM takes place continuously in mitotically active normal tissues. Therefore, rather than being aberrations of invasive cancer cells, the activities of MMPs and other extracellular proteases are part of the program associated with normal cell proliferation. Of relevance here are clinical trials of certain MMP-inhibiting drugs, which were launched in order to curtail cancer cell invasiveness and thus a key aspect of high-grade malignancy. These trials were terminated due to the effects of these inhibitors on a variety of normal tissues; because these agents suppressed the normal ongoing remodeling of cartilage and other components of the ECM in joints, they created unacceptable levels of joint stiffness and pain.

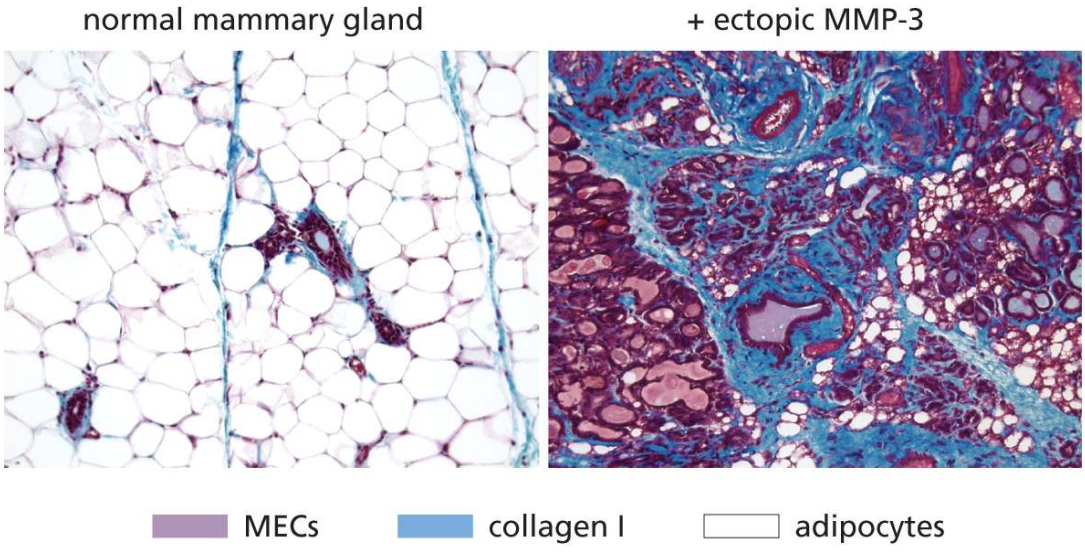
Each type of MMP usually acts on a well-defined set of substrates (see Table 13.1), doing so in a highly regulated and localized fashion. It is likely that these enzymes continue to show such substrate specificity during the process of cancer cell invasion. However, in the case of invasive cancer cells, such proteolysis seems to proceed continuously rather than in the well-controlled, brief spurts that accompany normal cell growth and division.

As cited earlier, many of the MMPs found in tumors originate in various cellular components recruited to the tumor-associated stroma. For example, the best-studied of the matrix metalloproteinases, MMP-9, is expressed largely by the macrophages (see Section 13.5), neutrophils, and fibroblasts that are recruited to the invasive fronts of tumors. MMP-9 expression at these fronts correlates positively with the metastatic ability of a primary tumor, suggesting that MMPs like this one can act at several stages

of the invasion–metastasis cascade, including local invasion of the primary tumor stroma, intravasation, and extravasation, the latter steps described in more detail below. *In vitro* assays indicate that MMP-9 can degrade collagens that are prominent components of the ECM including basement membranes, specifically collagen types IV, V, XI, and XIV. Other targets of MMP-9 include laminin (another key constituent of the basement membrane; see Figure 13.10), chemokines, fibrinogen, and latent TGF-β. In the case of the latter, cleavage by MMPs converts this factor from a latent form into its activated form, as mentioned earlier.

These widely ranging functions of MMPs indicate that their enzymatic activity must be tightly controlled, at least in normal tissues. One critical control mechanism has already been described: Soluble MMPs, such as MMP-2 and MMP-9, are initially synthesized as inactive pro-enzymes that can only function, like the caspases (see Section 9.13), following their activation by other proteases (see, for example, Figure 14.31). Negative regulation is also provided by a class of proteins termed tissue inhibitors of metalloproteinases (TIMPs), which bind MMPs and place them in an inactive configuration.

Although MMPs have been depicted as one of a group of downstream effectors of certain steps in invasion and metastasis, it is clear that the deregulation of MMPs can, on its own, drive the progression of cells through all of the stages of multi-step tumorigenesis including completion of the invasion–metastasis cascade. Thus, when expression of MMP-3 is forced in the mammary gland of transgenic mice, these mice initially develop mammary hyperplasias (**Figure 14.32**). Some of these growths eventually progress to carcinomas that become invasive and metastatic. These mice reveal how critical the regulation of MMP function is and why it must be kept under control in normal tissues.



Two histology stain images pertaining to the Ectopic expression of MMP-3 and mammary tumor progression. On the left is normal mammary gland tissue. The structure is dominated by white globular adipocytes, separated by purple mammary epithelial cells. Two blue lines of collagen 1 fibers run through the image. On the right is tissue positive with ectopic M M P-3. It is much darker and denser, thick with epithelial cells and only a few veins of adipocytes. The center of the image is dominated by a thick tangle of collagen 1 fibers.

Figure 14.32 Ectopic expression of MMP-3 and mammary tumor progression
The normal mouse mammary gland (*left panel*) is composed of resting ducts formed by mammary epithelial cells (MECs, *purple*) and abundant adipose tissue (lipid-filled cells, *white*), as well as collagen fibers (*light blue*). However, when the gene encoding MMP-3 (also known as stromelysin-1) is expressed constitutively as a transgene in the mammary epithelium, the mice develop abundant hyperplasias (*right panel*), including extensive islands of hyperplastic epithelial cells (*purple*) that form ducts, as well as a fibrotic, collagen-rich stroma (*light blue*) and abnormal adipocytes (*white oval structures*, *lower right*). Many of these areas subsequently progress to invasive, metastatic tumors (*not shown*). (From M.D. Sternlicht et al., *Cell* 98:137–146, 1999. With permission from Elsevier.)

These brief vignettes of proteases and their contributions to cancer cell invasiveness describe only small parts of what are surely highly complex networks of interacting proteases, protease inhibitors, and substrates. The total number of proteases made by mammalian cells is vast and rivals the number of proteins that form the highly complex intracellular signal-processing circuits described in Chapter 6. To date, the actions of only a tiny proportion of these enzymes have been studied in the context of cancer pathogenesis (see **Supplementary Sidebar 14.7**).

OceanofPDF.com

Glossary

pro-enzyme
: Catalytically inactive precursor form of an enzyme that requires some type of alteration (often proteolytic cleavage) in order to become catalytically active.

invadopodium
: (pl., **-ia**) An organized structure on the surface of a cell in which plasma membrane–bound proteases degrade adjacent extracellular matrix, apparently to enable subsequent invasion by the cell as a whole. *Sometimes termed* **podosome**.

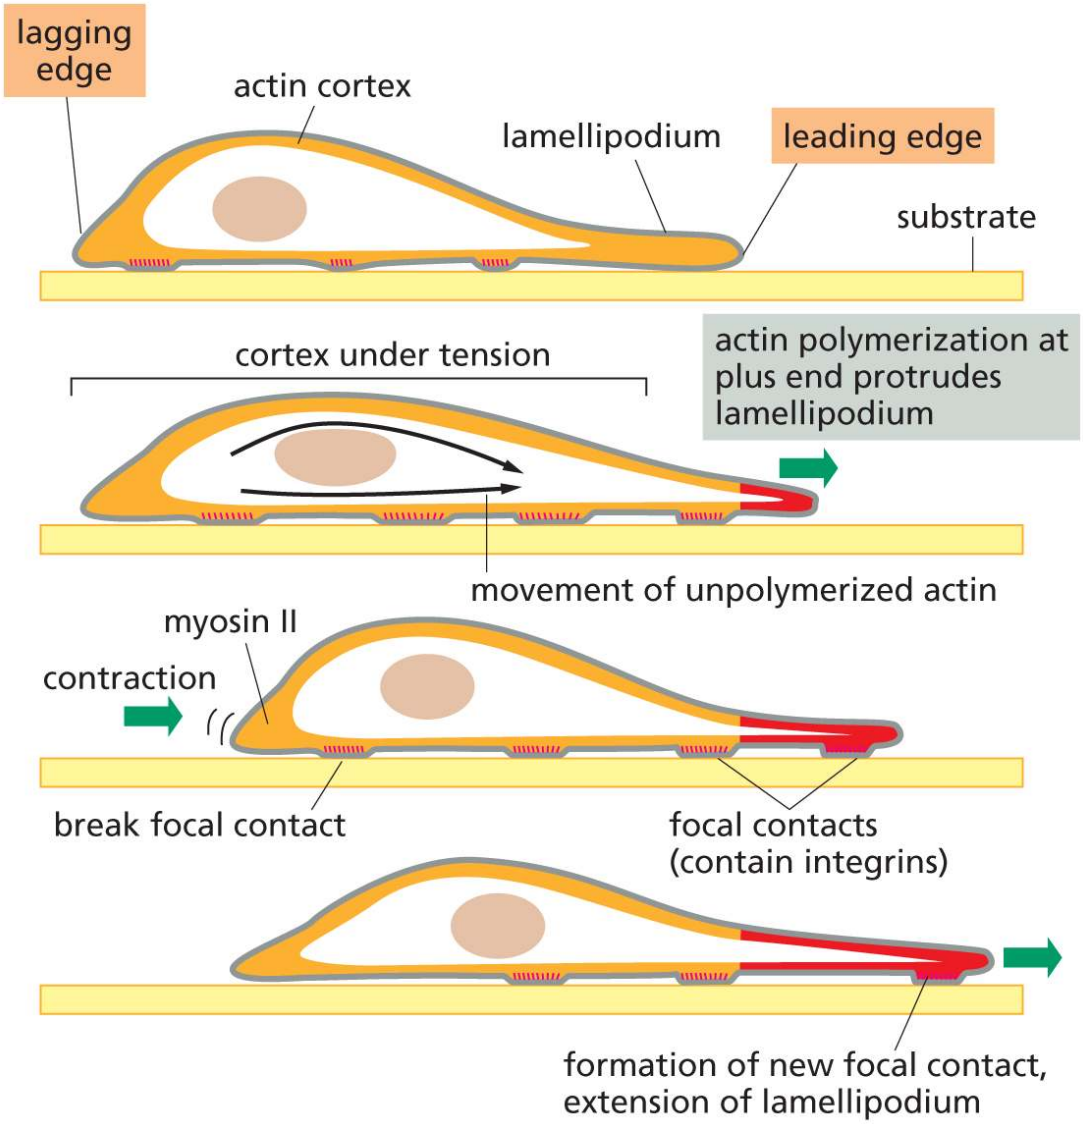
OceanofPDF.com

14.9 Motility enables cancer cells to move into space excavated by MMPs

The actions of extracellular proteases, notably the MMPs, explain at the biochemical level how paths are cleared for the advance of invasive cancer cells through the extracellular matrix and thus through tissues. They fail, however, to tell us how individual cancer cells take advantage of these cleared paths to move ahead—the trait of cell motility. The motile behavior of cells has been studied extensively with cultured cells, and it is presumed that their crawling on solid substrates *in vitro* reflects the *in vivo* behavior of cancer cells as they invade nearby cell layers and intravasate. Such motility is also presumed to be important for cancer cells' escape from blood vessels or lymph ducts—the process of extravasation.

Motile behavior can be induced in cultured cells by exposing them to a variety of growth factors. (Those GFs able to induce such locomotion are sometimes designated as being motogenic in addition to being mitogenic.) In the case of epithelial cells, the most potent inducer of motility is hepatocyte growth factor (HGF); this protein is also called scatter factor (SF) in recognition of its ability to induce multidirectional movement of cells in monolayer culture. Many types of epithelial cells express Met, the receptor for HGF, and such cells have been found to acquire motility in response to HGF treatment. Similarly, EGF is clearly able to induce motility of breast cancer cells.

The cellular machinery that responds to motogenic signals and operates as the engine of motility is extraordinarily complex at the molecular level. Cell motility involves continuous restructuring of the actin cytoskeleton in different parts of a cell, as well as the making and breaking of attachments between the migrating cell and the extracellular matrix (**Figure 14.33**). (In the case of cultured cells, the ECM in question is the network of proteins that has previously been laid down by these cells on the surface of the Petri dish; see Figure 1.11.) The outlines of these complex cellular and molecular mechanisms are described in **Supplementary Sidebars 14.7** and **14.8**.

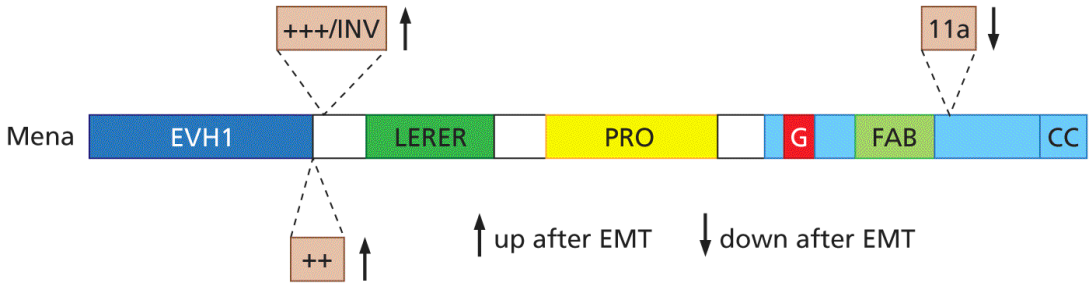


The Locomotion of cells on solid substrates. A cell resting on a flat substrate surface is shown in cross section, with the nucleus and cytoplasm surrounded by an actin cortex. The cell's underside is flat and adheres to the substrate with three focal contacts containing integrins. The high point of the rounded upper surface of the cell is toward the rear, and the lagging edge is blunt. The leading edge is greatly elongated and is labeled lamellipodium. When the cortex comes under tension, unpolymerized actin in the cytoplasm is squeezed forward, and actin polymerization at the plus end protrudes the lamellipodium forward, and a new focal contact with is formed. Myosin 2 brings about contraction of the lagging edge, pulling it forward, and the rearmost focal contact breaks. The cycle then repeats.

Figure 14.33 Locomotion of cells on solid substrates The locomotion of a cultured cell depends on the coordination of a complex series of changes in the cytoskeleton, as well as the making and breaking of focal contacts with the underlying solid substrate. The cell organizes actin fibers at their plus ends in order to extend lamellipodia at its advancing/leading edge and to establish new focal contacts. At the same time, stress fibers, also consisting of actin, are used to contract the lagging/trailing edge of the cell, where focal contacts are being broken. The making and breaking of the focal contacts depend on localized modulation of the affinities of various integrins for extracellular matrix (ECM) components, represented here by the *yellow* substrate. (From B. Alberts et al., *Molecular Biology of the Cell*, 5th ed. New York: Garland Science, 2008.)

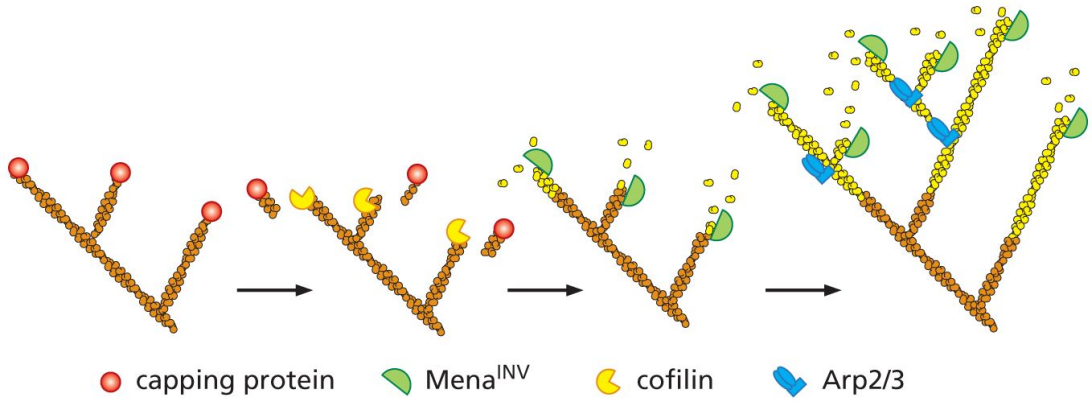
We can summarize our understanding of the motility of cancer cells by relating it to the actions of EMT programs. As was apparent from earlier discussions of epithelial cells, they are largely immotile unless induced to move by processes such as wound healing (see, as an example, Figure 14.15).

To present a highly interesting example of motility mechanisms, among the many mRNAs altered by EMT programs, is the one that encodes Mena, a cytoplasmic protein that plays a key role in regulating the extension of actin fibers (**Figure 14.34**).



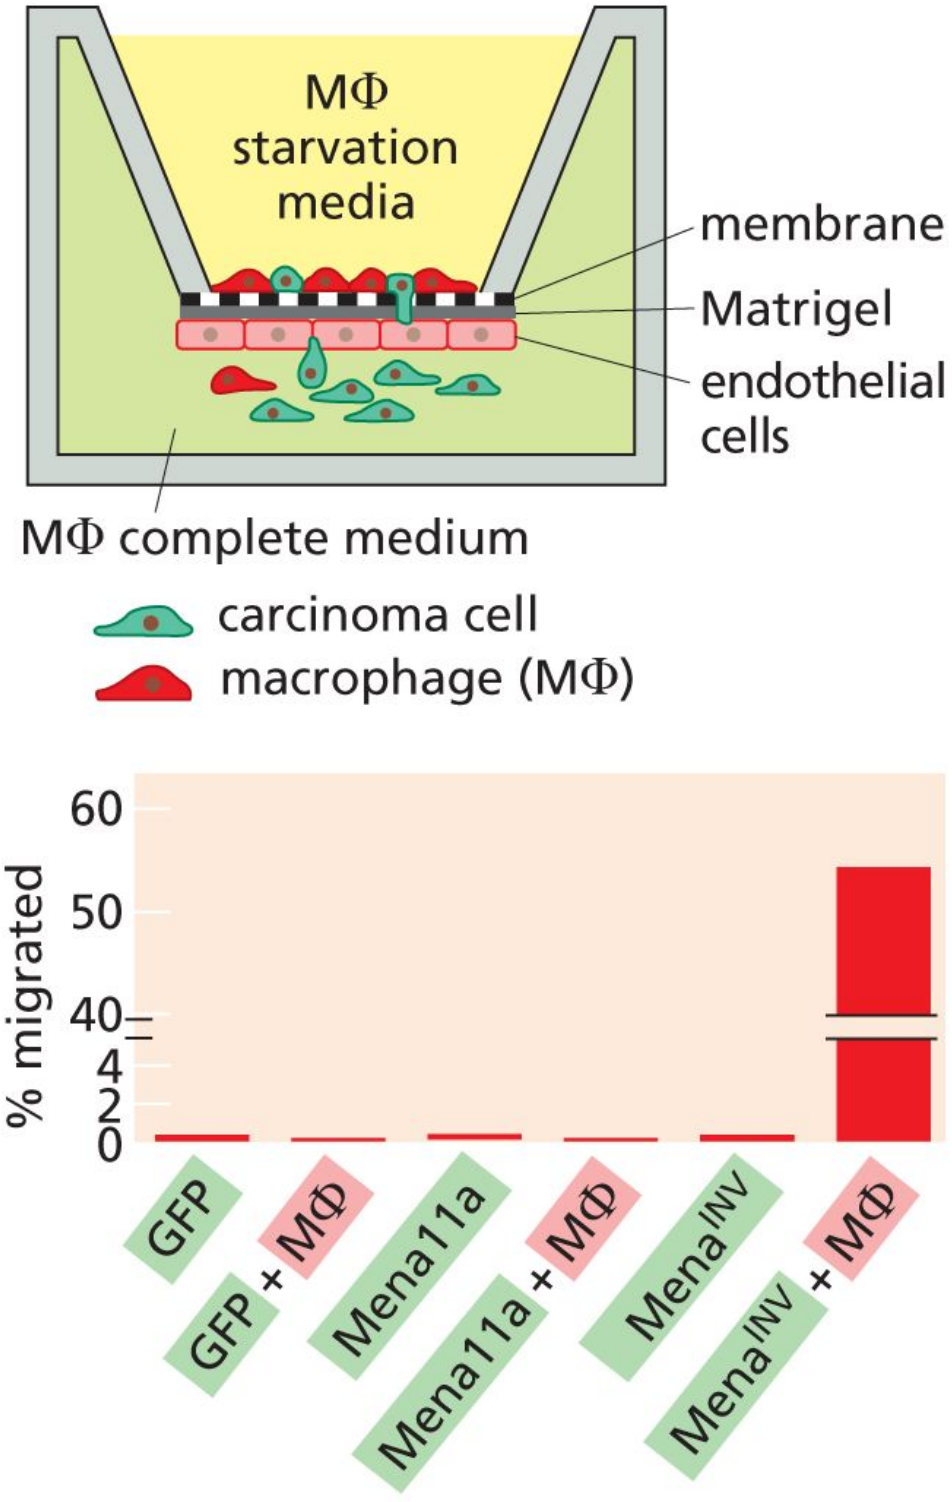
A mapping of the MENA protein. From left to right, the standard domains are E V H1, LERER, PRO, G, FAB, and C C. In epithelial cells, a short 11 a domain may also be present between FAB and C C. Cells that undergo E M T lose the 11 a domain, if present, and gain a double plus and a triple plus slash I N V domain between E V H1 and LERER.

(A)



A diagram of the growth of branching actin fibers. Initially, each terminus of a branch ends in a capping protein. The capped ends are trimmed off by cofilin. The ends then begin to grow after I N V isoform Mena attaches to each. As growth continues, branching is facilitated by A r p 2 slash 3.

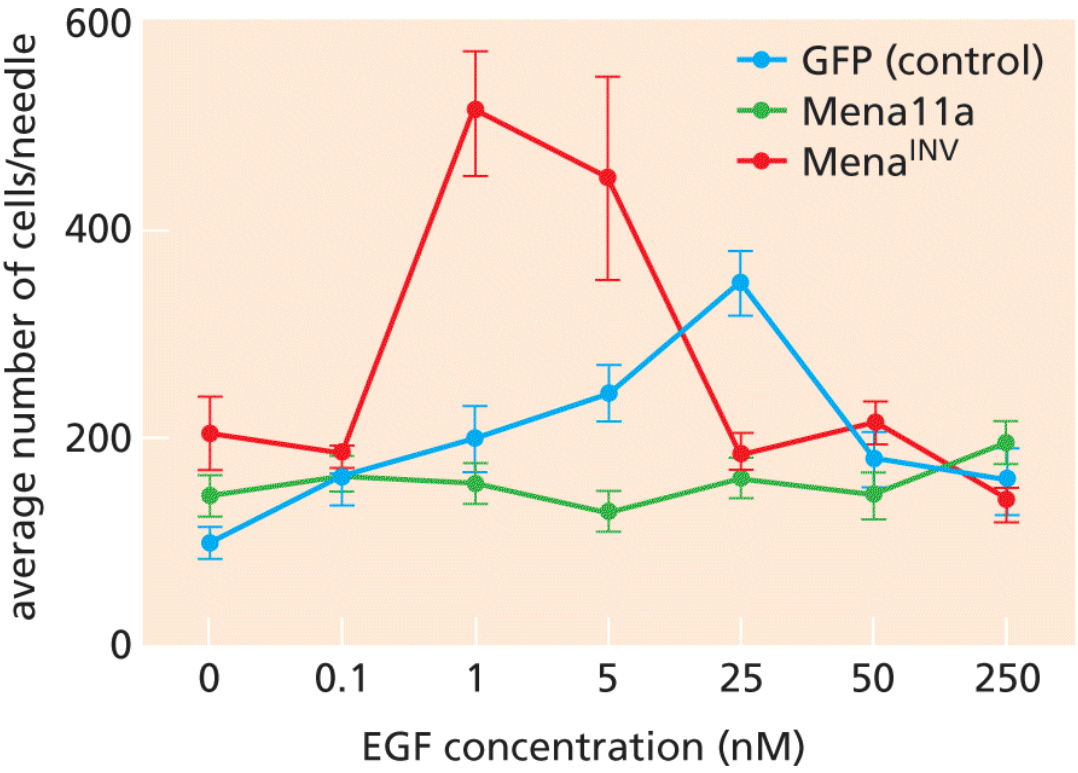
(B)



An experimental setup involving a container with macrophage starvation media in the upper chamber, macrophage complete medium in the lower chamber, and a horizontal wall separating the two chambers. This wall has an upper layer labeled membrane, a middle layer labeled matrigel, and a lower

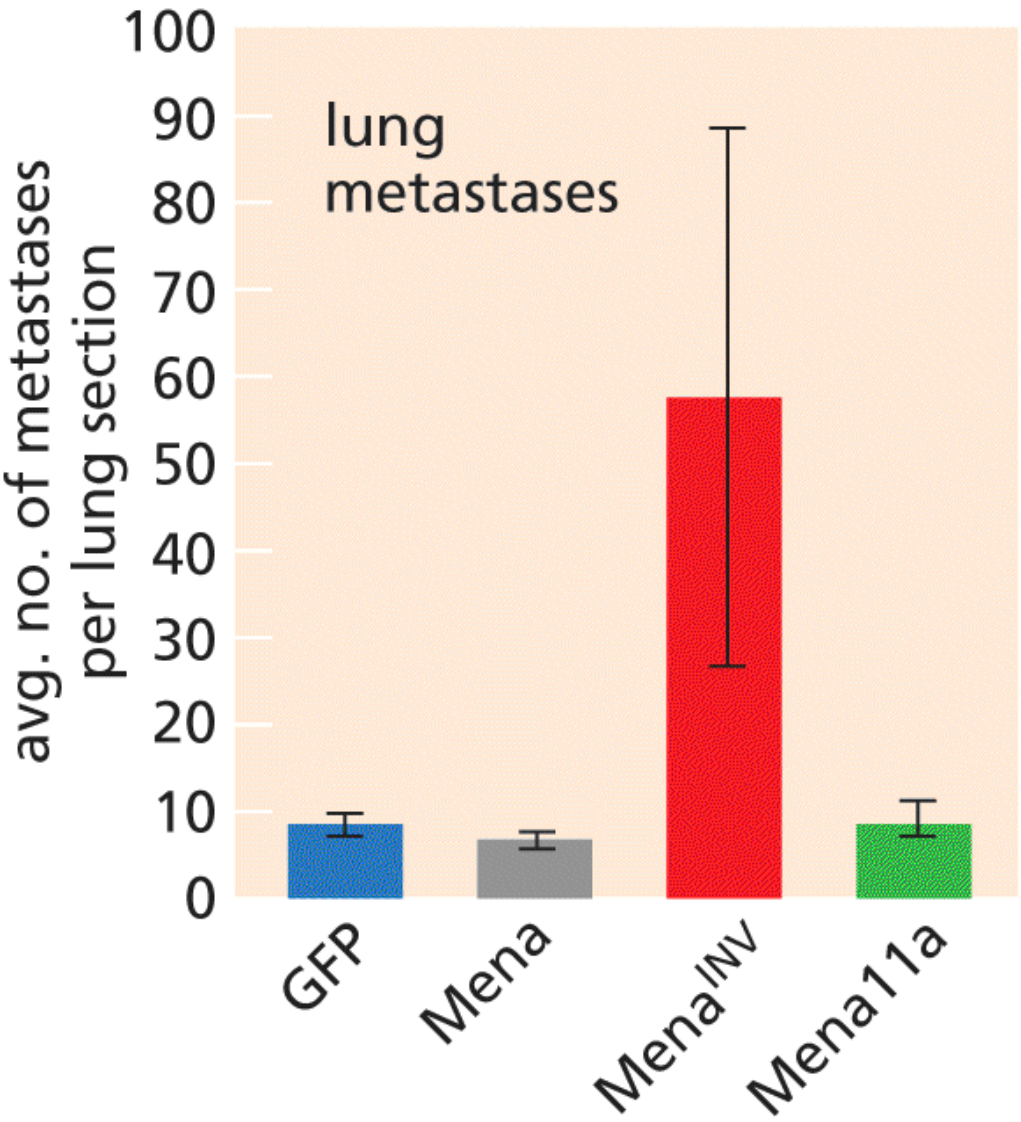
layer consisting of endothelial cells. A mix of carcinoma cells and macrophages rest atop this wall, within the macrophage starvation media. Cells, nearly all carcinoma calls and just a few macrophages, penetrate the wall down into the macrophage complete medium. A bar graph shows that this only happens when the carcinoma cells are incubated with macrophages and forced to express I N V isoform Mena.

(C)



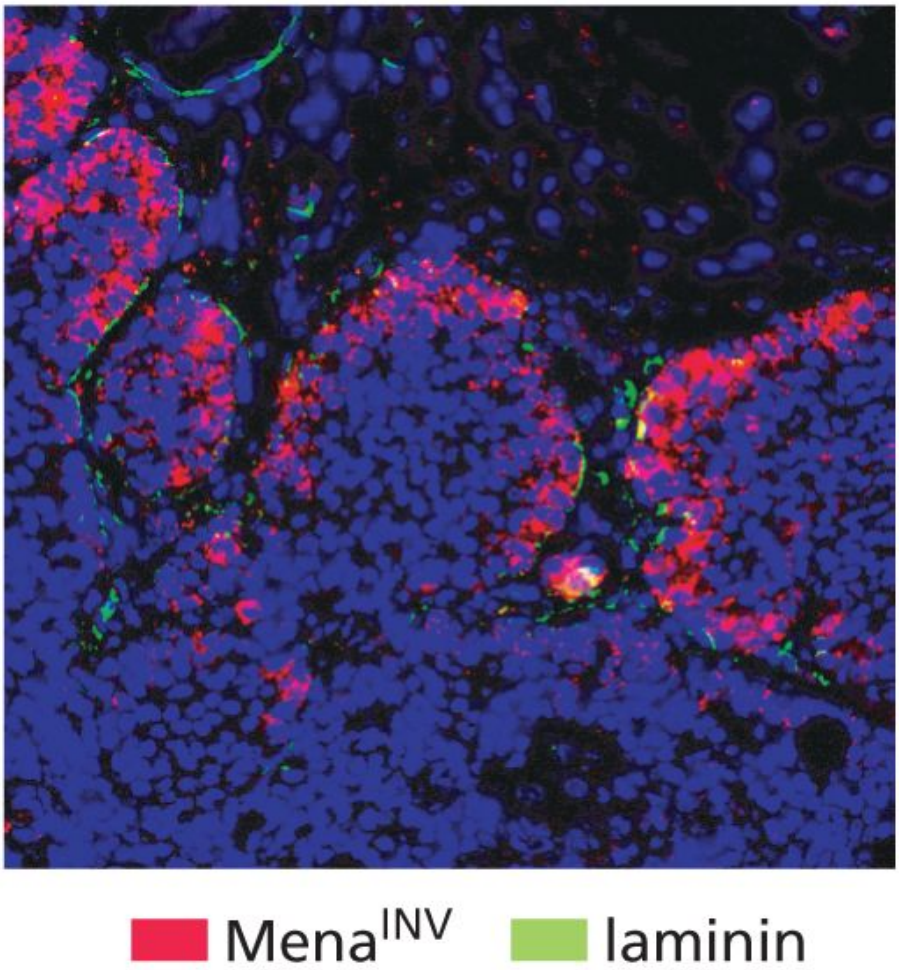
A line graph showing average number of cells per needle as a function of E G F concentration for three different proteins. G F P, the control, has a peak of about 350 cells per needle at 25 nanoMolar. Mena 11a remains fairly flat across all concentrations, just below 200 cells per needle. Mena I N V has a peak of about 500 cells per needle at 1 nanoMolar.

(D)



A bar graph of average number of lung metastases per lung section. For G F P, Mena, and Mena 11a, the average is less than 10. For Mena I N V it is almost 60.

(E)



A fluorescence microscopy image in which a region of densely packed blue nuclei is separated from a region of less densely packed nuclei by an undulating border. This border is edged on the side of the denser nuclei by much pink, indicating the presence of Mena I N V. Flecks of green, signifying laminin, are also visible.

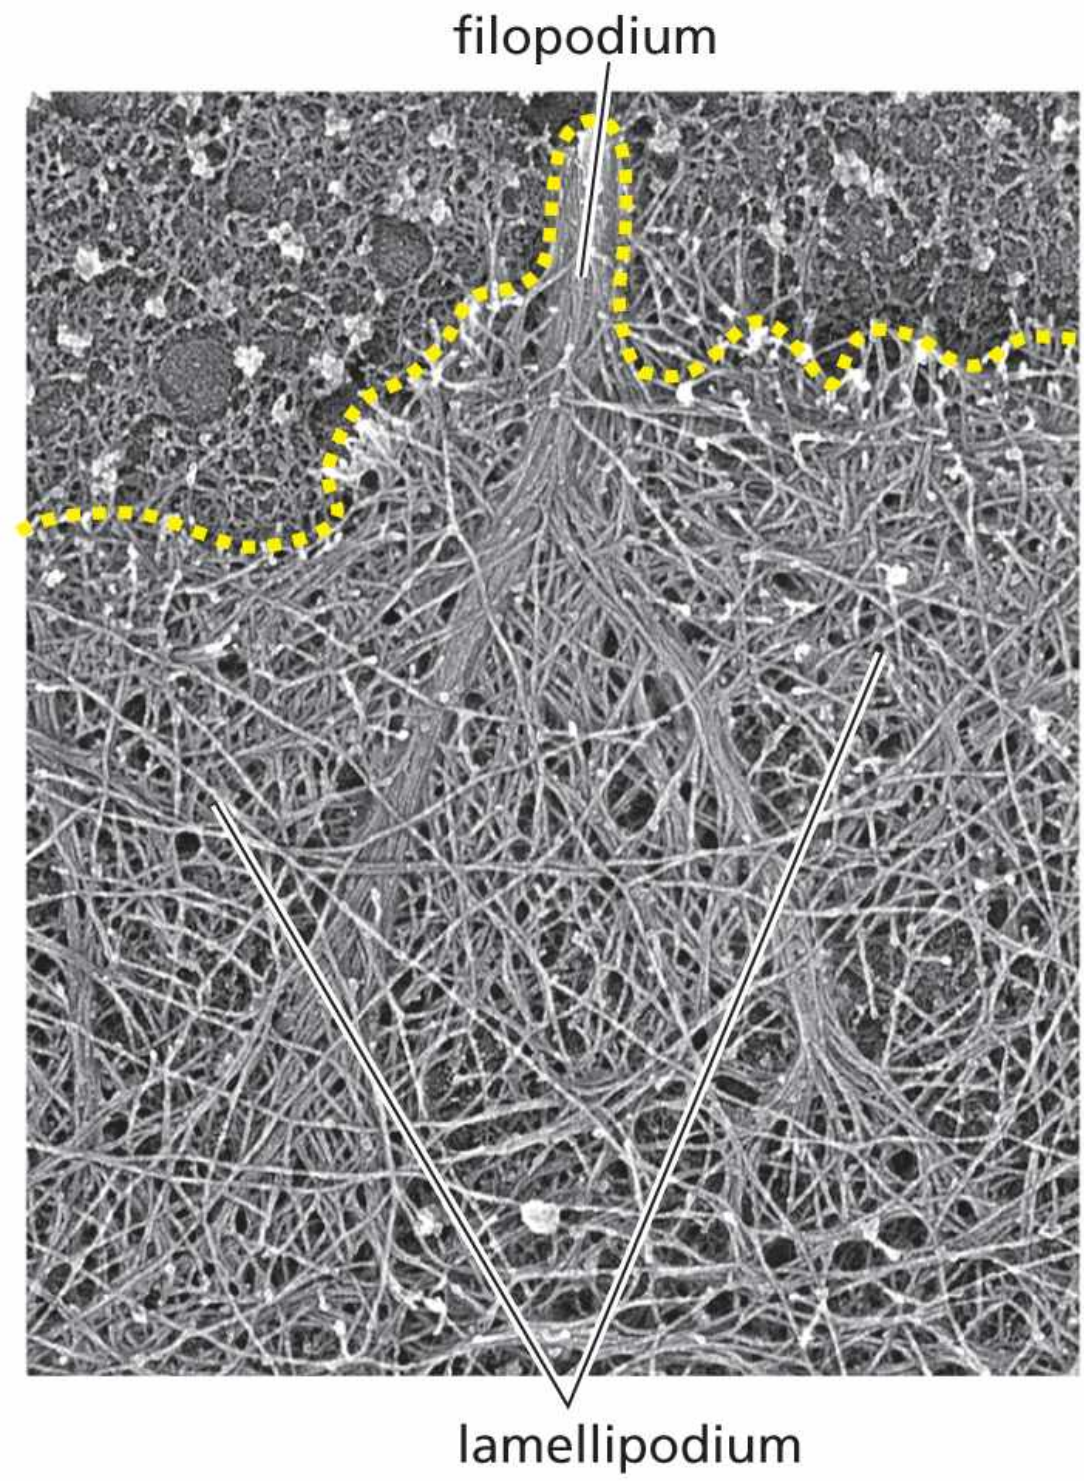
(F)

Figure 14.34 How EMT drives alternative splicing, cell motility, and increased invasiveness When carcinoma cells undergo an EMT, the result is a major shift in the expression of certain splicing factors that govern alternative splicing patterns. For example, several splicing factors that favor the epithelial phenotype are depressed, resulting in the synthesis of alternatively spliced mRNAs that encode proteins fostering a mesenchymal cell phenotype. (A) The usually synthesized version of the Mena protein seen both in normal epithelial cells and in localized carcinomas are composed of multiple domains and are specified by mRNAs encoding all the colored domains with the exception of the

three light brown domains (termed simply “Mena”) or these colored domains plus the 11a segment (“Mena11a”). In contrast, the form of Mena seen in cancer cells that have undergone an EMT and, in addition, are growing *in vivo* within a tumor contains segments encoded by exons INV (also known as +++) and ++ and lacks segment 11a. The Mena domain encoded by the INV exon seems to play an especially important role in carcinoma cell invasiveness. The arrows indicate the changes seen in association with activation of an EMT program. (B) The various forms of Mena promote the elongation of actin fibers that are essential for the growth of both lamellipodia and filopodia; only lamellipodial growth is illustrated here. Normally, a capping protein (*red circle*) blocks the further extension of actin fibers. Cofilin (*yellow*) cleaves the ends of actin fibers, removing the capping protein, and Mena (*green*) then prevents the reattachment of capping protein, permitting further fiber elongation; the INV isoform of Mena is especially effective in promoting this elongation, thereby driving actin fiber elongation and the growth of both lamellipodia and filopodia. Yet another protein—Arp2/3 (*blue*)—enables the branching of actin fibers that is critical for stable lamellipodial extension. (C) As described in Figure 14.22, macrophages interact with breast carcinoma cells via bidirectional signaling that promotes carcinoma cell invasiveness. (As shown in Figure 14.23, such invasiveness was manifested by an increased ability to intravasate.) Invasiveness through an endothelial cell layer can be measured in an *in vitro* assay (*above*), in which carcinoma cells (*green*) are introduced into the upper chamber of a two-chamber “transwell” incubation vessel, either together with or in the absence of macrophages (*red*). These cells are separated from the lower chamber by a perforated membrane (*dotted black line*), below which are a layer of ECM formed by Matrigel (a mixture of basement membrane proteins, *solid gray line*) and a monolayer of endothelial cells (*pink*). Conditioned medium in the bottom chamber attracts the carcinoma cells to migrate from the upper chamber, requiring their invasion through the endothelial cell monolayer. Carcinoma cells were genetically modified by vectors expressing either GFP, Mena11a, or $Mena^{INV}$. As shown *below*, a control expression vector encoding GFP (green fluorescent protein) has no effect on trans-endothelial migration, even in the presence of added macrophages (MΦ). Similarly, no effect was seen when these carcinoma cells were forced to express the Mena11a (epithelial) isoform. Moreover, the presence of both macrophages and the Mena/Mena11a isoforms fails to induce trans-endothelial migration. Only when the carcinoma cells are incubated with macrophages and forced to express the $Mena^{INV}$ isoform does this migration proceed efficiently, resulting in a ∼200-fold increase in invasiveness. (D) Expression of the $Mena^{INV}$ isoform also sensitizes carcinoma cells to the presence of EGF, such as that secreted by nearby macrophages (see Figure 14.22). Insertion of a large-bore EGF-filled needle into a carcinoma can be used to assay invasiveness by counting the number of carcinoma cells that are sensitized to motogenic EGF signals, which respond by migrating

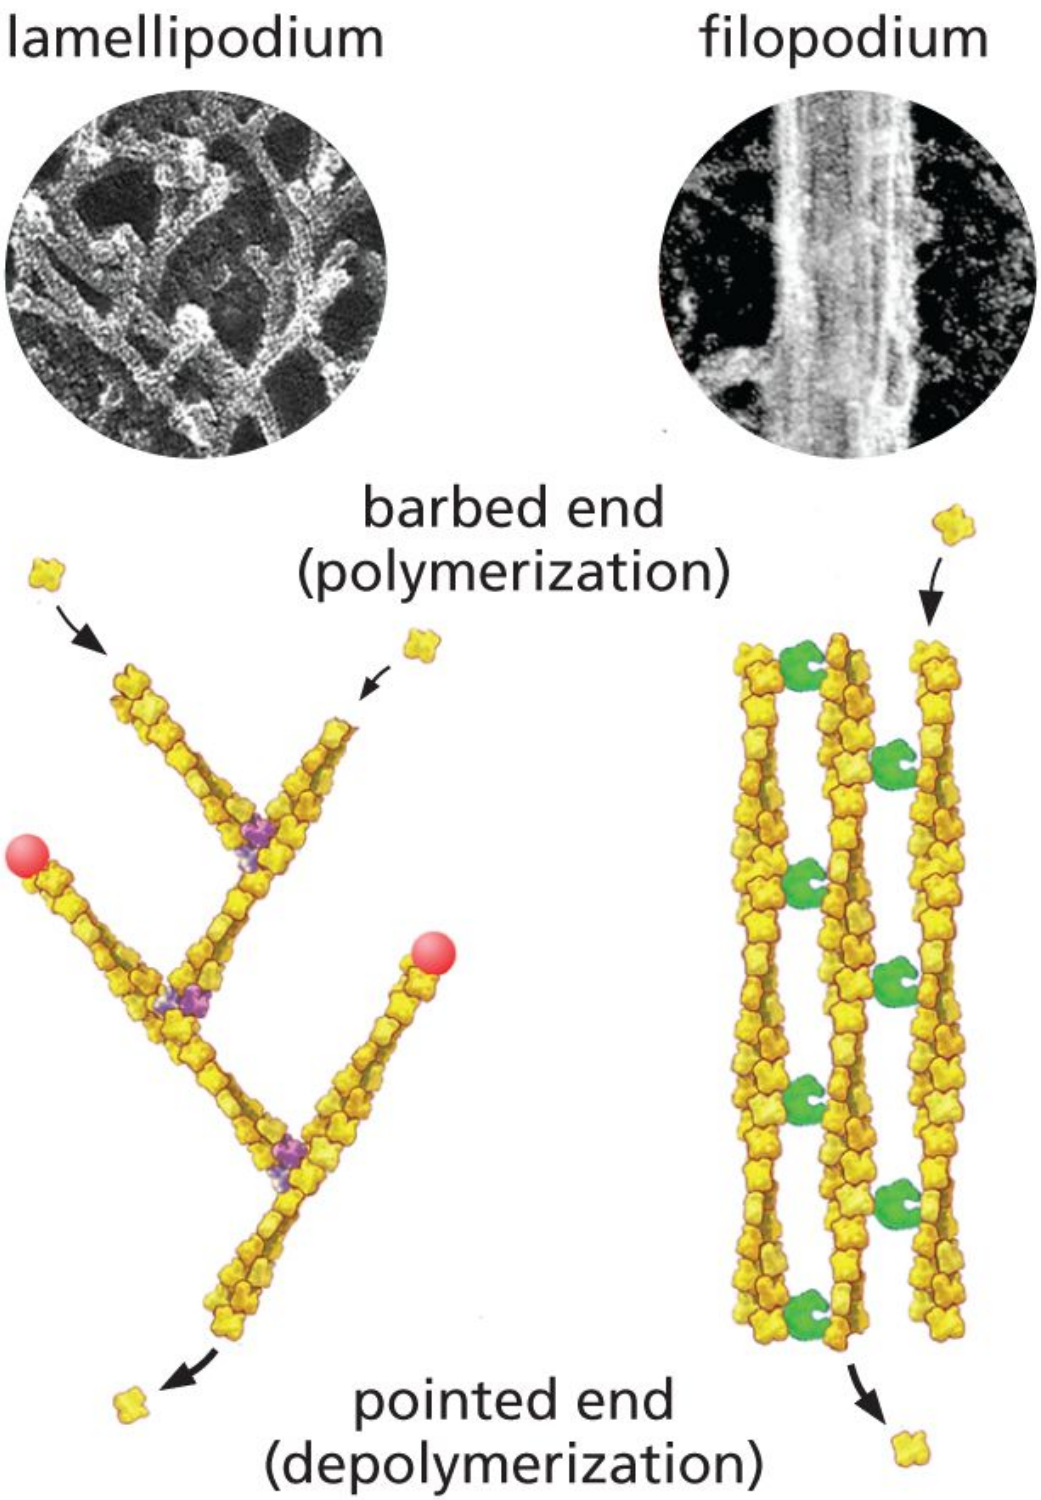
into the bore of the needle. As seen here, carcinoma cells that express the Mena^{INV} isoform are recruited by a 25-fold lower concentration of EGF than is required to recruit carcinoma cells expressing the control GFP plasmid, whereas expression of the Mena11a isoform actually suppresses the control/basal level of recruitment; this indicates that profound changes in sensitization to EGF are elicited by the different Mena isoforms. (E) These various effects on increased invasiveness and EGF responsiveness collaborate to affect the rate of metastasis to the lungs from primary tumors that express either a GFP control vector, a Mena11a vector, or a Mena^{INV} vector. (F) Mena^{INV} can be seen to be widely expressed among cells at the outer, invasive edge of an island of carcinoma cells (*pink*), where the remnants of the former basement membrane, visualized here by an antibody stain specific for laminin (*green*) are barely apparent, most of it having already been degraded by the invasive carcinoma cells. (A, from S. Goswami et al., *Clin. Exp. Metastasis* 26:153–159, 2009. With permission from Springer. B, from U. Philippar et al., *Dev. Cell* 15:813–828, 2008. With permission from Elsevier. C and D, from E.T. Roussos, M. Balsamo, S.K. Alford et al., *J. Cell Sci*. 124:2120–2131, 2011. With permission from The Company of Biologists. E, adapted from U. Philippar, E.T. Roussos, M. Oser et al., *Dev. Cell* 15:813–828, 2008, and E.T. Roussos et al., 2011. F, Courtesy of F. Gertler.)

Carcinoma cells that have been driven through an EMT by the actions of the Twist EMT-TF exhibit changes in the splicing patterns of hundreds of pre-mRNAs, these being products of alternative splicing. Among the altered mRNAs is the one encoding Mena. The normally synthesized *Mena* mRNA is replaced by a new version that specifies a form of the Mena protein (see Figure 14.34A) containing an invasion-associated domain (Mena^{INV}). Mena^{INV}, in turn, affects a variety of cell behaviors associated with invasion including responsiveness to EGF-induced cell motility (see **Supplementary Sidebar 14.9**) and trans-endothelial invasiveness. These changes conspire to generate significant increases in metastatic dissemination by the carcinoma cells within primary tumors (see Figure 14.34B–E). Resulting changes in the actin cytoskeleton, mediated in part by filopodia and lamellipodia, then enable the motility that underlies the invasive behavior of carcinoma cells (**Figure 14.35**). Lamellipodia are thin, sheet-like protrusions from the plasma membrane (**Supplementary Sidebar 14.8**) that enable the cytoplasm of a cell to extend forward in the direction of migration while filopodia protrude from lamellipodia and serve to sense guidance cues ahead of migrating cells and to provide attachment to the ECM. The detailed understanding of cell motility proteins garnered from studies like these is increasingly illuminating how an EMT works at the molecular level to power high-grade malignancy.



An electron microscopy image of the leading edge of a moving cell. The lamellipodium appears as a dense mat of fibers. A fingerlike forward protrusion that is especially dense with fibers is labeled filopodium.

(A)



Two sets of images contrast the structure of the fibers in lamellipodium and those in filopodium. As shown in a micrograph and a diagram, lamellipodium

fibers have a kind of zigzag structure, with the branch tips at each zig or zag pointing toward the barbed end, where polymerization is occurring, and away from the pointed end, where depolymerization is happening. Each tip has a pink ball on it. Filopodium fibers, again as shown in a micrograph and a diagram, run parallel. Three strands are shown connected by green linking proteins. Here, too, polymerization is happening at one end and depolymerization at the other.
(B)

Figure 14.35 The actin cytoskeleton and the restructuring of the cell surface
The formation of both lamellipodia and filopodia depends on assembly of specific configurations of the actin cytoskeleton that lies immediately beneath the plasma membrane. (A) Use of platinum replica electron microscopy reveals the configuration of the actin fibers that form both a lamellipodium and a filopodium. All membranes have been removed to reveal the actin cytoskeleton. The dashed line indicates the imputed location of the plasma membrane, which previously separated the cytoplasm (*below*) from the extracellular matrix (*above*). The lamellipodium (see also **Supplementary Sidebar 14.8**) extends broadly across the entire micrograph, and a single filopodium protrudes from the leading edge of the lamellipodium. (B) The actin fibers within a lamellipodium, seen here at higher magnification (*above left*), are extended at their growing "barbed" ends by addition of actin monomers (*yellow balls, top in lower diagram*) and are disassembled at their retreating "pointed" ends by liberation of individual monomers (*below*). The same dynamic operates to enable the extension of filopodia (*right*). Ancillary proteins involved in forming the branched fiber networks of the lamellipodium are depicted in *pink*, whereas those involved in forming the tightly bundled, parallel actin fibers of the filopodium are depicted in *green*. The plasma membrane wraps over and around these structures in a fashion that is poorly understood. (A, from T.M. Svitkina, E.A. Bulanova, O.Y. Chaga et al., *J. Cell Biol*. 160:409–421, 2003. OceanofPDF.com

Glossary

motogenic
: Referring to an agent or signal that stimulates cell movement or motility.

filopodium
: Filamentous, spikelike protrusion from the surface of a cell, usually extending from the leading edge of a lamellipodium, that may be used by the cell to explore territory that lies ahead in its path and to forge focal adhesions with the extracellular matrix lying in this path. *See also* **lamellipodium**.

lamellipodium
: (pl., **- ia**) A broad, sheetlike ruffle extending from the plasma membrane into the extracellular space that is typically found at the leading edge of a motile cell.

14.10 Intravasation and the formation of circulating tumor cells: first steps in perilous journeys

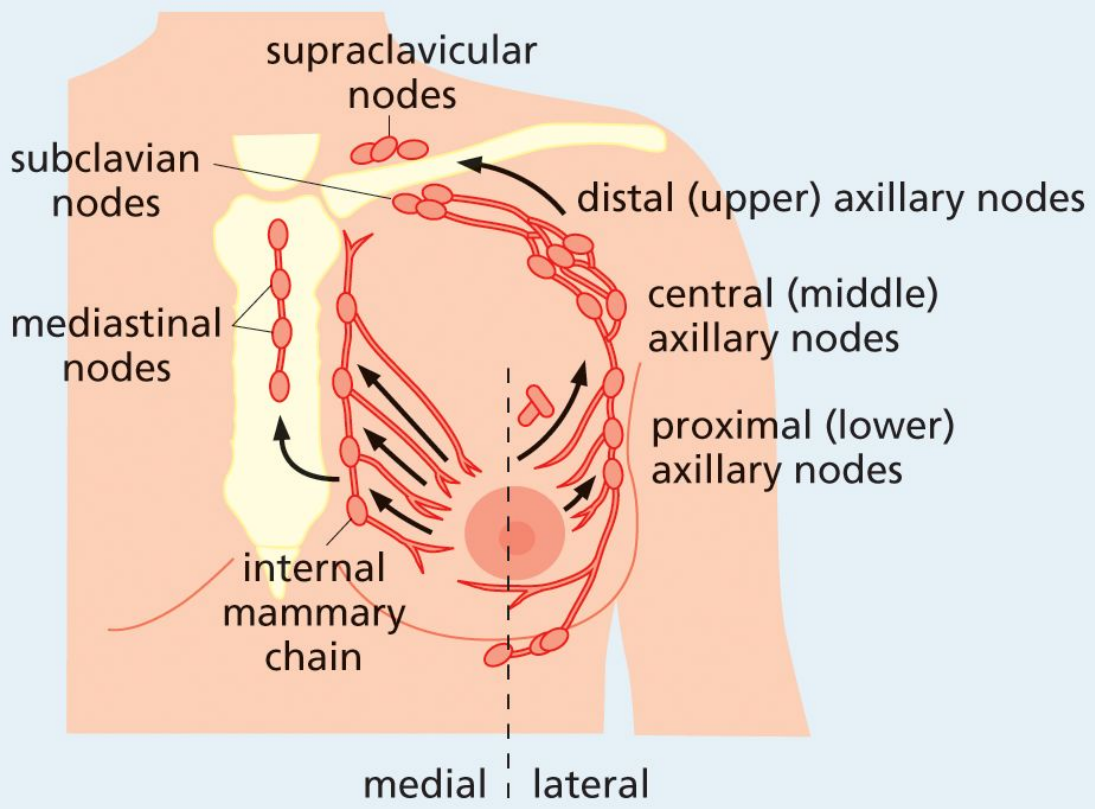
The invasiveness that we read about immediately above allows carcinoma cells to take advantage of the "doorways" in microvessels that we encountered in Figure 14.23. Recall that these openings in the walls of microvessels are formed by three-way collaborations between carcinoma cells, macrophages, and endothelial cells. These structures provide an entryway for carcinoma cells, resulting in the process of intravasation. In addition, and not mentioned previously, as individual carcinoma cells enter the lumina of microvessels, they may also acquire stemness, which may qualify them to serve later as founders of metastatic tissues. Still, these intravasation events are only the beginnings of long and difficult journeys. Similar processes, not yet studied, may also permit intravasation into the lumina of lymphatic vessels. Equally unclear are the cellular mechanisms that allow clumps of neoplastic cells to enter into the circulation. Such clumps, more than single intravasated cells, may actually represent the founders of most metastatic colonies.

The entrance into blood vessels in principle allows the neoplastic cells to spread via the process of hematogenous dissemination. Primary tumor cells may also seek out the alternative route of spreading via the lymphatic vessels that drain tumors and carry cells together with tumor-associated debris into the "draining lymph nodes." As will be discussed in Chapter 15, such lymph nodes are the sites where antigen-presenting cells, notably dendritic cells, present tumor-associated antigenic peptides to T lymphocytes as an initial step in the formation of an adaptive immune response. It is unclear whether the lymph nodes represent dead ends for disseminating cancer cells or, alternatively, staging areas for further spread to distant tissues (**Sidebar 14.4**). One study of the genomes of distant metastases found that two-thirds of cancer cells in these metastases arose from subpopulations of primary tumor cells that were genetically distinct from the subpopulations that spawned the lymph node-associated cancer cells. This might suggest two independent, parallel routes of dissemination from primary tumors to either draining lymph nodes or, alternatively, to blood vessels that lead from primary tumors directly into the venous circulation and ultimately to distant anatomical sites throughout the body.

Sidebar 14.4 The lymphatic system represents an alternative route to metastasis

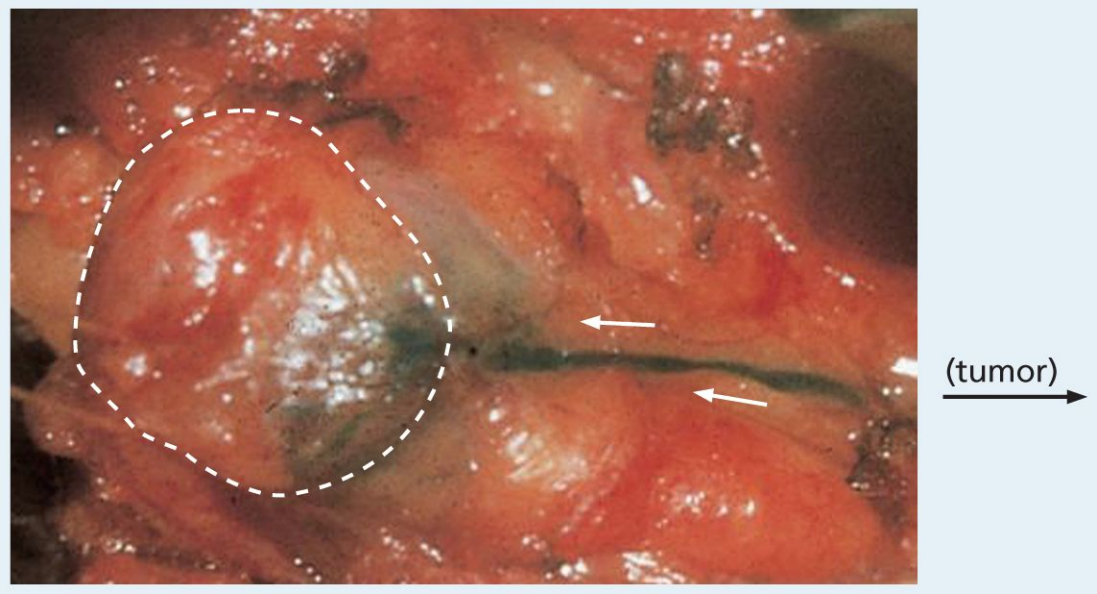
After invasive, motile cells enter into the vessels of blood or lymphatic systems—the process of intravasation—they disperse and, should they survive the rigors of the voyage, eventually settle in tissue sites that lie at some distance from the primary tumor. The hematogenous route of dissemination is clear and well established. Less obvious is the alternative route via the lymphatic system. Virtually all tissues in the body carry networks of lymphatic vessels that are responsible for continuously draining the interstitial fluid that accumulates in the spaces between cells (see Figure 13.8C). Most of these vessels converge on a major abdominal vessel that empties its lymph into the left subclavian vein near the heart and thence into the general circulation. Consequently, cancer cells present in lymphatic vessels may occasionally enter through this cross connection into the general circulation.

Tumor cells and recruited stromal companions may secrete VEGF-C, which drives lymphangiogenesis—the formation of new lymphatic vessels (see Section 13.6). Moreover, experimental tumors forced to secrete increased levels of VEGF-C will seed larger numbers of metastatic cells in nearby draining lymph nodes—the lymph nodes associated with the lymphatic ducts that drain the tissue in which the tumor lies (**Figure 14.36**). However, detailed histological analyses of spontaneously arising solid tumors indicate that functional lymphatic vessels are rarely found throughout tumor masses. Instead, they largely occupy a zone at the periphery of solid tumors. Those few lymphatic vessels detected in the central regions of tumors are usually collapsed (see Figure 13.34). As discussed in the previous chapter, it seems that the expanding masses of cancer cells within a tumor press on these vessels; because the lymphatic ducts have little internal hydrostatic pressure, they cannot resist these forces and collapse.



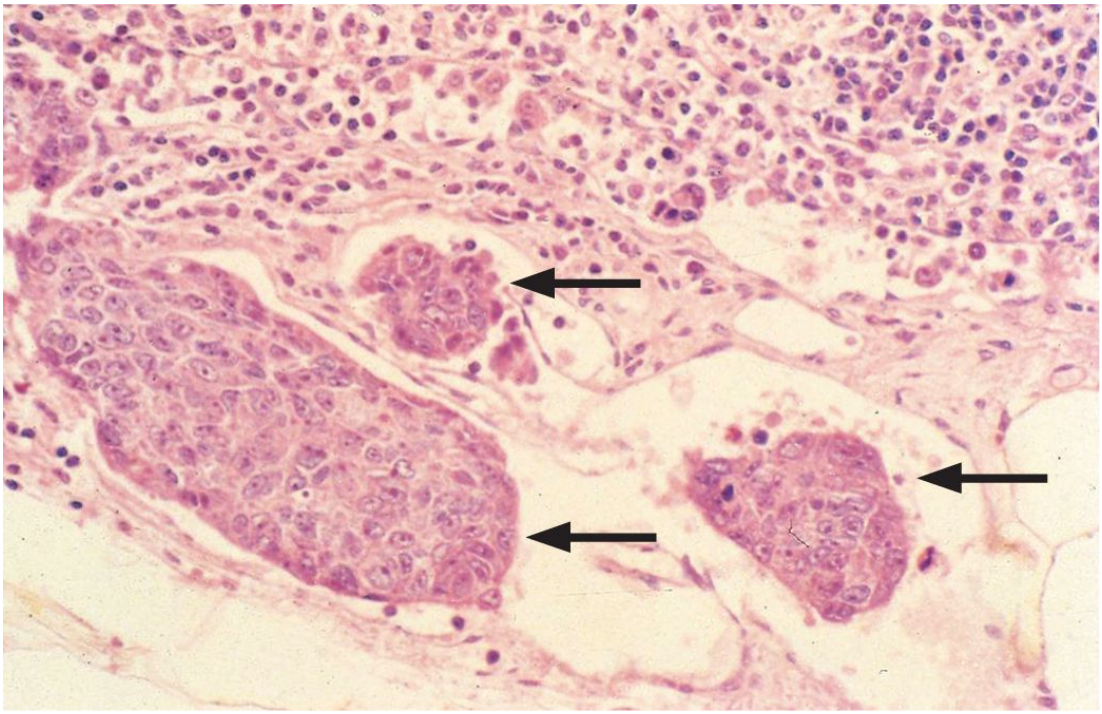
A diagram of the lymph nodes associated with the human female breast. These include three sets of nodes along the breast's outer edge, near the armpit. From top to bottom, they are the distal or upper, central or middle, and proximal or lower axillary nodes. These are connected by a network of lymph vessels through which lymph moves upward, away from the breast. Other nodes include the inner mammary chain, which runs vertically along the inner edge of the breast, near the sternum. These, too, are connected to lymph vessels that lead away from the breast. Finally, there are the mediastinal nodes down the center of the sternum, and the subclavian and supraclavian nodes, which lie, respectively, just below and just above the collarbone.

(A)



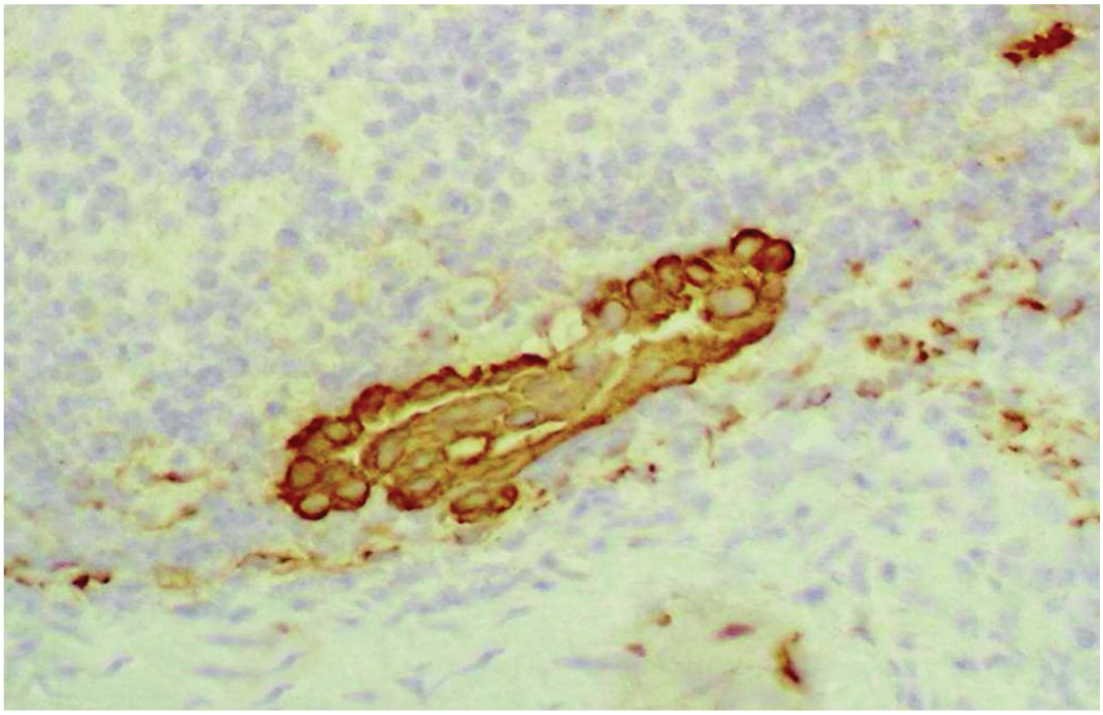
A color photograph of a tumor. A thickened mass of tissue is outline by a white dashed line. A dark blue line leads horizontally toward from the mass from the right.

(B)



A histology stain image showing three dark pink lumps, indicated by arrows, surrounded by paler tissue. Higher up in the image is an area of cells with

many small but distinctly visible nuclei.
(C)



A color image showing a small, elongated patch of brown cells, surrounded by tissue that is translucent and white with barely visible pale blue-purple nuclei.

(D)

Figure 14.36 Draining lymph nodes of the mammary gland and its tumors (A) The lymphatic ducts (*red*) and the lymph nodes draining the breast (swellings along ducts) are initial sites of metastatic spread, carcinoma cells being carried there by the flow of lymph (*arrows*) leaving various sectors of the breast. The discovery of carcinoma cells in these lymph nodes, which is observed in more than 30% of human breast carcinoma patients at the time of initial diagnosis, suggests the possibility of deposits of metastatic cells in more distant sites in the body, particularly if large numbers of draining nodes are found to carry breast cancer cells. (B) The lymph node that serves as the sentinel node of a tumor can usually be identified among all of the lymph nodes draining the breast by injecting a blue dye into the tumor (outside photographic field to right) and following the trail of the dye via the lymphatic duct (*arrows*) to the draining node (outlined in dashed line, *left*). (C) Hematoxylin–eosin (H&E) staining of a section of an axillary lymph node reveals that three micrometastases (*arrows*) arising from a primary breast tumor have grown in the space between the capsule surrounding this node (not seen, *below*) and the mass of lymphocytes within the node (small

cells, dark nuclei, *above*), displacing the latter upward. (D) Immunohistochemistry using an antibody specific for cytokeratins (*brown*) reveals this small micrometastasis in a sentinel node. This procedure is far more sensitive than H&E staining (panel C) in detecting micrometastases, because the mesenchymal cells of the lymph node do not express cytokeratin, which is made by epithelial cells and thus by most carcinoma cells. (A–C, from A.T. Skarin, *Atlas of Diagnostic Oncology*, 4th ed. Philadelphia: Elsevier Science Ltd., 2010. With permission from Elsevier. D, from J.P. Leikola, T.S. Toivonen, L.A. Krogerus et al., *Cancer* 104:14–19, 2005. With permission from John Wiley & Sons.)

The absence of functional lymphatic vessels within tumor masses must influence the paths used by metastasizing cancer cells to leave the primary tumor. Without ready access to lymph ducts, most motile cancer cells are likely forced to emigrate via the far more numerous functional capillaries, which are threaded throughout the tumor mass. In spite of such limited access, some cancer cells do indeed succeed in entering the lymphatic system. In the specific case of mammary carcinomas, some metastasizing cancer cells enter into the lymphatic vessels that directly drain the mammary gland and collect in the nearby downstream lymph nodes (see Figure 14.36A). These wandering carcinoma cells are readily detected because their appearance differs so strongly from the surrounding lymphoid cells (see Figure 14.36C) and they express epithelial proteins, such as cytokeratins, that are otherwise absent from lymphatic tissues (Figure 14.36D). Histological examination of draining lymph nodes is routinely used to determine whether a primary breast cancer has begun to dispatch metastatic pioneer cells to distant sites in the body.

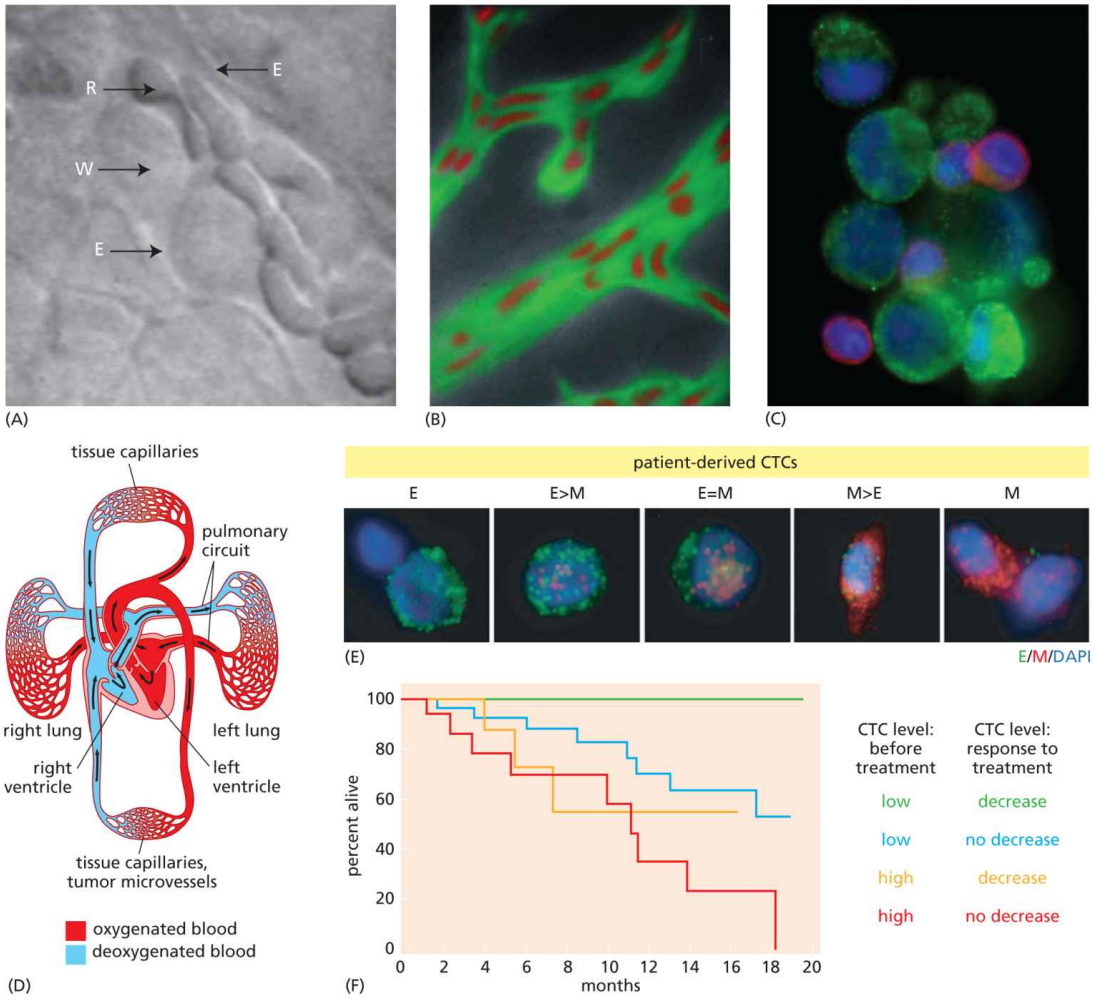
The fact that lymph nodes operate as collection points for subcellular debris and cells shed by tissues explains why draining nodes are routinely examined to determine whether cancer cells have been released by primary tumors growing in those tissues (for example, the mammary gland; see Figure 14.36A and B). As examples, upon initial diagnosis, about one-third of breast, colorectal, cervical, and oral carcinoma patients have disseminated cancer cells in the lymph nodes near their primary tumors (see Figure 14.36C and D).

These draining lymph nodes serve as proverbial “canaries in the mine,” by providing early warning of the presence of metastasizing cells in the body. Among these regional lymph nodes, the single node that directly drains the primary tumor growing in the breast is often termed the “sentinel” node (see Figure 14.36B). Patients with small numbers of affected nodes often have only localized spread of the breast cancer and may never develop metastatic disease, whereas those with many affected nodes are far more likely to harbor other deposits of metastatic cells in distant sites in the body. For example, in one study, 90% of long-term survivors of a variety of carcinomas had one, two, or occasionally three “positive” lymph nodes at diagnosis. Conversely, fewer than

5% of patients with more than five positive lymph nodes when their primary tumors were removed enjoyed long-term, disease-free survival. Accordingly, in multiple types of primary tumors, cancer cell–positive lymph nodes represent "surrogate markers" of metastasis by providing useful diagnostic and prognostic data without being directly involved in the processes that lead to widespread cancer cell dissemination and metastatic disease.

Once cancer cells intravasate into the general circulation, either directly by entering the microvessels that empty into the venous circulation or indirectly following time spent in the lymphatic system, such cells are considered circulating tumor cells (CTCs). The long-range migrations through the general circulation are fraught with great danger for the CTCs. Like normal cells, the wanderers may continue to depend on anchorage to solid substrates; without such attachment, the migrating cells may die rapidly from anoikis, the form of apoptosis that is triggered by detachment of a cell from a solid substrate such as an extracellular matrix (see Section 9.13). Also, like their forebears in the primary tumor, these pioneers may depend on various types of stromal support, which will usually be lacking the moment they leave the primary tumor mass. Recall that the stroma can benefit carcinoma cells in multiple ways by supplying both mitogenic and trophic (survival) factors.

The blood, in particular, represents an actively hostile environment for disseminating cancer cells (**Figure 14.37**). Hydrodynamic shear forces in the circulation, which are often substantial in smaller vessels, may tear apart the wandering cancer cells. Some experimental models of metastasis in the mouse provide clear indication that the survival of metastasizing cancer cells in the general circulation is greatly enhanced if they can attract an entourage of blood platelets to escort them through the rapids into safe pools within tissues (see **Supplementary Sidebar 14.5**). These tightly adhered passengers form a protective cloak that reduces the likelihood that the CTCs will be ambushed by natural killer (NK) lymphocytes lying in wait in the circulation (to be described in Chapter 15). In addition, after adhering to carcinoma cells, platelets may release a variety of growth factors that are usually instrumental in supporting wound repair, among them mitogenic and trophic signals. Some of the platelet-secreted factors may activate or sustain EMT programs in the adhered carcinoma cells, thereby rendering them more resistant to various forms of cell death.



A six-part figure pertaining to the Passage of tumor cells through the body's circulatory system. Part A is a grayscale micrograph showing white and red blood cells, labeled R and W, squeezing their way through a capillary whose walls are labeled with Ease. Part B is a fluorescence microscopy image of small blood vessels, appearing in green, and red blood cells passing through them. Part C is a fluorescence microscopy image of a clump of round, multi-colored cells. The cells have blue nuclei. Most of the cytoplasms are green, but two of the smaller cells have red cytoplasms. Part D is a schematic of the circulatory system, with the heart in the middle and blood circulating through the lungs and the upper and lower extremities. Red, oxygenated blood flows from the lungs through the heart's left ventricle into the extremities, deoxygenates, and turns blue as it passes through tissue capillaries and tumor microvessels. It then flows back to the heart, through the right ventricle, and from there to the lungs to be re-oxygenated. Part E is a series of fluorescence microscopy images of patient-derived circulating tumor cells. In the first image, labeled E, only green dots are visible around the blue nucleus. In the second image, labeled E greater than M, a few red dots have

appeared. In the third image, labeled E equals M, about half the dots are red. In the fourth image, labeled M greater than E, there are just a few green dots. In the final image, labeled M, all the dots are red. Part F is a line graph that gives percent alive as a function of time for four different groups of patients. Of patients whose C T C levels were low to begin with and decreased in response to treatment, 100 percent remained alive out to 20 months. Of patients whose C T C levels were low to begin with but did not decrease in response to treatment, about 50 percent remained alive out to 20 months. Of patients whose C T C levels were high to begin with but decreased in response to treatment, about 55 percent remained alive after 8 months, and all of those remained alive after 16 months. Of patients whose C T C levels were high to begin with and did not decrease in response to treatment, none survived past 18 months.

Figure 14.37 Passage of tumor cells through the circulation Cancer cells moving through the circulation are found amid densely packed cells of hematopoietic origin. (A) Intra-vital microscopy reveals the two endothelial walls of a capillary (E), erythrocytes (R), and some leukocytes (W). The small size (∼7 μm diameter) and deformability of the erythrocytes and leukocytes allow them to pass through capillaries without becoming trapped. (B) The vessels in this intra-vital fluorescence micrograph are slightly larger than capillaries. The plasma has been stained with a *green* dye, and the erythrocytes have been colorized *red*. The high deformability of these red blood cells is apparent. Most cancer cells have more than twice the diameter of erythrocytes and are not deformable, and they are less able to negotiate narrow passages, such as those created by the lumina of capillaries. (C) The difficulties of negotiating passage through the narrow microvessels of various tissues are compounded by the fact that intravasated cancer cells often attract clouds of platelets around them (see Supplementary Sidebar 14.5) and the fact that they are often found in the circulation as multicellular aggregates, as is seen in this cluster of circulating tumor cells (CTCs) isolated from the circulation of a patient with metastatic prostate cancer. Cells were immunostained with an antibody reactive with the prostate-specific membrane antigen (*green)* and another reactive with the CD45 displayed by many types of hematopoietic cells (*red*). DNA was stained *blue* with DAPI. (D) This diagram of the mammalian circulation indicates that venous blood (*blue*) leaving a tissue (and thus cancer cells that have escaped from a primary tumor and intravasated, *below*) must first pass through the right ventricle of the heart and thence through the lungs before it enters the left ventricle and is pumped into the general arterial circulation. Because passage through the pulmonary circulation of the lung requires passage through its capillaries, many metastasizing cells entering into the venous circulation are rapidly trapped in the pulmonary capillary beds. (E) Circulating tumor cells present in the blood of breast cancer patients were analyzed for their expression of epithelial (E, *green*) and mesenchymal (M, *red*) RNAs by *in situ* hybridization. As is apparent, cells expressing various proportions

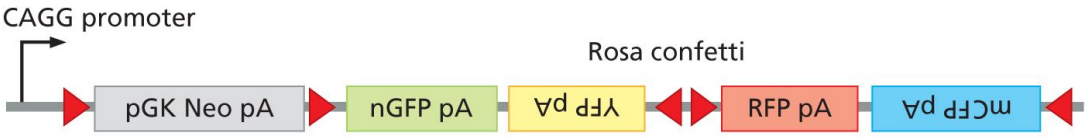
of E and M marker-expressing CTCs were present in the blood of various patients. Not shown is the fact that as tumor progression proceeded in individual patients, the proportions of M-marker-expressing cells increased in the CTCs. (F) While a measurement of the levels of CTCs in a patient relative to other patients often does not provide clinically useful information. Instead, it is useful to monitor individual patients longitudinally, that is at various time points over the course of treatment. As is seen here, the responses of individual patients to therapy can be gauged by measuring levels of CTCs following therapy relative to their initial levels of CTCs. (A and B, from I.C. MacDonald, A.C. Groom and A.F Chambers, *BioEssays* 24:885–893, 2002. With permission from John Wiley & Sons. C, from S.L. Stott, C.H. Hsu, D.I. Tsurkov et al., *Proc. Natl. Acad. Sci. USA* 107:18392–18397, 2010. With permission from National Academy of Sciences, U.S.A. E, from M. Yu, A. Bardia, B.S. Wittner et al., *Science* 339:580–584, 2013. With permission from AAAS. F, from T.T. Kwan, A. Bardia, L.M. Spring et al., *Cancer Discov*. 8:1286–1299, 2018. With permission from American Association for Cancer Research.)

The concentrations of CTCs in the blood of patients under treatment often represent powerful prognostic markers (Figure 14.37F). In the analyses illustrated in this figure, individual patients were monitored longitudinally, that is, at different times during the course of their treatment and diagnosis. In the analyses shown, the responses of CTC concentrations to patients' therapy were monitored. As is clear, patients who began treatment with low CTC concentrations that decreased following treatment fared well, showing no mortality during the 20 months of clinical observation. Conversely, patients who began treatment with high CTC concentrations that failed to respond to treatment by decreasing showed a high level of mortality, all dying by the end of the observation period. The monitoring of CTC concentrations rather than direct observations of tumor masses is often termed a form of liquid biopsy. Importantly, longitudinal observations of CTC concentrations in individual patients often provide highly useful prognostic information, as revealed by Figure 14.37F. However, different patients harboring tumors of comparable sizes and degrees of progression may often exhibit very different levels of CTCs, indicating the limitations of using liquid biopsies to assess the sizes of their primary tumors and the numbers of derived metastases.

CTCs may either be present in the blood of cancer patients as single cells or as multicellular clumps, sometimes termed microemboli (see Figure 14.37C), their migration being termed collective metastasis. As mentioned earlier, accumulating evidence indicates that the CTC clumps are actually more effective than individual CTCs in founding metastatic colonies in distant organ sites. Their multicellularity may confer several benefits. Cells buried within these clumps may be shielded from attacks by NK cells. Because of the larger diameter of these clumps, they are likely to be physically trapped in small-bore microvessels far more quickly than individual CTCs

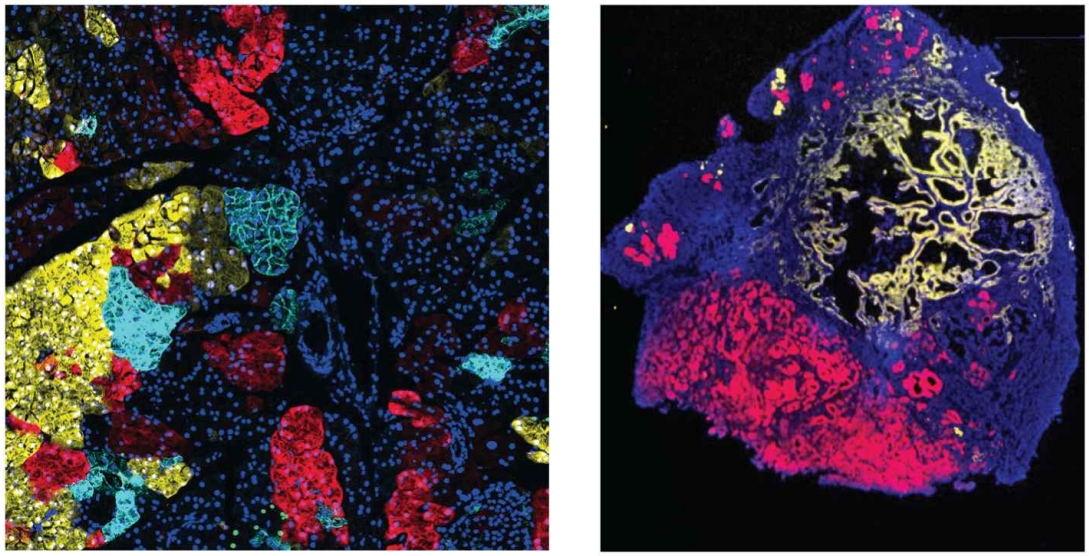
traveling on their own; this short lifetime in the general circulation may, on its own, confer significant benefit, allowing these cells to quickly find refuge away from the raging torrents of the general circulation.

Related molecular evidence indicates that many metastases can be initiated by multicellular aggregates. This insight comes from labeling the individual cancer cells within primary tumors growing in a mouse with a diversity of unique DNA markers, sometimes termed barcodes, that have been stably introduced into their genomes. In individual metastases spawned by these primary tumors, one finds multiple barcodes, indicating that the descendants of multiple distinct cells within a primary tumor served as cofounders of each metastatic colony (**Figure 14.38**). Such evidence suggests that these polyclonal metastases were initiated by multicellular, genetically heterogeneous cell clumps. (Additional evidence indicates that these metastases are unlikely to arise from individual disseminated tumor cells (DTCs) that converged independently of one another on the site of dissemination.) Moreover, in these barcode experiments, at least 80% of the metastases gave evidence of oligoclonality, that is, at least two distinct clonal subpopulations in a given metastatic colony. Hence, many metastases represent oligoclonal growths rather than the monoclonal growths that would be expected if they traced their origins to single founder cells.



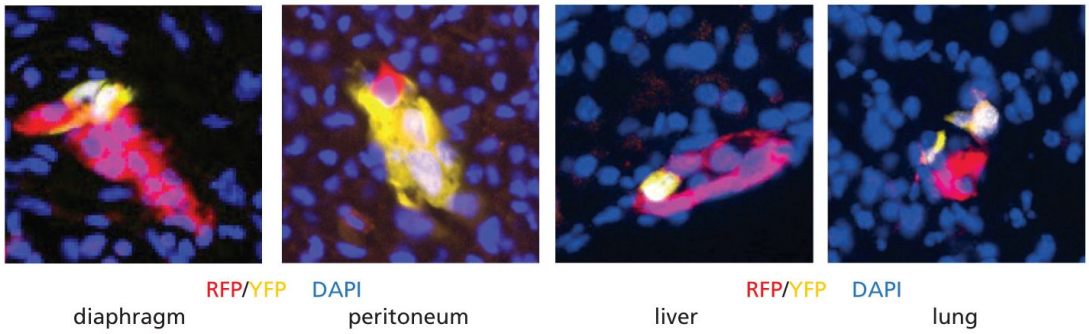
A map of a vector used to generate expression of one of four randomly activated fluorescent marker proteins. The map begins on the left with C A G G promoter. Markers from left to right are p G K Neo, n G F P, Y F P upside down, R F P, and m C F P upside down.

(A)



A comparison of a fluorescence microscopy image of normal pancreatic tissue with G F P, R F P, and Y F P to an image of a primary tumor in which there is no G F P. Both images contain dark blue nuclei alongside the protein markers.

(B)



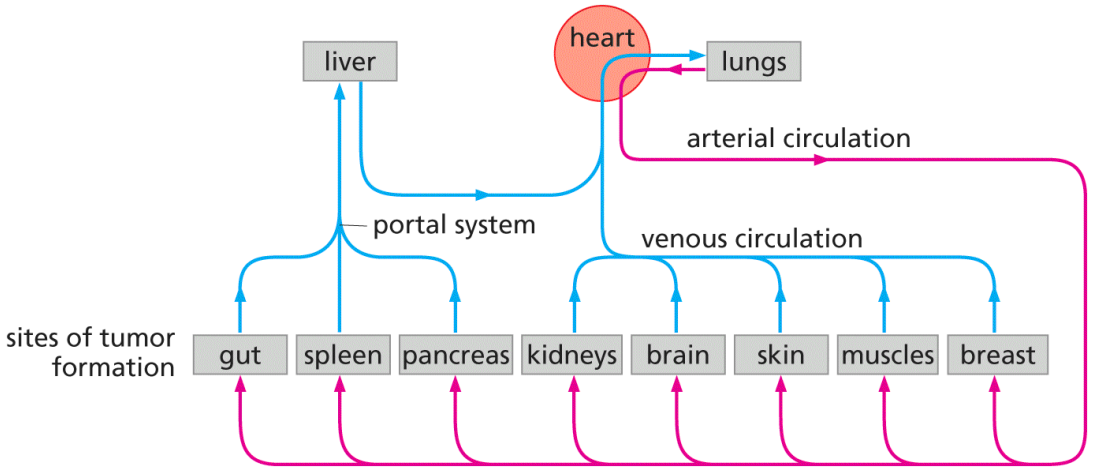
A series of four fluorescence microscopy images, one each from the diaphragm, peritoneum, liver, and lung. Each contains R F P and Y F P, along with the dark blue D A P I in nuclei.

(C)

Figure 14.38 Genetic barcodes reveal the multicellular origins of many metastases An important question concerns the origins of metastatic colonies, specifically whether they arise from single, individual founder cells or multiple founders, yielding monoclonal or polyclonal metastases. A powerful strategy to demonstrate the polyclonal origins of metastases derives from the strategy of

"confetti labeling," in which one of a series of fluorescent proteins of different colors are expressed in a random fashion in the individual cells of a primary tumor and in the lineal descendants of each of these initially labeled cells. (A) As seen in this map of a vector used to generate expression of one of four randomly activated fluorescent marker proteins, the reading frames of all four proteins are randomly expressed in various alternative configurations. Upon activation of the Cre-Lox recombinase, two successive excisions and reorientations occur, resulting in the expression of only one of the four fluorescent proteins and being expressed within a cell. (B) The confetti labeling procedure was employed to label the cells within a mouse model of primary pancreatic cancer, yielding sectors that express the four alternative fluorescent protein markers. (C) Liver metastases from these pancreatic primary tumors were analyzed for their marker protein expression, revealing the oligoclonality of these metastases. (A, from R. Maddipati and B.Z. Stanger, *Cancer Discov.* 5:1086–1097, 2015. With permission from American Association for Cancer Research. B and C, courtesy of Ben Stanger and Ravi Maddipati.)

The CTCs have been the objects of intensive investigation in recent years. They presumably are representative of the cancer cells moving from primary tumors to sites of metastasis formation. But this notion is at best an inference, since only a tiny proportion of CTCs cells ever succeed in founding new metastatic colonies, explaining why individual CTCs have rarely, if ever, been viewed in the act of extravasating and thereafter spawning macroscopic metastases. In one analysis, the CTCs were measured in the portal circulation (**Figure 14.39**) of 18 patients bearing pancreatic ductal adenocarcinomas. These measurements yielded an average of ~15 CTCs/ml. of portal blood, which could yield in aggregate 3×10^7 carcinoma cells entering from a pancreatic tumor into a patient's liver each day. However, the number of pancreatic metastases formed after several months' time (including the extended time prior to diagnosis) could be numbered on the fingers of one hand.



A schematic of the venous circulation and sites of trapping of circulating tumor cells. Arterial circulation routes blood oxygenated by the lungs from the heart to the body's many organs, which are sites of tumor formation: the gut, spleen, pancreas, kidneys, brain, skin, muscles and breast. There the blood is deoxygenated. Venous circulation then routes blood from the kidneys, brain, skin, muscles and breast back to the heart. Blood from the gut, spleen and pancreas is routed through the portal system into the liver, from where it then also travels to the heart. From the heart, all blood flows to the lungs to be reoxygenated.

Figure 14.39 The venous circulation and sites of trapping of CTCs The layout of the general circulation dictates that cancer cells disseminating from most primary tumor sites via the venous circulation (*blue lines*) will soon be trapped, at least transiently, in the microvessels within the lungs. However, the veins draining the gut, pancreas, and spleen are organized differently, in that their venous blood empties directly into the liver via the hepatic portal circulation before being dispatched thereafter to the heart and lungs. Consequently, vast numbers of metastasizing colorectal carcinoma and pancreatic adenocarcinoma cells are trapped in the microvessels of the liver within seconds of leaving the colon and pancreas. (As drawn, this diagram omits mention of the liver as a site of primary tumor formation.) (Adapted from I.C. MacDonald, G.C. Groom and A.F. Chambers, *BioEssays* 24:885–893, 2002.)

Another calculation revealed that even after arriving in the bone marrow, only one in a thousand disseminated breast cancer cells (DTCs) ever forms a micrometastasis, and only a single macroscopic metastasis arises from a thousand previously formed micrometastases. These calculations, which by necessity are only rough estimates, illustrate the phenomenon of metastatic inefficiency, that is, the profound discordance between the numbers of metastasizing cells released by primary tumors and the eventual outgrowth of clinically detectable metastases.

A variety of techniques are being developed to measure the concentrations of CTCs in the circulation of cancer patients (**Supplementary Sidebar 14.10**). These numbers may prove useful in gauging the efficacy of therapies directed against a primary tumor within a single patient; thus, a decrease in viable cells in the primary tumor following therapy will presumably be accompanied by a corresponding decrease in the release of such cells into the general circulation and a resulting decline in the number of CTCs. Techniques like these may also be used to determine an elusive number—the lifetime of CTCs in the general circulation (**Sidebar 14.5**).

Sidebar 14.5 Lifetimes of CTCs in the population may vary dramatically

Multiple factors contribute to the short lifetime of CTCs in the circulation; in a mouse, most of these cells spend less than 2 minutes in the circulation. Unlike red and white blood cells, the cells released by solid tumors are ill-suited to negotiate the passage through microvessels in various tissues (see Figure 14.37A–C). Thus, the internal diameters of most capillaries—3 to 8 μm—are far too small to accommodate the >20 μm diameter of individual cancer cells. Erythrocytes, for example, are only about 7 μm in diameter and are easily deformed, facilitating their passage through capillaries. Most cancer cells, in contrast, are not especially deformable. [Moreover, if cancer cells in the blood are coated with platelets (see **Supplementary Sidebar 14.5**), their effective physical diameters become even larger, causing them to be trapped in vessels larger than capillaries, such as the small arteries known as arterioles.] These factors dictate that within seconds of entering into the venous circulation many cancer cells will encounter the capillary beds of the lungs (see Figure 14.37D), in which they lodge.

Indeed, the lifetimes of CTCs as truly free-floating cells in the circulation may be so short that CTCs cannot respond via anoikis (see Section 9.13) to their loss of anchorage to solid substrates and the absence of stromal support. If so, this particular type of attrition sustained while these cells are swimming through the circulation may not play a major role in limiting their lifetime. Some measurements have been made by examining the attrition rate of carcinoma cells in the mouse by injecting such cells into the venous circulation via the tail vein, that is, using the procedure termed "experimental metastasis." Once in the circulation, the great majority of such cells are rapidly trapped in the microvasculature of the lungs (see Figures 14.37D and 14.39). As an example, in one experiment, within 10 minutes of injection into the venous circulation of a mouse more than 98% of the cells were already cleared out of the circulation; the corresponding half-life in humans is longer (∼1–2 hours), because the human systemic circulation time is ∼1 minute compared with the ∼4 seconds within a mouse. Although convenient, such experiments may represent artifacts of experimentation because other work utilizing conjoined mice suggests that CTCs spend several minutes in the circulation before disappearing. These latter experiments would seem to more closely represent the behavior of CTCs released by primary tumors, since they gauge the lifetimes of cell released by autochthonous primary tumors, that is, tumors initiated and growing within the hosts in which these measurements are made.

Importantly, the dynamics of physical trapping in the narrow-bore microvessels of many tissues hold important implications for measuring the numbers of the multicellular clumps of cells seen in Figure 14.37C and studied genetically in Figure 14.38. Because of their far larger effective diameters, these microemboli are likely to be trapped far more quickly in the microvasculature of various tissues and accordingly to exhibit far shorter half-lives in the circulation. This, in turn, will proportionately

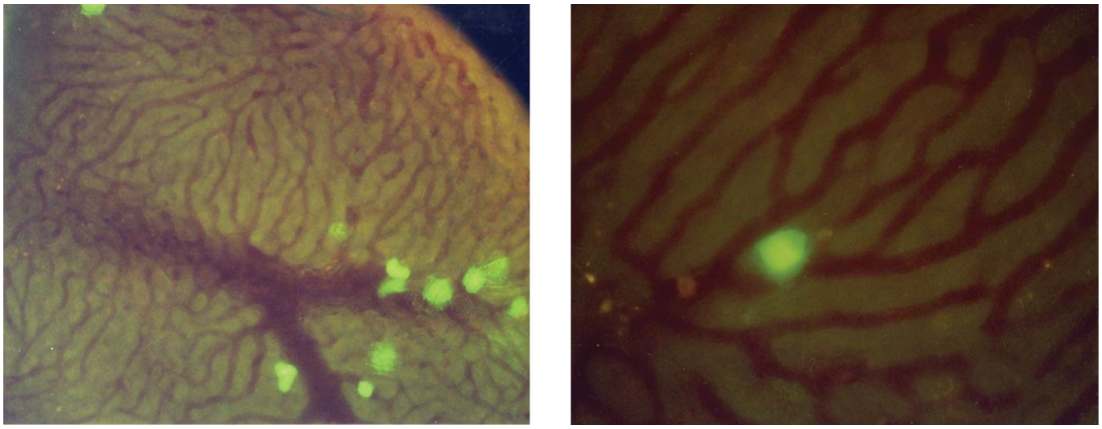
reduce their steady-state concentrations in the general circulation, leading to underestimates of the rates at which these clumps are actually formed and released into the circulation.

Once trapped within the lungs, some metastasizing cancer cells may attempt to found metastases there. However, the metastases spawned by many types of human tumors are often found elsewhere throughout the body, indicating that cancer cells usually succeed in escaping from initial trapping in the lungs and travel further to other sites in the body. How they do so is unclear. In some experiments, cancer cells trapped in capillaries have been observed to pinch off large amounts of cytoplasm, leaving behind cells that, although greatly reduced in size, seem to be viable; once they have undergone this amputation, such slenderized cells may succeed in negotiating passage through the narrow straits of the lung capillaries. A more plausible explanation is that wandering cancer cells may avoid being trapped altogether: in many organs, including the lungs, metastasizing cells can bypass capillaries by traveling through arterial–venous shunts, which form large-bore, direct connections between the two halves of the circulatory system. Finally, it is worthwhile noting that multicellular CTC clumps have been observed to work their way through microvessels whose luminal diameter is far smaller than the dimensions of these clumps.

Having snaked their way through the lungs and arrived in the general arterial circulation, roaming cancer cells, either as individual cells or in clumps, can then scatter to all tissues in the body. Some experiments have suggested that cancer cells use specific cell surface receptors to initially adhere to the luminal walls of arterioles and capillaries in certain tissue sites. However, far more extensive evidence indicates that simple physical trapping within small vessels throughout the body, as discussed above in the context of the lungs, provides most wandering cancer cells with their first solid foothold within a tissue.

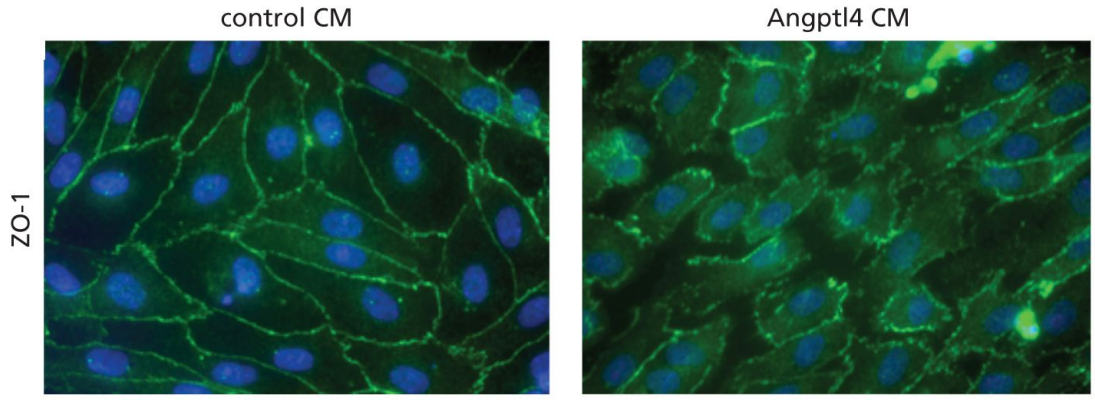
Once lodged in the blood vessels of various tissues, cancer cells must escape from the lumina of these vessels and penetrate into the surrounding tissue—the step termed extravasation (**Figure 14.40**). The process of extravasation depends on complex interactions between cancer cells and the walls of the vessels in which they have become trapped. Cancer cells can use several alternative strategies to extravasate. They may proceed immediately to elbow their way through the vessel wall. Alternatively, and possibly more typical, their ability to extravasate may depend on their secretion of angiopoietin-like protein-4 (Angptl4), which is released by carcinoma cells that are experiencing TGF-β signaling. This secreted factor stimulates the retraction of endothelial cells from one another, leaving gaps in the vessel walls as the initial step of extravasation (Figure 14.40B). The loosening of endothelial tight junctions may also be facilitated by recruited myeloid cells, notably neutrophils, which can supply proteases that dissolve the junctions between adjacent endothelial cells lining the walls

of blood vessels. The gaps in the endothelium created by this loosening expose vascular basement membrane (BM). The ability of the cancer cells to proceed further with extravasation seems to depend on their expression of integrin β1 (see Table 5.4 and Figure 5.22) which, together with associated α integrin subunits enables the tethering of the cancer cells to the laminin in the BM (Figure 14.40C; see also Figure 13.10). The cancer cells seem thereafter to deploy invadosomes (see Figure 14.30) to invade through the BM after which they may confront pericytes (see Figure 13.8) before they finally enter into the tissue parenchyma. Alternatively, trapped CTCs may begin to proliferate while still living within the lumen of a vessel, creating a small tumor that grows and eventually obliterates the adjacent vessel wall (see Figure 14.40D). In doing so, they push aside endothelial cells, pericytes, and smooth muscle cells that previously separated the vessel lumen from the surrounding tissue parenchyma (**Sidebar 14.6**).



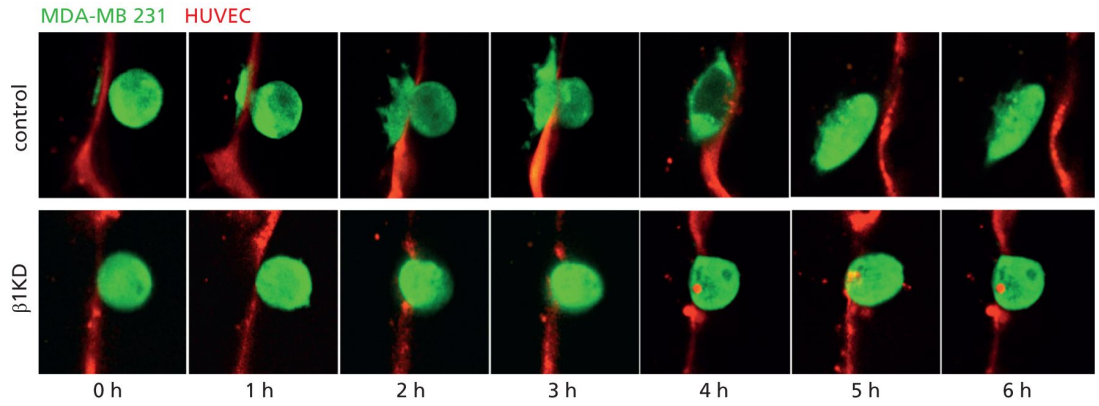
Two images of fluorescent green cells within liver tissue. The left image shows a dozen or so such cells lodged within small blood vessels fed by a larger one. The right image shows a single green cell that appears to lie between blood vessels.

(A)



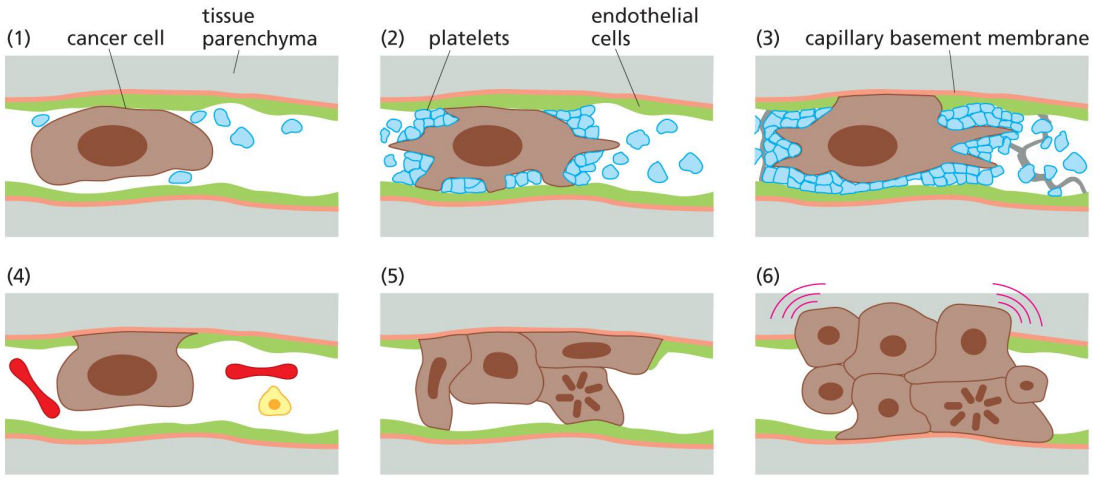
Two images of cells with blue nuclei and green plasma membranes. The left image, labeled Control C M, shows an irregular pattern of oblong cells packed tightly together, with fairly straight lines of contact between cells and no gaps. The right image, labeled Ang p t l 4 C M, shows an irregular pattern of oblong cells packed loosely together, with sometimes jagged outlines and dark gaps between cells.

(B)



Two sequences of fluorescence microscopy images, seven images each, taken at time 0 and then once every hour, up to 6 hours. In the images, green is M D A-M B 231 and red is HUVEC. The upper image sequence is labeled control; it shows a green tumor cell first attaching to and then breaking completely through a red vascular basilar membrane. The lower image sequence is labeled beta 1 K D; it shows a green tumor cell becoming lodged within a red vascular basilar membrane and remaining there.

(C)



A sequence of six diagrams. In the first diagram, a few platelets have begun to accumulate around a cancer cell lodged within a microvessel that is surrounded by tissue parenchyma. In the second diagram, the cancer cell has become fully encrusted with platelets, but at certain points, remains in contact with the microvessel's endothelial lining. In the third diagram, the cancer cell is even more encrusted with platelets, but on one side has broken through the endothelial lining and made direct contact with the capillary basement membrane that forms the microvessel's outer layer. In the fourth diagram, the platelets have disappeared, and normal blood flow through the microvessel has resumed, but the cancer cell remains in place, attached on one side to the outer capillary basement membrane. In the fifth diagram, the cancer cell has multiplied. There are now four cancer cells, and they have begun to obstruct the flow of blood. In the sixth and last diagram, the multiplying cancer cells have burst through the capillary basement membrane into the surrounding parenchyma.

(D)

Figure 14.40 Lodging and extravasation of circulating tumor cells (A) Tumorigenic, green fluorescent protein (GFP)–labeled Chinese hamster ovary cells were injected via the portal vein into a mouse liver. Large numbers of these cells (*green*) soon became arrested in the microvessels of the liver (*left panel*). However, within 24 hours, only an individual cell (*right panel; higher magnification*) has extravasated out of the microvessels (*dark red*) into the liver parenchyma (*light brown*). (B) Mammary carcinoma cells within a primary tumor experience TGF-β, which is produced in abundance in cells that have undergone an EMT and causes them to produce angiopoietin-like protein 4 (Angptl4). When these cells disseminate and become lodged in microvessels, the Angptl4 that they secrete induces nearby endothelial cells to retract from one another, leaving gaps in the capillary walls that facilitate extravasation. As seen here, cultured human vascular endothelial cells, when exposed to conditioned culture media (CM) produced by Angptl4-secreting cells (*right panel*), retract their associations with one another, as indicated by the dissolution of the ZO-1–containing tight junctions (*green*) between adjacent cells; CM produced by control cells (*left panel*) fails to induce this retraction. (C) The actions of Angptl4, as described in panel B, expose the underlying vascular basement membrane, a specialized BM that differs slightly from that underlying epithelial cell layers. In this *in vitro* microfluidic model of the microvasculature, MDA-MB-231 human breast cancer cells (*green*) have been introduced into an already-formed microvasculature formed by human umbilical vein endothelial cells (HUVECs; *red*). The ability of a carcinoma cell in the lumen of a microvessel to successfully extravasate (*above*) depends on their expression of integrin β1, which allows them to attach to the laminin of the BM. Subsequent invasion through the BM depends on their expression of invadopodia

and podosomes. Conversely, in the absence of normal integrin β1 expression by the carcinoma cell (β1KD *below*), achieved by shRNA knockdown, the carcinoma cannot attach to and advance beyond the vascular BM (*not visible*). (D) Electron-microscopic observations of metastasizing lung cancer cells injected into the venous circulation of mice (*not shown*) suggest that the process of extravasation often proceeds via steps involving the intraluminal proliferation of the cancer cells as drawn here. (1) A disseminated cell (*brown*) is trapped physically in a capillary. (2) Within minutes, a large number of platelets (*blue*) become attached to the cancer cell, forming a microthrombus. (3) The cancer cell pushes aside an endothelial cell (*green*) on one wall of the capillary, thereby achieving direct contact with the underlying capillary basement membrane (*orange*). (4) Within a day, the microthrombus is dissolved by the proteases that are responsible for dissolving clots. (5) The cancer cell begins to proliferate in the lumen of the capillary. (6) Within several days, sometimes sooner, the cancer cells break through the capillary basement membrane and invade the surrounding tissue parenchyma (*gray area*). (A, from G.N. Naumov, S.M. Wilson, I.C. MacDonald et al., *J. Cell Sci*. 112:1835–1842, 1999. With permission from The Company of Biologists. B, from D. Padua, X.H. Zhang, Q. Wang et al., *Cell* 133:66–77, 2008. Menter et al., *Cancer Res*. 48:4065–4072, 1988. Both with permission from American Association for Cancer Research.)

Sidebar 14.6 Cancer cells are clumsy escape artists

The complex task of escaping from the circulation into the surrounding tissue parenchyma is accomplished routinely by leukocytes, which must be able to enter into the parenchyma of tissues throughout the body in response to certain inflammatory stimuli, including the presence of infectious agents. Through a sequence of steps known as diapedesis, leukocytes are able to induce endothelial cells in postcapillary venules to retract and create portals into the underlying tissue. The entire process from attachment to the endothelial wall to entrance into the tissue parenchyma takes less than a minute and involves an elaborately choreographed program of biochemical and cell-biological changes!

In contrast, the vast majority of metastasizing cancer cells are not endowed with the receptors and biochemical response mechanisms required to execute diapedesis. Accordingly, if neoplastic cells do succeed in penetrating through the wall of a capillary or slightly larger vessel, they seem to do so by brute force, perhaps by degrading patches of endothelium in a process that may require many hours or even a day rather than a minute to complete (see Figure 14.40). Of additional interest is that the thrombin produced during the formation of microthrombi (see **Supplementary**

Sidebar 14.5) is quite effective in cleaving the various proteins used by endothelial cells to attach to the underlying vascular basement membrane; this activity may cause endothelial cells to retract from microemboli, thereby exposing the capillary basement membrane to direct attack by invasive cancer cells and the proteases that they and recruited neutrophils produce.

OceanofPDF.com

Glossary

hematogenous dissemination
: Metastatic dissemination occurring via the circulating blood.

surrogate marker
: A measurable parameter, often a diagnostic parameter, that serves to indicate the behavior of another process or agent whose behavior it parallels and reflects.

liquid biopsy
: Sampling of the contents of the blood rather than the contents of a solid tissue such as a tumor.

collective metastasis
: Process whereby a cluster of circulating tumor cells function as the founders of a metastatic colony, yielding a polyclonal growth formed by the lineal descendants of the multiple clustered disseminating tumor cells.

barcode
: Distinct labels, usually in the form of specific oligonucleotide DNA sequences, that are introduced into the individual cells within a cell population and used subsequently to identify each of these cells and their lineal descendants; the DNA sequences within a barcode library often represent randomly generated oligonucleotide sequences.

metastatic inefficiency
: Phenomenon in which only a minute portion of disseminated tumor cells succeed in spawning macroscopic metastases.

arteriole
: A small artery that empties into capillaries.

experimental metastasis
: Procedure for introducing cancer cells into the circulation via injection into the tail vein of a mouse; this procedure largely yields cancer cells trapped in the microvessels of the lungs.

autochthonous
: (1) Of native origin. (2) Referring to a tumor that arises within an organism (rather than from implanted cells or tumor fragments).

shunt

A passageway or connection that allows fluid to pass directly from one place to another, such as the direct connection between an artery and a vein that occurs without blood passing through intermediate microvessels, i.e., capillaries.

extravasation

Process of leaving a blood or lymphatic vessel and invading the parenchyma of the adjacent tissue. *See also* **intravasation**.

diapedesis

Complex sequence of steps enabling leukocytes to extravasate rapidly from the lumen of a blood vessel through the vessel wall into the underlying tissue parenchyma.

longitudinal

Referring to the repeated, successive monitoring of a single patient or a group of patients over an extended period of time.

microembolus

(pl., **microemboli**) Small body formed from cells or products of the clotting machinery that travels through the circulation and may be trapped in small vessels, often blocking further circulation through these vessels. *See also* **embolus**.

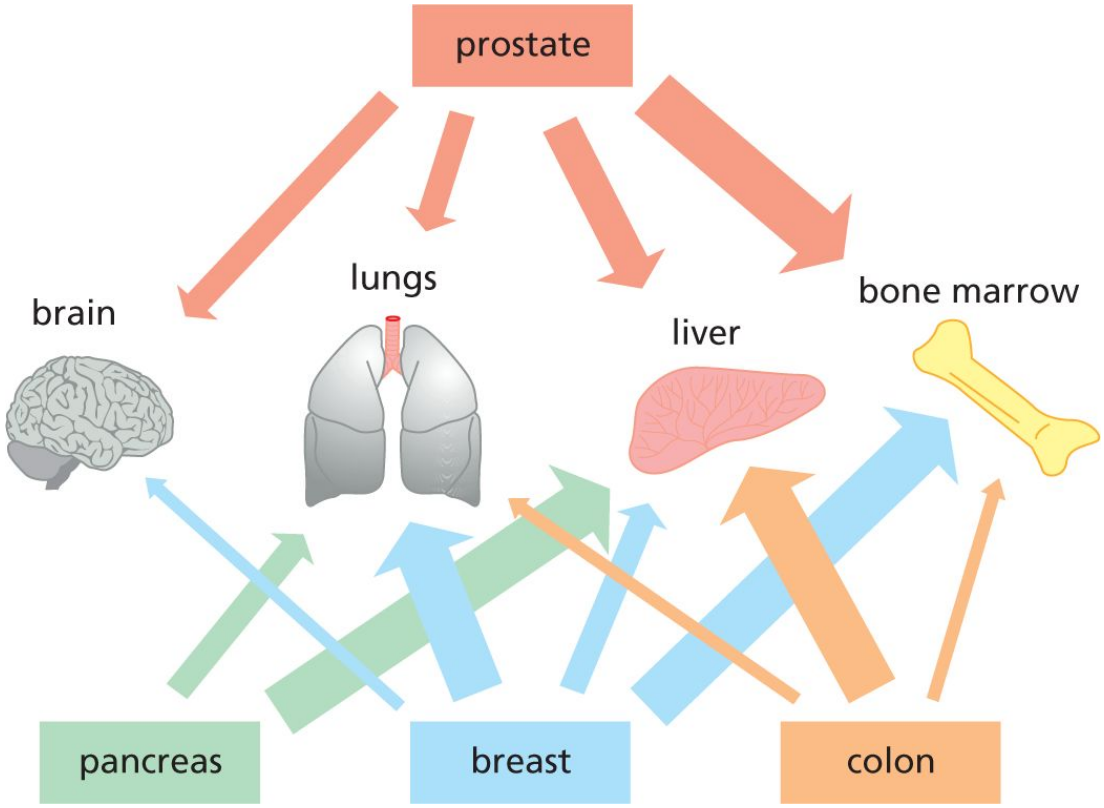
14.11 Colonization represents the most complex and challenging step of the invasion–metastasis cascade

Once they have arrived within the parenchyma of a tissue, metastasizing cancer cells may form micrometastases—small clumps of disseminated cancer cells, some of which are able to expand into clinically detectable masses; this growth of microscopic into macroscopic metastases is often termed colonization. It is plausible, if not likely, that CTCs are trapped in diverse tissues throughout the body and can seed micrometastases in most of them. If so, then the observed tendencies of different types of primary tumor cells to preferentially form macroscopic metastases in certain organs but not others may only reflect the efficiency of post-extravasation colonization, which is likely to vary drastically from one site of dissemination to another and reflect how permissive different tissues are for the colonization by various types of disseminated cancer cells. To be sure, there are clear exceptions to this thinking, specifically where the layout of the vasculature (as depicted, for example, in Figure 14.39) ensures that tumors arising in the gastrointestinal tract and pancreas dump vast numbers of cells via the portal circulation directly into the liver (as described in Section 14.10). In this situation, even if the liver were an intrinsically inhospitable host tissue for DTCs, the sheer numbers of cancer cells deposited directly into the liver from the portal vein may ensure that even low-probability events, specifically colonization, become possible.

The predilection to form metastases in one or another organ site was noted as early as 1889 by the British pathologist Stephen Paget (**Figure 14.41A**). He proposed the “seed and soil” hypothesis, in which he likened the seeding of cancer cells to the dispersal of the seeds of plants. After studying the clinical course of 735 breast cancer patients, Paget concluded that the patterns of metastasis formation in these patients could not be explained either by random scattering throughout the body or by the patterns of dispersal from the breast through the general circulation. He therefore proposed that the metastasizing cancer cells (the seed) find a compatible home only in certain especially hospitable tissues (the soil). He wrote, “a plant goes to seed, its seeds are carried in all directions; but they can only live and grow if they fall on congenial soil.”

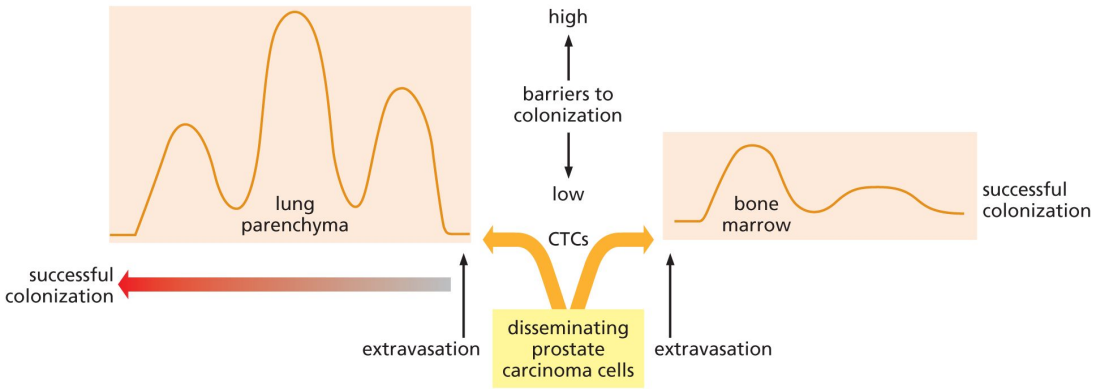
A black and white photograph of Stephen Paget, who is wearing pince-nez and reading a newspaper.

(A)



A schematic indicating the frequency with which various cancers metastasize into the brain, lungs, liver and bone marrow. Prostate cancer metastasizes into all four, but more frequently into bone marrow than into the others. Pancreatic cancer metastasizes into the liver and sometimes into the lungs. Breast cancer metastasizes into the brain, lungs, liver and bone marrow, but more frequently into lungs and bone marrow. Colon cancer metastasizes into the lungs, liver and bone marrow, but especially into the liver.

(B)



A schematic illustration of the metastasization of prostate cancer cells into the lung parenchyma and into bone marrow. The process begins with disseminating prostate carcinoma cells entering the bloodstream as circulating tumor cells. They undergo extravasation into the destination tissue, which is lung or bone, where they encounter barriers to colonization. These barriers are higher and more numerous in lung parenchyma than in bone marrow. Overcoming of the obstacles results in successful colonization.

(C)

Figure 14.41 Primary tumors and their metastatic tropisms (A) The British physician Stephen Paget (1855–1926) was the first to enunciate the "seed and soil" hypothesis, which states that the ability of a disseminated cancer cell to successfully found a metastasis depends on whether a distant tissue offers it a hospitable environment to survive and proliferate. (B) In this diagram, the relative width of each arrow indicates the relative proportion of clinically apparent metastases in various tissue sites of metastatic colony outgrowth that are generated by four types of common primary human carcinomas: prostate, breast, pancreas, and colon. In some cases, a tumor's tendency to spawn metastases in one or another tissue reflects the facility of the cancer cells from the primary tumor to adapt to (and thus colonize) the microenvironment of distant tissues, which likely explains the strong tendencies of prostate and breast cancers to generate metastases in the bone marrow. In other cases, the layout of the circulation (see Figure 14.39) may strongly influence the site of metastasis. For example, the high proportions of liver metastases deriving from primary colon cancers and pancreatic adenocarcinomas likely reflect the drainage via the portal vein of blood from the colon and pancreas directly into the liver. (C) One way to conceptualize the biological bases of metastatic colonization portrays the adaptations that disseminating carcinoma cells (circulating tumor cells, CTCs) must undertake in order to surmount multiple barriers to their successful adaption, given their initial differentiation program. Thus, prostate carcinoma cells encounter relatively few low biological barriers in the marrow (*right*) but multiple high barriers in the lung parenchyma (*left*). (A, from I.J. Fidler, *Nat. Rev. Cancer* 3:453–458, 2003.)

These tendencies are often termed metastatic tropism or organotropism. In some cases, the proclivity of primary tumors to seed certain sites of metastasis formation can be ascribed trivially to the organization of the circulation (see Figure 14.39). In other cases, such as the bone marrow metastases formed by prostate and breast tumors, more subtle biological mechanisms must be invoked, as described below. Moreover, use of the term "metastatic tropism" is actually misleading, because "tropism" usually implies the preferential, directed migration of agents to certain sites but not to others,

which clearly does not explain the anatomical sites of most types of metastasis formation.

Metastatic colonization is, without question, the most challenging step of the invasion–metastasis cascade, ostensibly because the foreign tissue environments encountered by recently arrived cancer cells do not provide them with the collections of familiar growth and survival factors as well as extracellular matrix components that allowed their forbears to thrive while still residing within the confines of the primary tumor in which they arose. Without these various types of familiar physiological support, poorly adapted disseminated cancer cells may rapidly die or, at best, survive for extended periods of time as micrometastases that can only be detected microscopically and rarely increase beyond this size.

Of note, the actions of EMT programs, as described in Sections 14.3 and 14.4, would not seem to explain the metastatic tropisms of cancer cells. Instead, it seems that, at least in the case of carcinoma cells, EMT programs are capable of moving these cells physically from primary tumors into the parenchyma of distant tissues. However, once arrived in these distant sites, disseminated tumor cells (DTCs) must devise their own tissue-adaptive programs, an undertaking that seems to be highly challenging for most types of DTCs. In these situations, the DTCs clearly experience enormous selective pressure, with variants succeeding only on rare occasion in contriving adaptive programs that permit survival and subsequent robust proliferation of these cells and their descendants.

In fact, at present, the problem of metastatic colonization represents the major puzzle for cancer researchers intent on understanding the pathogenesis of human neoplastic diseases. As will be apparent below, this is a problem of daunting complexity, given the large number of distinct subtypes of human primary tumors, the number of distinct sites at which metastases may grow out, and the possibility that each successful adaptive program may vary from others that arise independently in other patients and in other anatomical sites (Figure 14.41B).

Note, by the way, that these tissue-specific “adaptations” may be of two sorts. DTCs may acquire the ability to respond to the contextual signals naturally provided by their newly encountered tissue microenvironments; at the same time, they may need to learn how to perturb these microenvironments, forcing the latter to undergo shifts that create congenial metastatic niches.

As depicted here, successful adaptations and outgrowth represent a form of Darwinian evolution in which rare variants successfully adapt to newly encountered environments and associated stresses. Not addressed by this thinking is precisely *how* DTCs succeed in assembling biological programs that ensure their success as the founders of macroscopic metastases. Darwinian evolution is thought to depend largely if not

exclusively on heritable changes in the genomes of organisms under selective pressure. However, extensive searches for recurring somatic mutations that function to allow the outgrowth of DTCs in certain destination sites have provided few insights. These failures suggest the alternative mechanism: that effective adaptive programs are largely cobbled together at the epigenetic level, that is, they depend on changes in the transcriptomes of cells without underlying changes in the nucleotide sequences of their genomes.

Such epigenetic programs, once assembled, must be transmitted in a cell-heritable fashion, that is, being perpetuated from generation to generation of cells in cell lineages over extended periods of time. In addition, the invention of such programs by DTCs must depend on their phenotypic plasticity, that is, their ability to readily shift from one phenotypic state to another. Such plasticity would seem to echo another type of phenotypic plasticity—the behavior of cells that have activated EMT programs and, as a consequence, shift frequently between multiple phenotypic states lying between the extremes of fully epithelial and fully mesenchymal, as depicted in Figure 14.12.

At the same time, the ability of a DTC to succeed in cobbling together an effective adaptive program (that is, one that adapts them to their new tissue microenvironment) is likely to be governed by this cell's starting point—the differentiation program that it brought along from the primary tumor. This starting point may place the DTC in a position that allows it to adapt with ease to the foreign tissue that now hosts it or, conversely, may require a complex, challenging set of changes in transcriptional programs (and thus shifts in cell state).

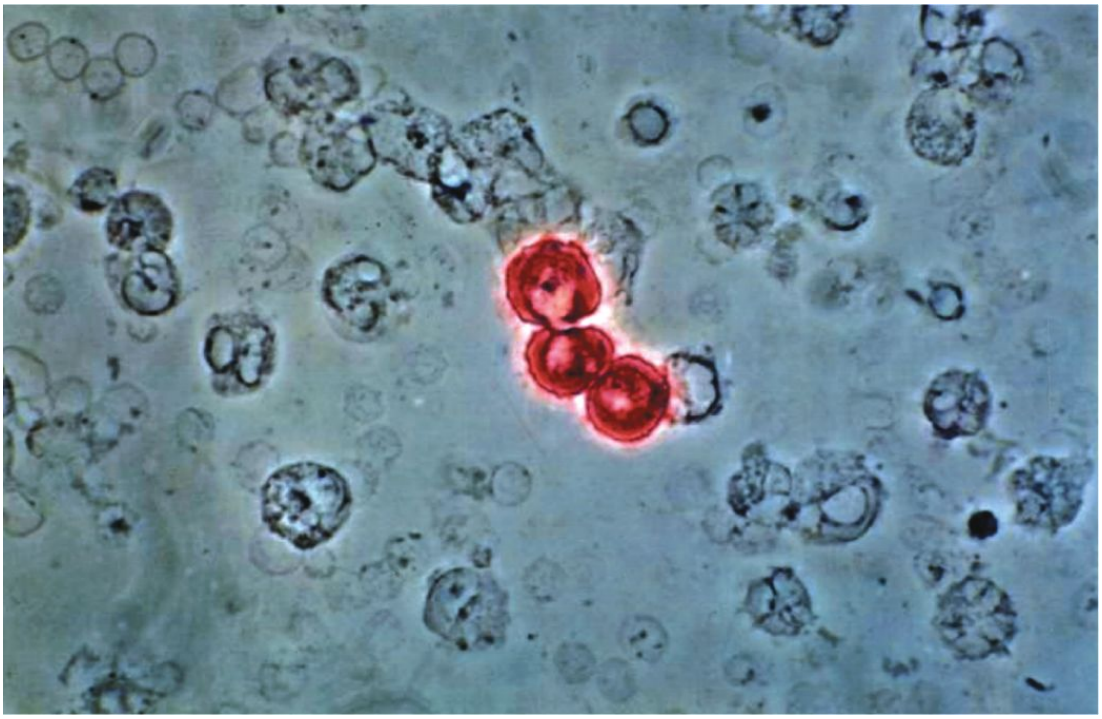
Stated in this way, circulating tumor cells (CTCs) originating from certain primary tumors may already be well poised to acquire effective tissue-adaptive programs simply because relatively few adjustments need to be made to their existing transcriptomes in order to thrive in certain sites of eventual dissemination. In contrast, CTCs originating in other types of primary tumors may confront multiple, almost-insurmountable barriers to developing successful adaptation programs in certain destination sites (Figure 14.41C). As an example, metastasizing cutaneous melanoma cells may already be poised to readily acquire adaptive programs that function in a variety of tissues, but distantly related uveal melanomas of the eye may be hard-pressed to devise diverse adaptive programs. As a consequence, cutaneous melanomas may found metastatic colonies in diverse tissue sites, whereas uveal melanomas, because of their limited phenotypic plasticity and unique differentiation program, may be limited to successfully seeding metastases only in the liver.

At present, we understand almost nothing about the mechanisms that enable DTCs within micrometastases to develop novel adaptive programs that power their proliferation thereafter in their newfound homes, doing so ostensibly by shifting from one transcriptomic state (and thus phenotype) to another. Moreover, it is possible in

principle that some of the changes in DTCs that optimize colonization efficiency in certain tissues may be achieved by genetic alterations, that is, mutations of their genomes occurring long after they have left the primary tumor; at present, however, there are no anecdotal accounts supporting this notion.

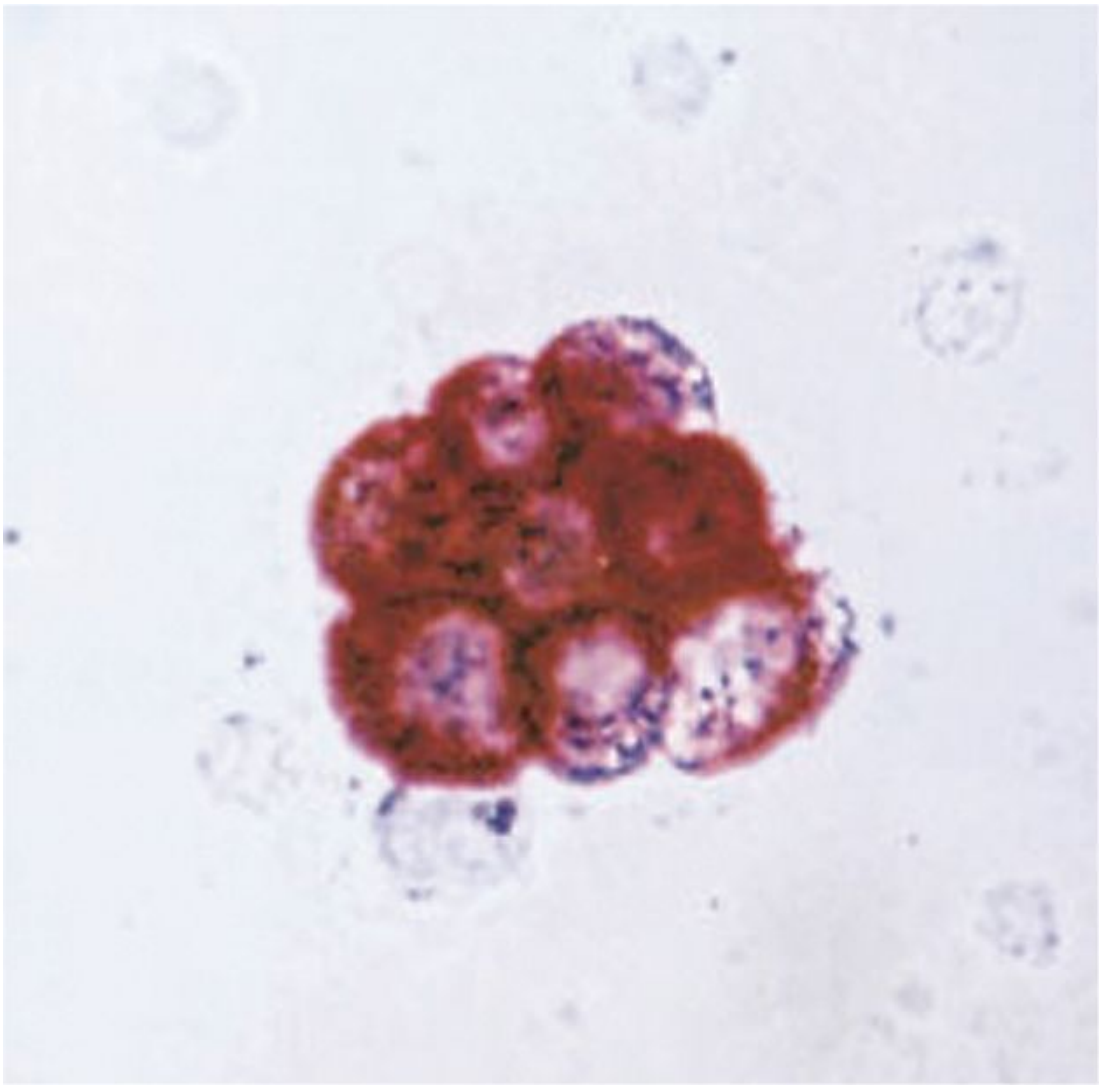
The barriers to post-extravasation proliferation are encountered almost immediately in the tissue parenchyma. To begin, carcinoma cells need to anchor to the surrounding extracellular matrix (ECM) via the integrins displayed on their surface (see Section 5.9). Without this anchorage, they are unable to activate a key source of mitogenic signals transduced by focal adhesion kinase (FAK, see Figure 6.17). This obstacle dooms the extravasated cells to remain as single-cell or several-cell micrometastases. Yet other barriers to successful colonization may also prevent them from thriving in their sites of dissemination. For example, the ability of a growing micrometastatic colony to successfully acquire access to a neovasculature may differ greatly from one site of dissemination to another (see Section 13.6). Moreover, for complex reasons, the stromal microenvironments of certain tissues may be fundamentally incompatible with the needs of DTCs originating in certain types of primary tumors.

Our descriptions of metastatic inefficiency in the previous section can be revisited here but from a slightly different angle. A frequently quoted statistic describes the clinical progression of breast cancer patients: more than 30% of these patients harbor hundreds, likely thousands of micrometastases in their bone marrow at the time of initial clinical presentation, but only half of the women in this group will ever develop metastatic disease. These numbers have implied to many that the bone marrow is the major site of dissemination of breast cancer cells, whereas in fact, it only represents the tissue in which micrometastases involving single DTCs and small clusters of DTCs are readily visualized and quantified (**Figure 14.42**). In reality, micrometastases are likely to be widely disseminated throughout many other tissues of a cancer patient, invariably in tissues where their detection is far more challenging than in the bone marrow, explaining our almost-total ignorance of where most DTCs end up, at least transiently, in the body; some of these occult micrometastases may lead, on occasion, to disastrous outcomes (**Supplementary Sidebar 14.11**).



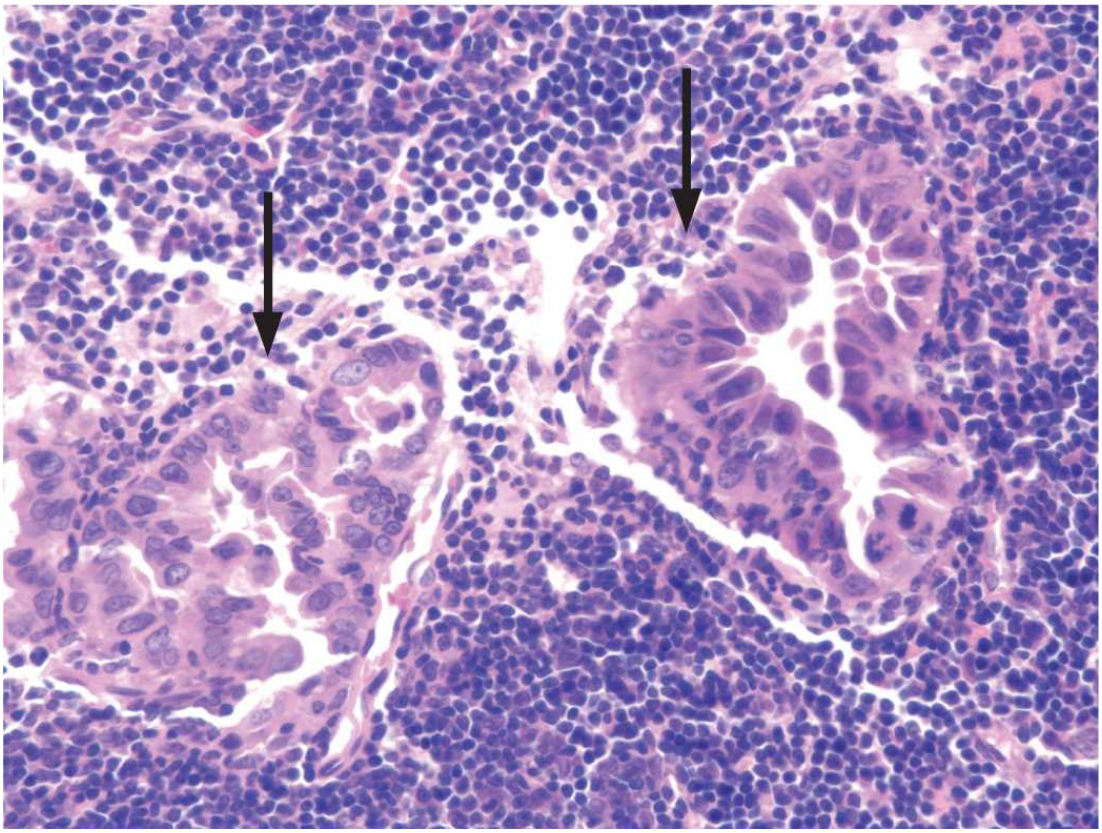
A color image showing a cluster of 3 bright red, distinctly outlined cells against a background of less distinctly defined cyan blue tissue.

(A)



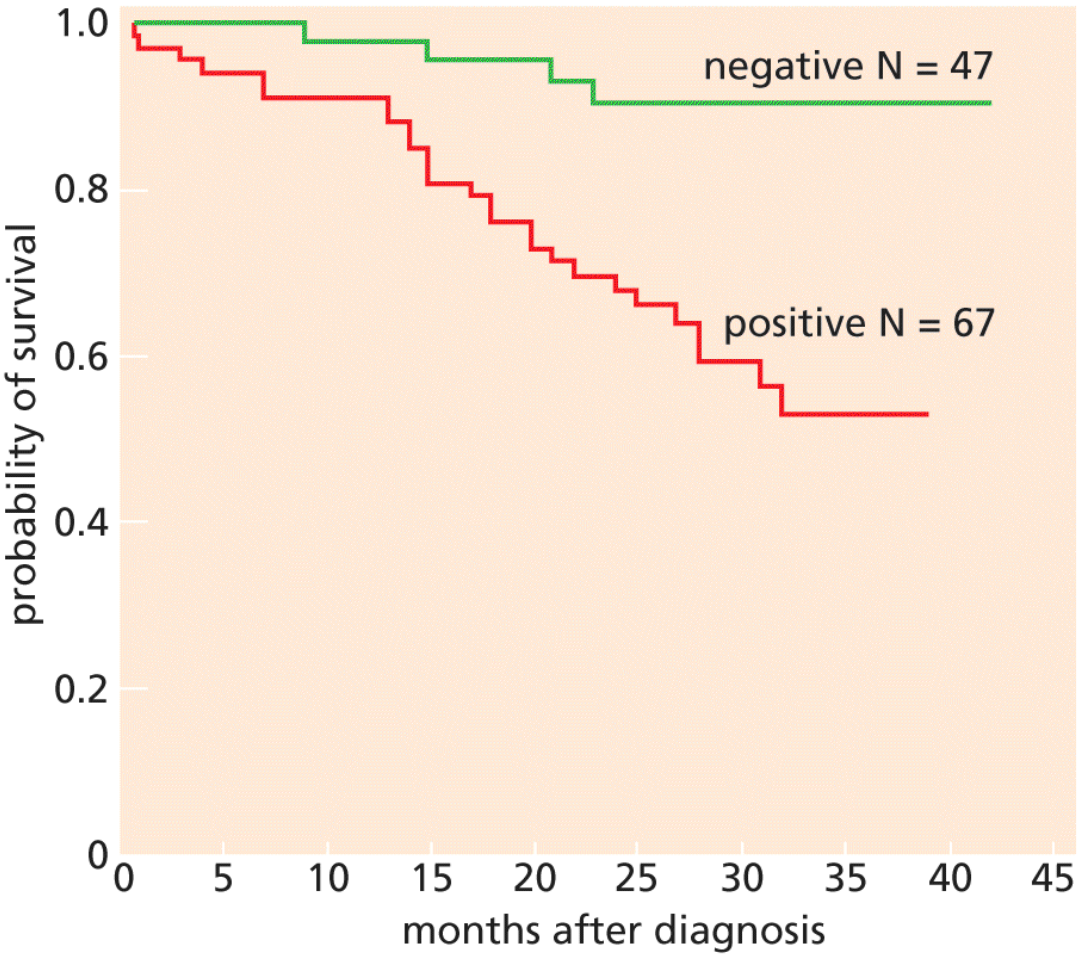
A color image showing a cluster of at least 8 bright red, distinctly outlined cells against a gray-white background.

(B)



A histology stain image of two ductlike structures in cross section, but the left one has no well-defined lumen and is surrounded by small, densely packed cells with dark nuclei.

(C)



A line graph showing the probability of survival as a function of time for two patient groups. For 47 cytokeratin-negative patients, the survival probability dropped from 100 percent at time zero to 90 percent at 25 months and remained flat thereafter. For 67 cytokeratin-positive patients, the survival probability dropped to 70 percent at 20 months and below 60 percent at 30 months.

(D)

Figure 14.42 Presence of micrometastases in the marrow and lymph node (A) Metastasis of cancer cells to the bone marrow is usually determined by withdrawing marrow from the iliac crest of the pelvis. In this micrograph, the presence of a micrometastasis containing several cancer cells in the bone marrow of a colon cancer patient has been detected by staining with an anti-cytokeratin antibody (*red*). This staining is highly specific because normal marrow cells are of mesenchymal/hematopoietic origin and thus do not express cytokeratins. In contrast, epithelial cells and their neoplastic descendants usually express

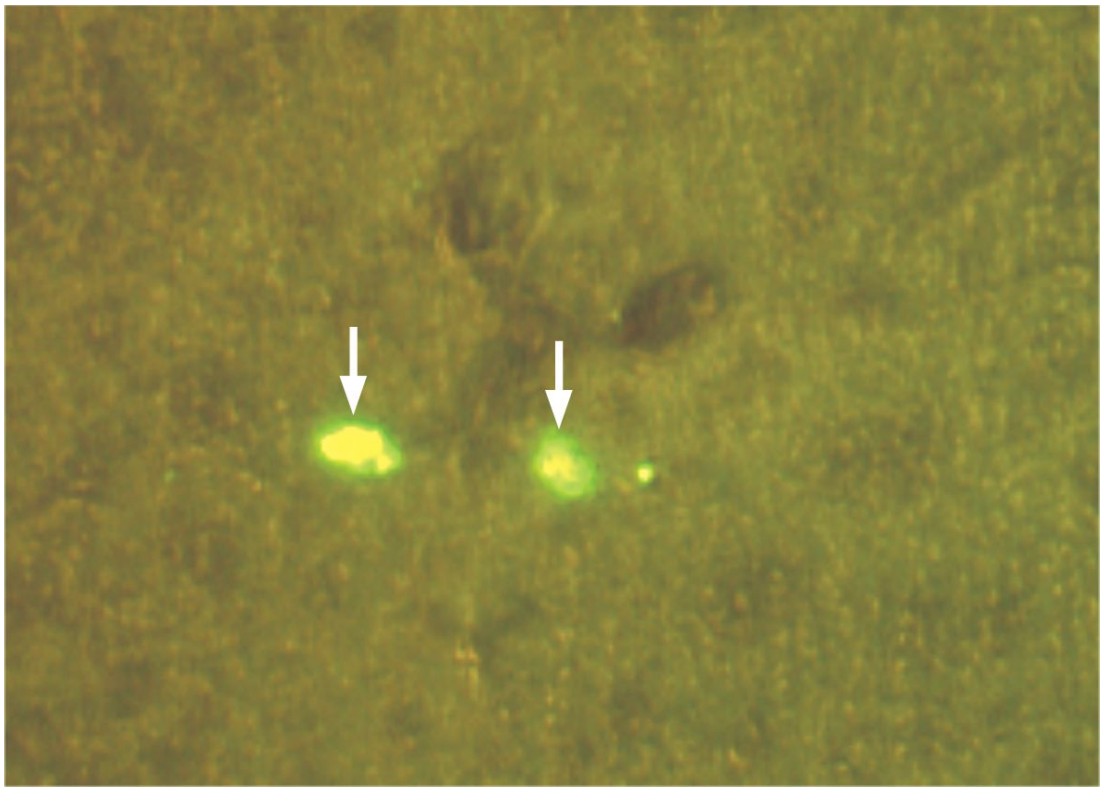
cytokeratins at significant levels. (B) Clusters of mammary carcinoma cells (*red*), viewed at slightly lower magnification, can often be found in the marrow of breast cancer patients. Although not demonstrated here, these cells are apparently the products of post-extravasation proliferation in the marrow. (C) Micrometastases often form in a draining lymph node—one that is directly connected with the primary tumor via a lymphatic duct that drains the tissue in which this tumor arose (see Figure 14.36). These growths are usually detectable by their strongly contrasting appearance from surrounding lymphocytes. Here two micrometastases of a mouse lung adenocarcinoma (*arrows*) to a lymph node are seen amid a sea of lymphocytes. Note the formation of a ductlike structure by the right micrometastasis, providing clear indication of proliferation after initial dissemination. (D) Cytokeratin-positive cells in the marrows of a cohort of breast cancer patients were counted, allowing the patients to be placed into two groups having either cytokeratin-positive or -negative marrows. As is evident, those with cytokeratin-positive cells in their marrow had a far worse prognosis, with almost 50% of them dying within three years of initial diagnosis. (A, courtesy of I. Funke and G. Riethmüller. B, from S. Braun, K. Pantel, P. Müller et al., *N. Engl. J. Med*. 342:525–533, 2000. With permission from Massachusetts Medical Society. C, courtesy of K.P. Olive and T. Jacks. D, from J.-Y. Pierga, C. Bonneton, A. Vincent-Salomon et al., *Clin. Cancer Res*. 10:1392–1400, 2004. With permission from American Association for Cancer Research.)

Although the probability that a given disseminated cancer cell will succeed in generating a macroscopic metastasis is extremely low, the very fact that a patient's primary tumor is actively dispatching neoplastic cells to sites throughout the body is itself an indication that the tumor carries a bad prognosis (Figure 14.42D). Indeed, at least at present, the number of DTCs in the marrow seems to represent a far more useful prognostic marker than the concentration of circulating tumor cells (CTCs) in the blood. This would seem to reflect the fact that the number of DTCs represents the accumulation of disseminated cancer cells over an extended period of time, whereas the concentration of CTCs may be dictated by complex kinetic processes governing their lifetimes—and thus their steady-state concentrations—in the circulation at one point in time.

Support for the existence of dormant micrometastases that persist in a nongrowing but viable state for extended periods of time comes from experiments in which living cancer cells were marked by brief exposure to fluorescent label–containing particles; the latter persist for long time periods within cells but do not affect the viability these cells, explaining why they are often termed vital dyes. However, the intracellular concentration—and thus the fluorescence intensity of the dye particles—is diluted by a factor of 2 each time a cell divides; hence, the residual fluorescence intensity in cells

allows the experimenter to estimate how many times the cells have divided since they were initially marked.

In one influential experiment, such dye-labeled cancer cells were introduced via the portal circulation into mouse livers, in which they formed large numbers of single-cell micrometastases. Eleven weeks later, cancer cells were recovered from these livers, and many of these still possessed full fluorescence intensity (**Figure 14.43**), indicating that they represented cells that had not divided even once since their arrival in the liver. Importantly, these recovered cancer cells remained capable of proliferating *in vitro* and were able to generate new tumors when injected subcutaneously into other host mice, that is, into an anatomical site where, for various reasons, they were able to proliferate more readily.



Two fluorescent green dots against a muted green background.

Figure 14.43 Persistence of solitary dormant tumor cells many weeks after introduction into the liver Tumorigenic mouse breast cancer cells were labeled by inducing them to take up styrene nanoparticles (48 nm diameter) that had been tagged with a fluorescent dye. These cells were then injected into a mesenteric vein, which carried them via the portal vein into the liver. Eleven weeks later, tumor cells could still be detected in the liver (*white arrows*). Importantly, the fluorescence intensity of many of these cells did not differ significantly from the

intensity of cells shortly after labeling, indicating that these cells had not divided even once following labeling and implantation in the liver. Following isolation and *in vitro* culturing, the descendants of many of these cells were tumorigenic when injected into the mammary fat pads of host mice. (Moreover, the dormant cancer cells were found to be fully resistant to a chemotherapy that reduced by 75% the size of metastases that were growing rapidly in the same mice.) (From G.N. Naumov, I.C. MacDonald, P.M. Weinmeister et al., *Cancer Res*. 62:2162–2168, 2002. With permission from American Association for Cancer Research.)

The above experiment shows dramatically that disseminated cancer cells can remain viable for extended periods of time in a nondividing, dormant state within foreign tissue sites. A quite different type of micrometastasis arises when disseminated cancer cells succeed in proliferating and forming colonies of a very small size within a foreign tissue; however, these subclinical micrometastases may never increase in size because the rate of cell proliferation in these clumps is counterbalanced by an equal rate of attrition, possibly as a result of the failure of these cells to execute the angiogenic switch (see Section 13.7). Alternatively, the outgrowth of such micrometastases may be held in check by the actions of both the innate and adaptive arms of the immune system (to be discussed in Chapter 15).

These micrometastatic colonies of various types are essentially undetectable clinically and represent what is often termed “residual disease.” The eruption of metastases that renders them clinically apparent may occur months or years after initial seeding; these delayed relapses are most notorious in the case of breast cancer, in which women who have been deemed cured may suddenly develop macroscopic metastases years after their initial, ostensibly successful treatment. As an example, as many as one-third of women treated years earlier by removal of their primary breast cancers exhibit occasional mammary carcinoma DTCs, even though they may remain symptom-free years after their primary tumor surgery. Such women may nonetheless experience metastatic relapses 10–20 years after their initial surgery.

We can imagine that such relapses can be triggered by at least two alternative mechanisms. DTCs may *evolve* on site, solving the problem of colonization by acquiring the ability to thrive in the foreign tissue microenvironments in which they happen to have landed and to resist ongoing attrition by immune-mediated attacks in those sites. Importantly, ongoing cell proliferation over extended periods of time would seem to be essential in order for the cells within disseminated micrometastases to spontaneously evolve to an aggressive state, that is, to generate the genetic or epigenetic heterogeneity that is essential for such diversification (and subsequent selection) via a form of Darwinian evolution (**Sidebar 14.7**).

Sidebar 14.7 Genetic analyses suggest that the evolution of metastatic ability can occur outside of the primary tumor

In perhaps 30% of breast, prostate, and colon cancer patients whose primary carcinomas have been surgically removed, one can still detect micrometastases in the marrow, lymph nodes, or blood; these patients are considered to have “minimal residual disease.” At this stage, analysis of the micrometastases indicates that they are genetically heterogeneous. However, years later, when a patient develops disease relapse and manifests readily detectable metastatic masses, the patient’s single-cell micrometastases are now much more similar to one another genetically (see Figure 11.16C).

This sequence of events suggests a stage of tumor progression in which the ability to colonize is acquired long after the acquired ability to disseminate to distant organ sites. Initially, genetically diverse cancer cells are seeded by a primary tumor throughout the body, but none of these succeeds in establishing a macroscopic metastasis simply because none is intrinsically capable of doing so. After a period of time, however, genetic and epigenetic evolution occurring in a micrometastasis somewhere in the body yields a clone of cells with the newly acquired ability to colonize efficiently. As this clone expands, it also begins to seed cancer cells throughout the body, and therefore generates a secondary wave of metastatic dissemination.

The individual cancer cells that are released by this colonizing clone soon constitute the majority of the single-cell micrometastases of a cancer patient, and these micrometastases are genetically very similar to one another because of their shared descent from the same clonal cell population. Importantly, because the cells in these new micrometastases all have inherited the ability to colonize, many may grow rapidly into macroscopic metastases, creating a life-threatening burden of disseminated cancer cells in the patient.

This cascade model suggests that the final evolution toward advanced malignancy often occurs at anatomical sites far removed from the primary tumor and that a secondary wave of dissemination (emanating from initially formed metastatic colonies) is responsible for most metastasis-associated death. (This secondary wave of dissemination is sometimes termed a “metastatic shower” to indicate the large number of new, robustly growing metastases that seem to appear simultaneously.)

A 1986 study of the autopsies of more than 1500 patients who died from colon carcinoma provided strong indications that metastases initially formed in the livers of these patients and spread from there to the lungs and finally to other sites in the body. Nevertheless, even with such evidence in hand, the cascade model is not yet validated by the genomic sequencing techniques and currently available bioinformatic algorithms.

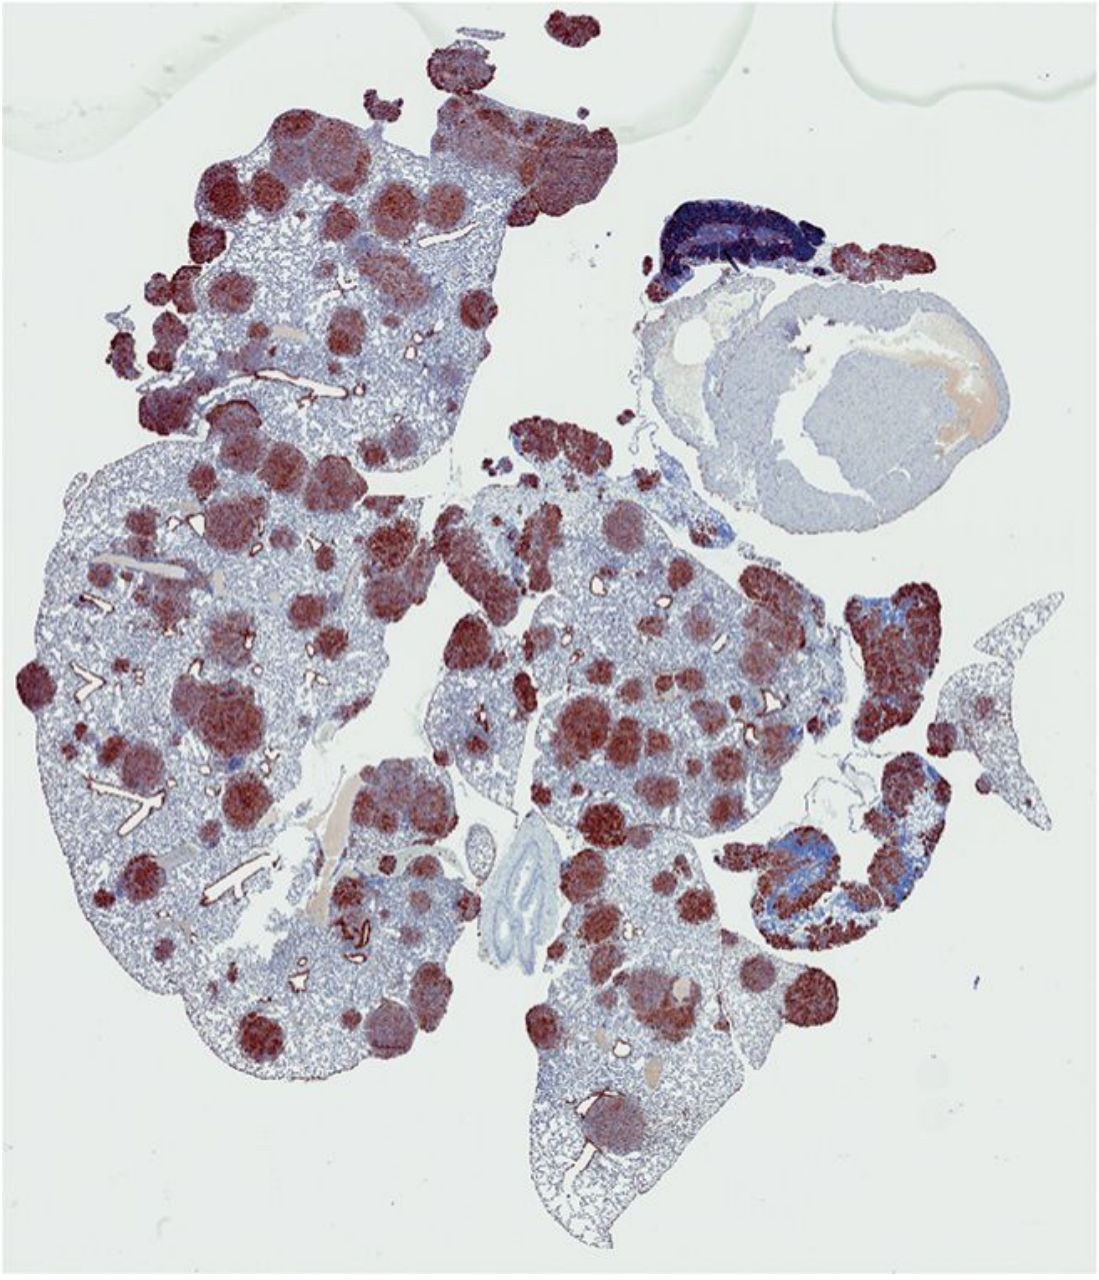
An entirely different, alternative mechanism of metastatic awakening and colonization is also plausible: changes in the tissue microenvironment surrounding dormant micrometastases, such as localized inflammation, might also trigger their outgrowth, perhaps by re-creating the stromal conditions that operated in the primary tumors in which the DTCs originated. Whatever their nature, micrometastases represent an imminent threat because they are often present in vast numbers throughout the body and may erupt years after a cancer has been thought to be cured.

The above discussions of sites of metastasis imply that the microenvironment of each potential target tissue (that is, a tissue in which a metastasis may actually form) represents a relatively stable constellation of biochemical and cellular traits that is typical of that particular tissue and of the niches encountered by recently arrived cancer cells.

The reality is, however, quite different, because certain tissue microenvironments may actually represent dynamically changing surroundings, that is, moving targets. Thus, rapidly accumulating evidence indicates that systemic signals released by primary tumors can actively reshape the microenvironments of distant tissues, often prior to metastatic dissemination, changing the parenchyma of these tissues and making them more hospitable to circulating tumor cells that happen subsequently to land in these tissues. These changes have been described as creating pre-metastatic niches in the destination tissues. Alternatively, as DTCs gain a foothold in the distant tissues and begin proliferation, they can then generate progressive changes in the tissue microenvironments around them that re-create the reactive stroma that was present in their corresponding primary tumors prior to the earlier dissemination. Hence, changes in the microenvironment at the site of eventual colony formation may occur both before and after the CTCs arrive.

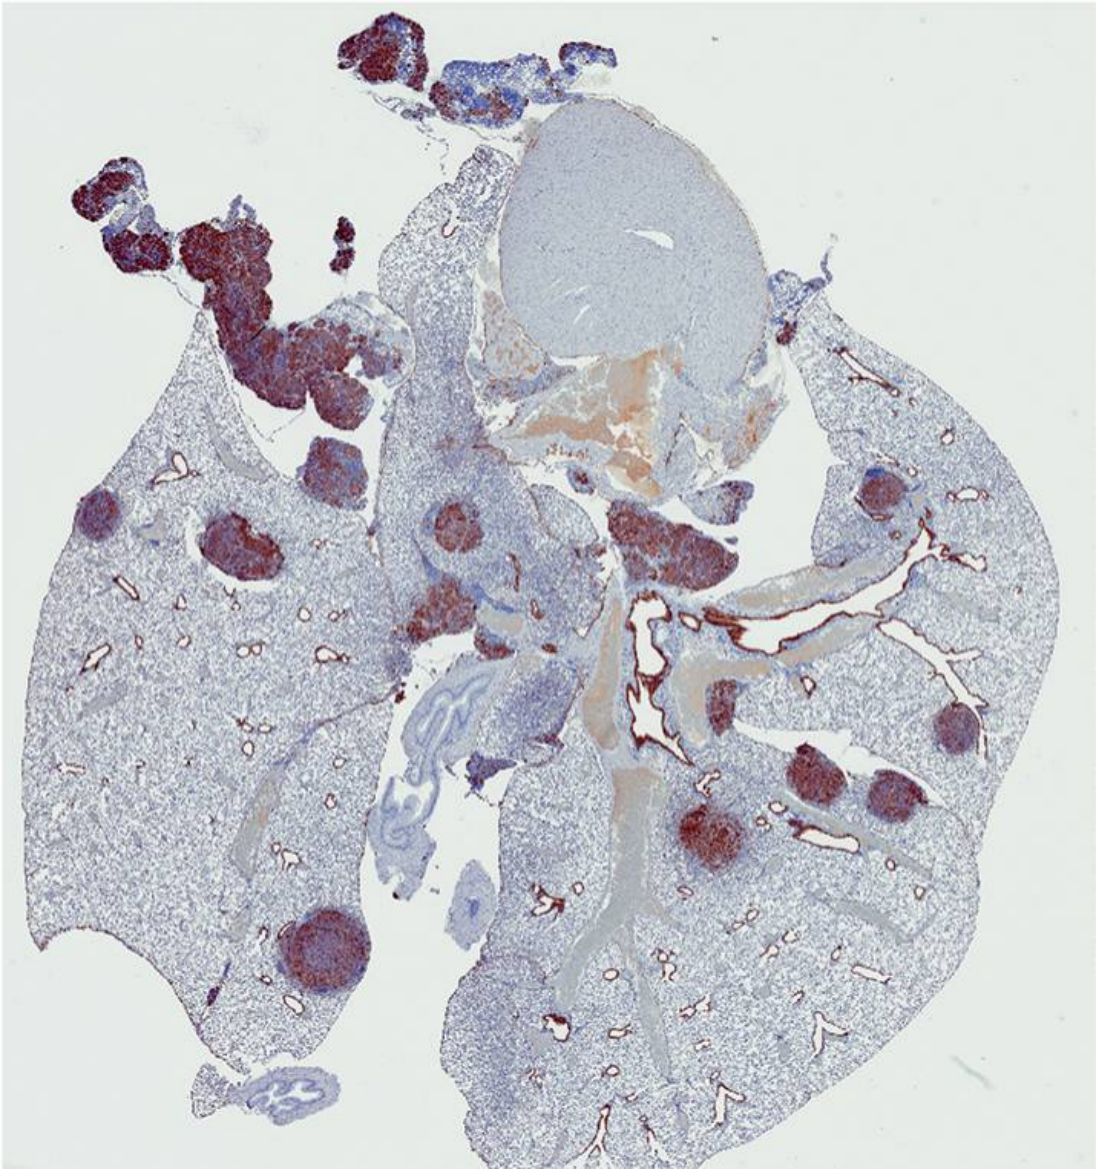
Moreover, the generation of a reactive, EMT-inducing stroma associated with a given metastatic colony implies that this colony could itself become the source of a new generation of CTCs and a resulting secondary wave of metastatic dissemination, as cited above. If so, the resulting secondarily generated CTCs may actually be more dangerous to the patient than the initially disseminated cells arriving earlier from the primary tumor, simply because these newer CTCs derive directly from precursors that have already undergone evolution in a site of dissemination and have therefore developed tissue-adaptive programs; these programs may allow this second wave of CTCs and derived DTCs to take root almost immediately in various newer sites of dissemination. Such behavior may explain the above-cited clinical observations of metastatic showers, in which individual patients seem to develop multiple metastases synchronously throughout the body (see Sidebar 14.7).

There are diverse ways in which primary tumors could favor the formation of pre-metastatic niches. One frequently observed mechanism involves the creation by primary tumors of neutrophilia, the state of elevated neutrophil concentrations present in the circulation. Doing so must involve the release by primary tumors of neutrophil-stimulating factors, such as G-CSF (granulocyte colony-stimulating factor), that impinge on the bone marrow and greatly increase the production of these myeloid cells, their concentrations in the general circulation, and their deposition in tissues throughout the body (**Figure 14.44**).



Pale blue lung tissue is riddled with many dark brown spots of varying size.

(A)



There are far fewer brown spots. Large areas of pale blue lung tissue are free of spots.

(B)

Figure 14.44 Role of neutrophils in facilitating the formation of pulmonary metastases Neutrophils operate in multiple ways to facilitate metastasis formation by circulating tumor cells, a process best documented in the context of the lungs. A variety of primary tumor types induce neutrophilia through the elaboration directly or indirectly of the G-CSF factor, which stimulates neutrophil expansion in the marrow and then in the systemic circulation. Neutrophils thereafter

contribute to the formation of pre-metastatic niches in the lungs. (A) In a mouse model of spontaneous mammary carcinoma metastasis, large numbers of metastatic colonies are readily detected in the lungs. (B) However, if circulating neutrophils are largely depleted using the anti-Ly6G antibody, which is used to specifically deplete neutrophils and reverse neutrophilia, the number of pulmonary metastases is greatly reduced. (From S.B. Coffelt, K. Kersten, C.W. Doornebal et al., *Nature* 522:345–348, 2015. With permission from Nature.)

The resulting neutrophils may actually operate in at least three distinct ways to increase the numbers of successfully launched metastases. Thus, these myeloid cells have been found to protect circulating tumor cells (CTCs) from attacks and thus attrition launched by NK cells in the general circulation. Neutrophils can also facilitate extravasation by CTCs. And finally, neutrophils may create changes in the parenchyma of a destination site that favor rapid outgrowth of extravasated cells.

A variety of noncellular messengers have also been found to serve as agents that are dispatched by primary tumors and contribute to pre-metastatic niche formation. By 2016, more than a dozen signaling molecules had been associated with the formation of these niches, in each case substances that are released by primary tumors, travel systemically to various sites throughout the body, and facilitate the establishment of metastases by subsequently arriving cancer cells. To extend the seed-and-soil metaphor of Paget, it would seem that the agents creating pre-metastatic niches function by tilling the soil, preparing tissues for possible seeding by subsequently arriving cancer cells.

This concept of pre-metastatic niche formation implies a purposive action on the part of a primary tumor that undertakes to pave the way for its metastatic offspring to spread throughout the body. Although attractive in theory, this notion ascribes an almost-intentional behavior to primary tumors, suggesting that preparing destination sites for eventual metastatic outgrowth is advantageous for the growth of cancer cells in the primary tumors. Instead, it is far more plausible that mechanisms that create these niches, like the process of metastasis itself, are unintended side-products of primary tumor growth, representing consequences of the formation of reactive stroma within primary tumors and associated systemic changes in a variety of bone marrow-derived cells that occur in connection with localized wound-healing and inflammation.

OceanofPDF.com

Glossary

colonization
: Proliferation of cells within a micrometastasis that leads to the formation of a macroscopic metastasis.

metastatic tropism
: The observed tendency of cancer cells from one specific primary tumor type to colonize preferentially one target organ or another.

organotropism
: The tendency of cancer cells in a specific type of primary tumor to spawn metastases in a specific subset of normal tissues in the body.

plasticity
: Describing an ability to readily transit between alternative states, such as distinct phenotypic states.

vital dye
: Dye that can be used to stain living cells or tissues and is retained for extended periods of time in these objects without compromising viability.

cascade model (of metastasis)
: A hypothetical model that posits that initially formed metastatic colonies rather than corresponding primary tumors are the sources of a secondary wave of metastatic dissemination and thus metastatic colonies.

metastatic shower
: Clinical observation of an apparent synchronous formation of multiple new metastases at multiple sites of metastatic dissemination.

pre-metastatic niche
: A site within a tissue that is altered in some fashion to facilitate the survival and/or proliferation of subsequently arriving disseminated cancer cells.

neutrophilia
: A condition in which the concentration of neutrophils in the circulation is elevated above its normal value.

steady state
: The condition reached when a series of dynamic, often countervailing processes have placed a complex system in a balanced, relatively

constant, unchanging state.

14.12 Successful metastatic colonization often involves complex adaptations

Abundant evidence supports the notion that metastatic cancer cells that have colonized a certain target organ must become highly specialized to do so: (1) Of the 75% of young patients with papillary thyroid carcinomas that are accompanied by significant lymph node metastases, only 3% will ever develop distant metastases. Hence, adaptation to the lymph nodes by metastasizing thyroid carcinoma cells does not empower them to colonize other tissues in the body. (2) Similarly, duodenal carcinoid tumors greater than 1 cm in diameter (containing $>10^9$ cells) have a high rate of lymph node metastasis, yet they rarely proceed to metastasize to the liver, which is the common site of metastasis of the tumors that arise in the nearby colon. (3) Cancer cells isolated from human lymph node metastases have been found, after injection into the venous system of mice, to grow preferentially in the lymph nodes of their mouse hosts rather than in other possible sites of colonization, suggesting specialized adaptations to these sites in humans that persist and influence tissue tropism in mice. (4) Mouse melanoma cells can be selected that metastasize preferentially to the lungs and human breast cancer cells that metastasize either to the lungs or to the bone and continue to do so each time they are implanted in mouse hosts. (5) Cells that formed dormant micrometastases in the liver proliferate vigorously when removed from the liver and implanted subcutaneously, as described in Figure 14.43.

These disparate observations reinforce the notion that the ability to colonize a certain organ represents an acquired specialization. Arguably the most dramatic example of the need for such specialization comes of the clinical practice of introducing peritoneovenous shunts to reduce the ascitic fluid accumulated in patients afflicted with various types of inoperable primary tumors. In such patients, billions of cancer cells arising in peritoneal ascites

are transferred into the general venous circulation but few if any metastases seem to be seeded by these cells (**Supplementary Sidebar 14.12**).

To summarize, it seems that the frequency of metastases to an organ site is governed by two parameters—the frequency with which metastasizing cells are physically trapped in an organ, which is dictated in part by the layout of the circulation (see Figure 14.39), and the ease with which they can thereafter develop specialized adaptations that allow them to thrive in the microenvironment of that organ. Aside from metastases to the liver from the gut and pancreas, the layout of the circulation appears to represent a minor factor in governing the sites of metastasis formation.

There are also indications that tissues that are normally not hospitable sites for colonization may become so through specific pathological processes, such as localized wounding (**Supplementary Sidebar 14.13**). This suggests that areas of chronic inflammation within the body of a cancer patient may occasionally create congenial environments for metastasizing cancer cells, simply because they provide a spectrum of mitogenic and trophic signals, as discussed in Chapter 13. Such essential preconditions for metastatic seeding may explain why the microenvironment of the fully normal contralateral breast of a breast cancer patient is rarely the site of metastatic seeding, simply because it is not in a physiological state, such as one of inflammation, that is a key ingredient for effective colonization (**Sidebar 14.8**).

Sidebar 14.8 Contralateral metastases are relatively rare

Possibly the greatest embarrassment for the seed-and-soil hypothesis comes from its failure to explain the rarity of contralateral metastases. For example, cancer cells disseminated from a primary tumor in one breast should find that the contralateral breast provides the most hospitable environment for colonization by these cells. In fact, only about 2% of breast cancer cases result in contralateral metastases, comparable to the frequency of tumors in the breast that arise as metastases of primary tumors located elsewhere in the body. Similarly, primary kidney cancers metastasize infrequently to contralateral kidneys. These behaviors are clearly incompatible with the simplest version of the seed-and-soil hypothesis and

require explanation. One possibility is that, in addition to landing in an intrinsically compatible tissue, disseminating cancer cells prefer to take root in a tissue that has an activated stroma, such as is seen in sites of chronic inflammation or wound healing (see also **Supplementary Sidebar 14.13**).

Such metastasis to areas of wounding and inflammation may explain a phenomenon first described in 2009—tumor self-seeding. Circulating tumor cells (CTCs) released by an initially formed macroscopic metastasis may find that the most congenial tissue microenvironment to colonize is the stroma of the corresponding primary tumor. On the one hand, the reactive stroma of the primary tumor (see Section 13.3) would seem to provide the factors that are highly supportive of the survival and proliferation of many types of cancer cells. On the other, these CTCs do not need to undergo the adaptive changes that seem to be required when cancer cells arising in one organ attempt to colonize a different organ; here these traveling cells are returning to familiar territory.

Tumor self-seeding also holds implications for the genetic makeup of the primary tumor: if cancer cells undergo adaptive genetic and epigenetic changes in distant sites of metastasis in order to colonize those sites, secondary metastatic showers of cells released by those distant tumors (see Sidebar 14.7) may carry these genetic and epigenetic changes *back* to a primary tumor, causing its cells to increasingly exhibit the genotypic and phenotypic alterations developed elsewhere in the body!

One interesting and still-unresolved question involves the timing of metastatic dissemination: When during the course of primary tumor progression do cells begin to disperse to distant sites in which they eventually form metastases (**Sidebar 14.9**)?

Sidebar 14.9 Some cancer cells leave home early

Embedded in the discussions in this chapter is the notion that multi-step tumor progression occurs in the primary tumor site, and that only after cancer cells in these tumors have evolved to a certain state of aggressiveness do they begin to disseminate and attempt to found metastatic

colonies. In fact, clinical observations have demonstrated the presence of disseminated tumor cells in certain organs, such as the bone marrow, long before primary tumor progression has generated aggressive tumor cells. (In the case of carcinomas, these observations may one day be explained by the activation of EMT programs in the cells of relatively benign, early-stage tumors.)

This early dispersal suggests that once relatively early-stage cancer cells have settled in distant tissues, they may evolve within those tissues through the later steps of multi-step tumor progression (see Chapter 11). Accordingly, such parallel progression may occur at a great distance from and independently of the multi-step progression occurring in the primary tumor. If validated, this would force a fundamental rethinking of how multi-step tumor progression usually proceeds.

This model is encumbered, however, by certain realities if only because these early-disseminating cells are doubly handicapped: like their late-stage counterparts, they are poorly adapted, at the moment of their arrival, to proliferate in the foreign tissues in which they have landed. In addition, by definition, they lack the suite of mutations (for example, those affecting oncogenes and tumor suppressor genes) needed to proliferate vigorously wherever they land (see Sections 11.8 and 11.9). Because the genetic and epigenetic diversification of tumor cells (which is critical to tissue adaptation via multi-step cellular evolution) would seem to require active cell proliferation, these dual impediments to proliferation may well dictate that these dispersed cells represent dead ends, remaining as dormant micrometastases and undergoing slow, progressive attrition.

OceanofPDF.com

Glossary

contralateral
: Referring to the opposite side of the body of a bilaterally symmetrical organism.

tumor self-seeding
: Process whereby circulating tumor cells originating in a primary tumor or in its derived metastases return to the primary tumor and seed populations of cells within that tumor.

parallel progression
: Process whereby cancer cells advance through multi-step tumor progression at sites distant from and independently of the primary tumor. *See also* **primary tumor**.

14.13 An example of extreme metastatic specialization: metastasis to bone requires the subversion of osteoblasts and osteoclasts

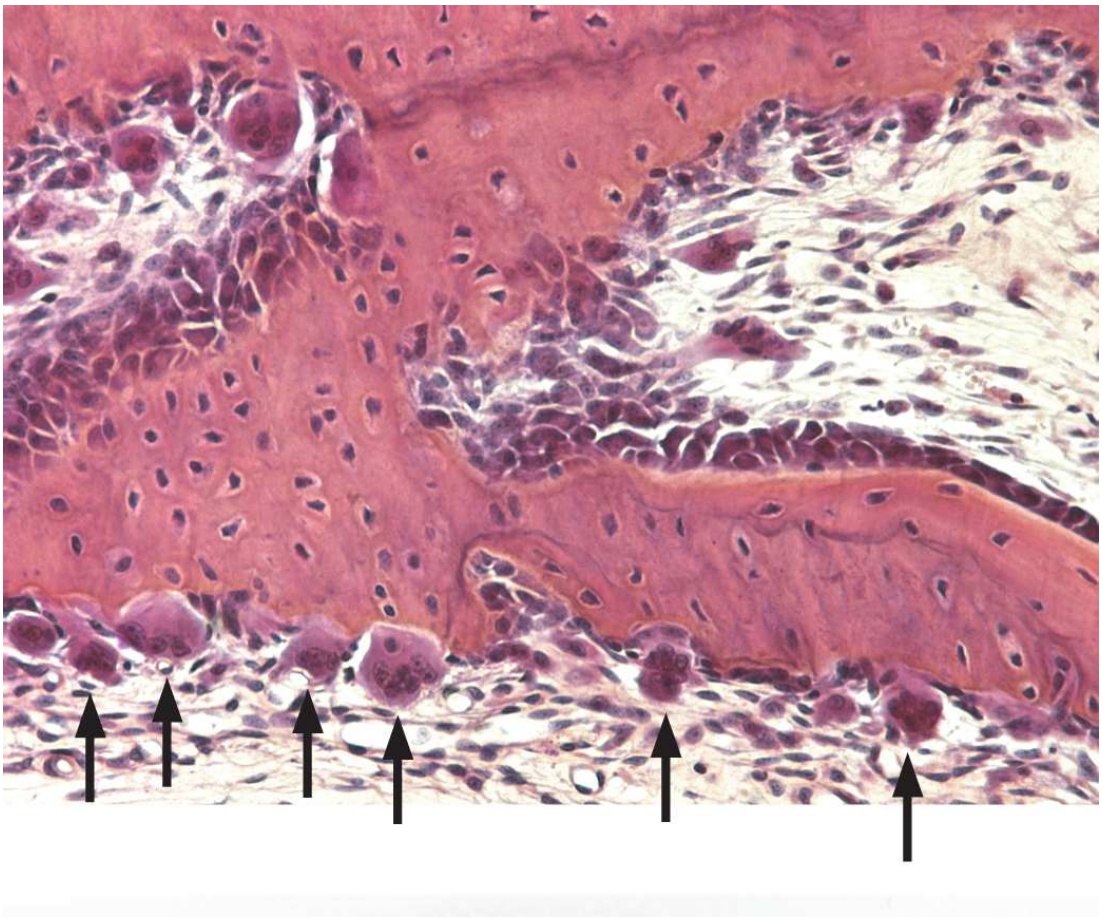
The adaptations that circulating tumor cells must make in order to succeed in colonizing various tissues have been studied in a variety of destination sites. Arguably the best understood of these concerns the formation of metastases in the microenvironment of the bone marrow and surrounding mineralized bone. Indeed, the development of bony metastases represents one instance in which we understand in extraordinary detail the biochemical and biological mechanisms that permit metastasized cancer cells to thrive in a specific tissue microenvironment. This fact, on its own, justifies a detailed discussion of osteotropic metastasis. In addition, the current, very detailed understanding of the mechanisms of bony metastasis formation should serve as a model for how comparable processes operating in other sites of cancer metastasis will be elucidated in the future.

Osteotropic metastases also warrant our attention because, as mentioned repeatedly, several of the most common types of cancer occurring in the Western world—carcinomas of the lung, breast, and prostate—show a strong tendency to metastasize to the bone. In fact, patients with advanced breast and prostate cancer almost always develop bone metastases. And in those patients who succumb to these cancers, the bulk of the tumor cells in their bodies at the time of death is often found among the metastases scattered throughout their bones.

We usually think of bone as being a static tissue which, once formed, retains its structure throughout life. The truth is far more interesting. In mammals, about 10% of skeletal bone mass is replaced each year, resulting in an essentially complete replacement over the course of a decade. This continuous remodeling enables the bones to respond to mechanical stresses by compensatory reinforcing of stressed regions. For example, the bones of the legs are continuously being remodeled in response to the weight-bearing signals that different portions of each leg bone receive.

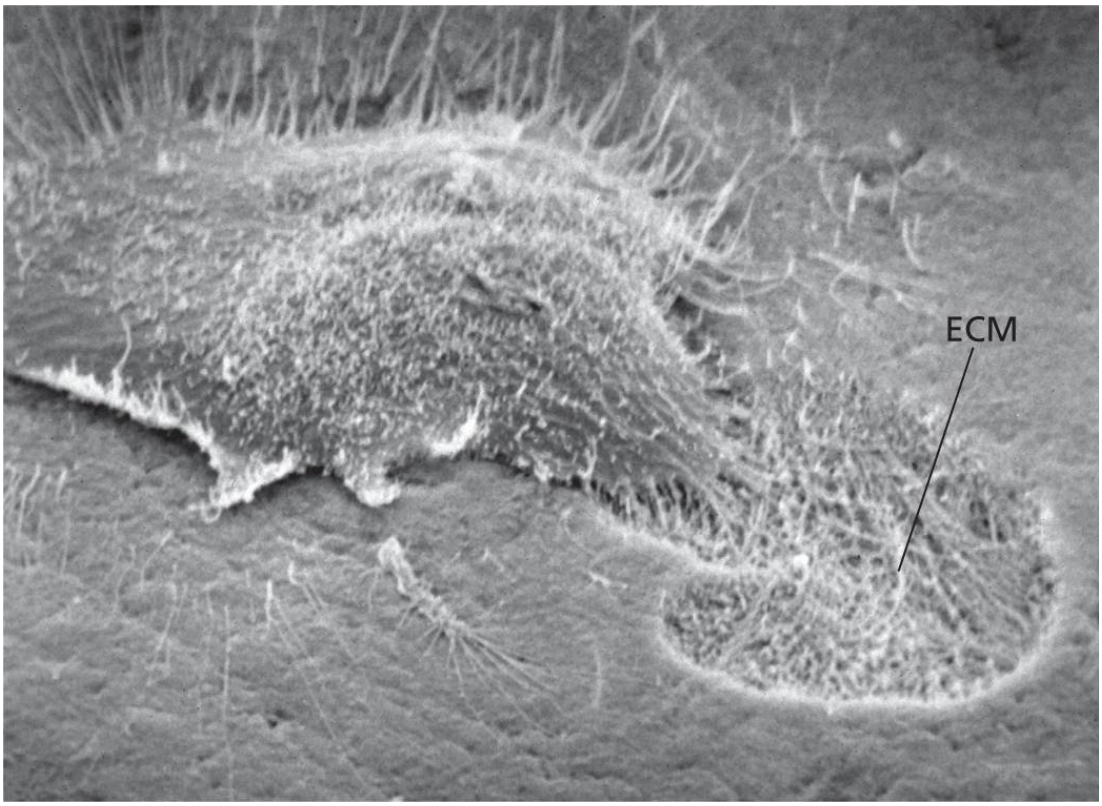
The turnover of bone is the work of osteoclasts, which break down mineralized bone, and of osteoblasts, which reconstruct it. The osteoclasts function first to demineralize

the bone (by dissolving its calcium phosphate crystals) and then to degrade the now-exposed extracellular matrix, which previously formed the organic scaffolding for the calcium phosphate crystals (the process together being termed resorption; **Figure 14.45**). Osteoblasts move in soon after the osteoclasts have completed their work in order to carry out reconstruction, which involves both the assembly of new ECM and the deposition of calcium phosphate crystals in the interstices of this matrix. As can be deduced from this description, the two cell types normally work in close coordination.



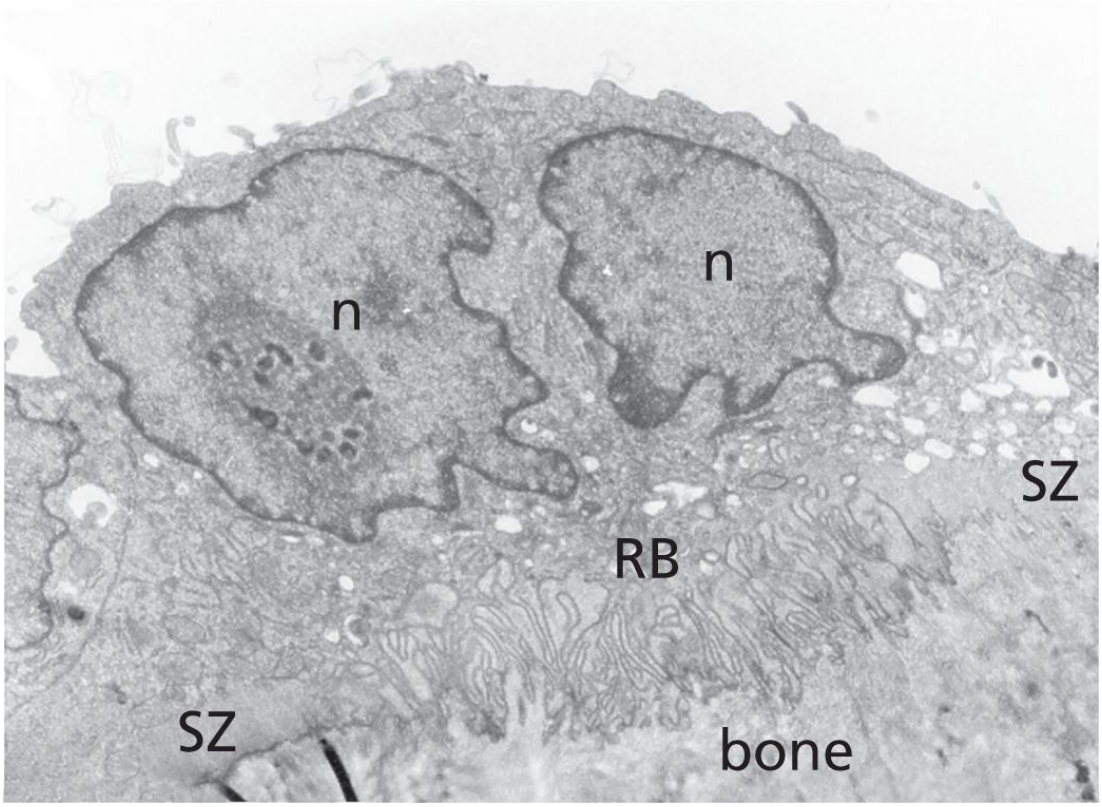
A histology image of dark pink tissue surrounded by lighter tissue. Near the bottom of the image, a series of purple nodules straddle the horizontal boundary between the two tissue types.

(A)



An electron micrograph of a flat, hairy cell making its way across a flat surface. Behind the trailing edge of the cell, a portion of the flat surface features a large indentation in which the fibrous character of the surface material is revealed. This is labeled E C M.

(B)



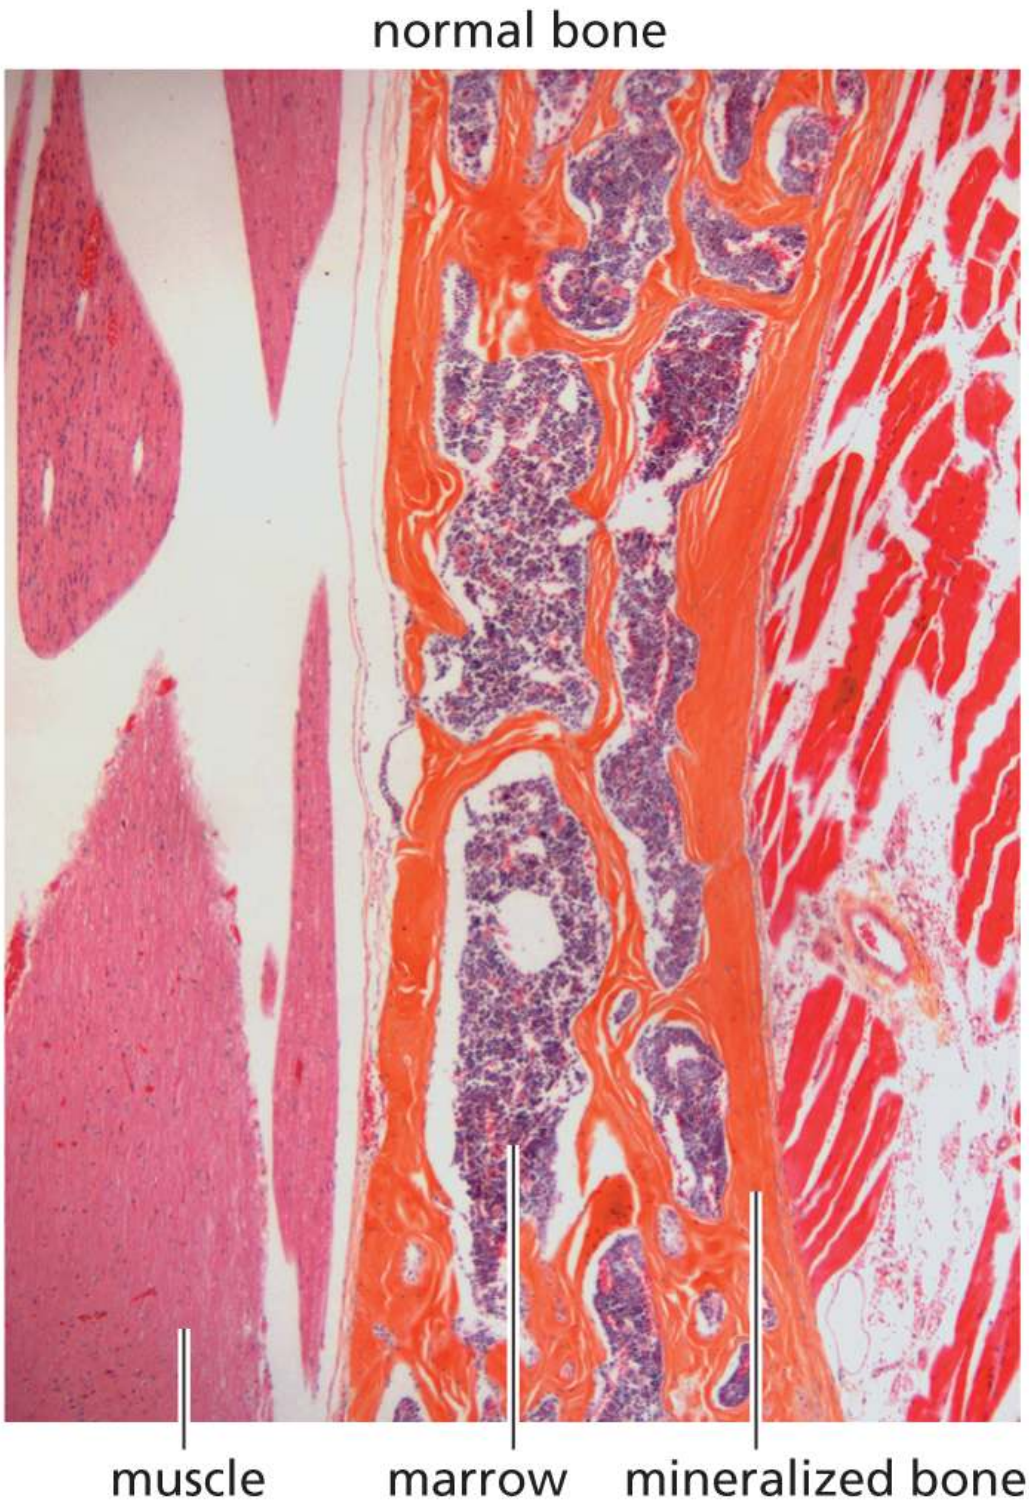
A cross section of a cell attached to a bone surface. The cell contains two large, irregular structures labeled n. The contact surface between the cell and the bone, labeled R B, is highly ruffled, so that cell and bone are intertwined. To the left and right of this ruffled border are areas labeled S Z.

(C)

Figure 14.45 Bone degradation by osteoclasts The degradation of bone, often termed *resorption*, depends on the complex actions of osteoclasts—large multinucleated cells deriving from the monocyte lineage that also generates macrophages. (A) This light micrograph shows osteoclasts (*purple*, *arrows*) excavating small pits in the surface of a mouse jawbone (*pink*). (B) At far higher magnification, this scanning electron micrograph shows a cat osteoclast that has excavated a shallow pit in the surface of mineralized bone. The calcium apatite crystals in the bone have been dissolved away by acid secreted by the osteoclast, revealing the complex meshwork of collagen-rich extracellular matrix (ECM) at the bottom of the pit. Associated with this ECM are mitogens and survival factors that become available to cancer cells after osteoclasts subsequently break down the ECM. (C) This transmission electron micrograph reveals at even higher magnification the details of how osteoclasts resorb bone. This section through an osteoclast (with multiple nuclei, n, *above*) and underlying bone (*below*) reveals the osteoclast's complex ruffled border (RB), which secretes protons to dissolve the

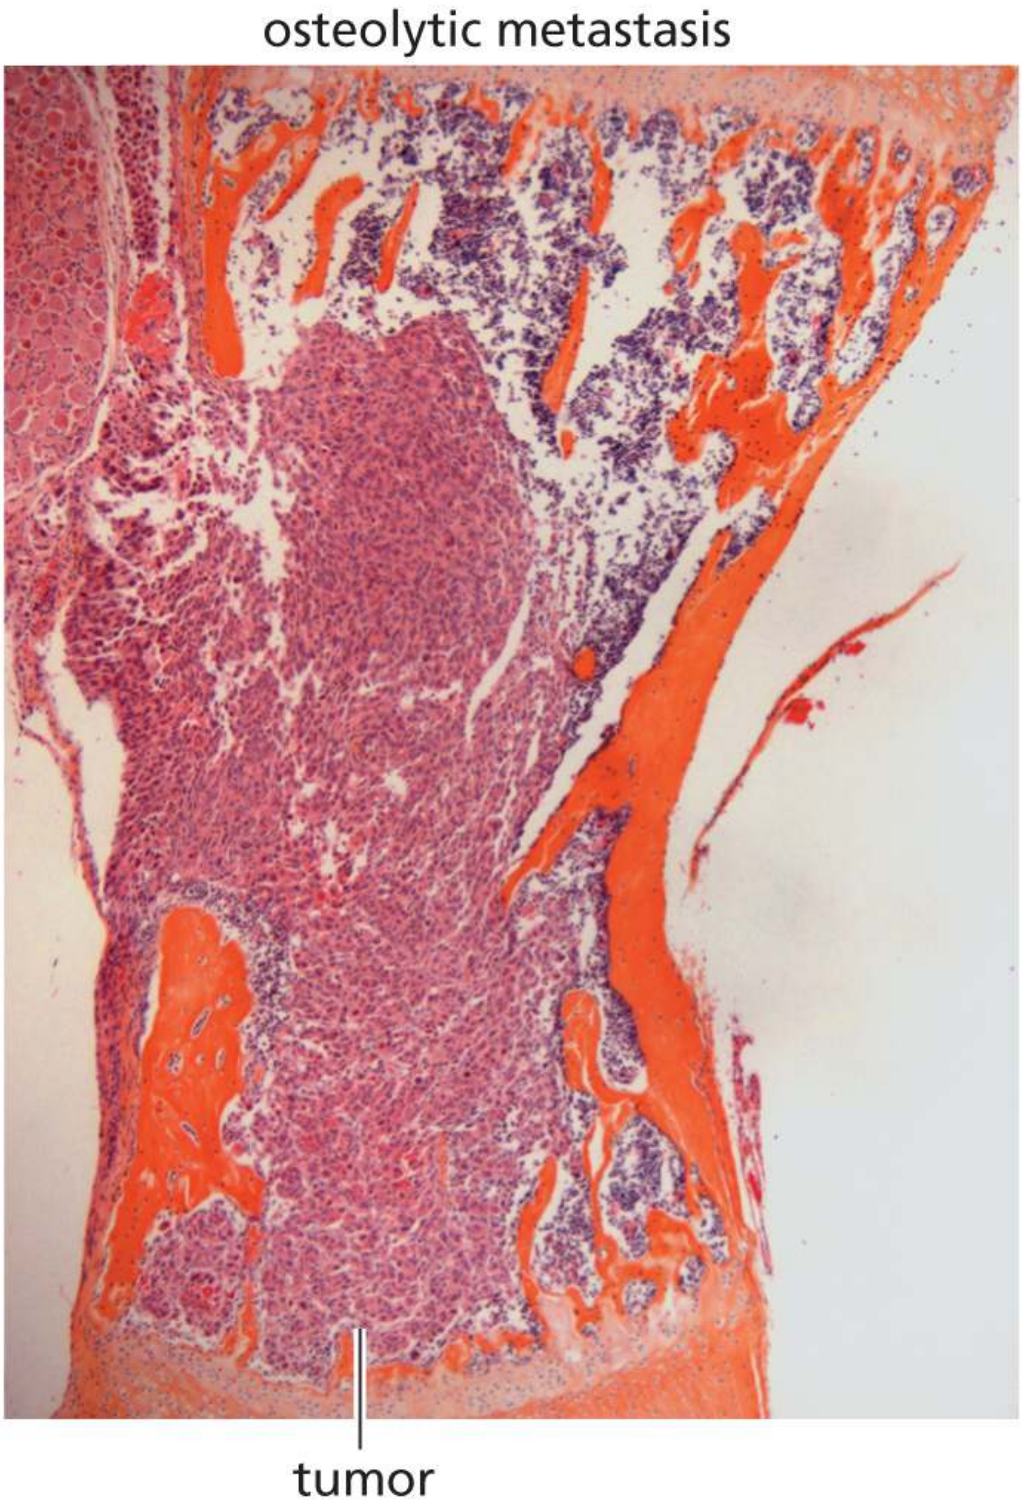
mineral component of the bone and acid proteases to degrade the collagen-rich extracellular matrix that is exposed following demineralization. Surrounding this area of contact is a circular sealing zone (SZ) containing substantial amounts of filamentous actin, which functions as a gasket to confine these secretions to a small localized interstitial area between the osteoclast and bone. (A, courtesy of T.R. Arnett. B, from T.R. Arnett and D.W. Dempster, *Endocrinology* 119:199–124, 1986. With permission from Oxford University Press. C, from H. Zhao, T. Laitala-Leinonen, V. Parikka et al., *J. Biol. Chem*. 276:39295–39302, 2001. © 2001 ASBMB. This article is available under a Creative Commons Attribution (CC BY 4.0) license.)

Most kinds of metastasizing cancer cells are, on their own, incapable of remodeling bone structure. Instead, they manipulate and exploit these two types of cells normally present in the bone. Thus, breast cancer cells preferentially activate the osteoclasts, resulting in osteolytic metastases—literally, metastases that dissolve bone. Prostate cancer cells tend, on the other hand, to activate osteoblasts, yielding osteoblastic lesions, in which immature mineralized bone (sometimes termed osteoid) actually accumulates in the vicinity of the metastases (**Figure 14.46**).



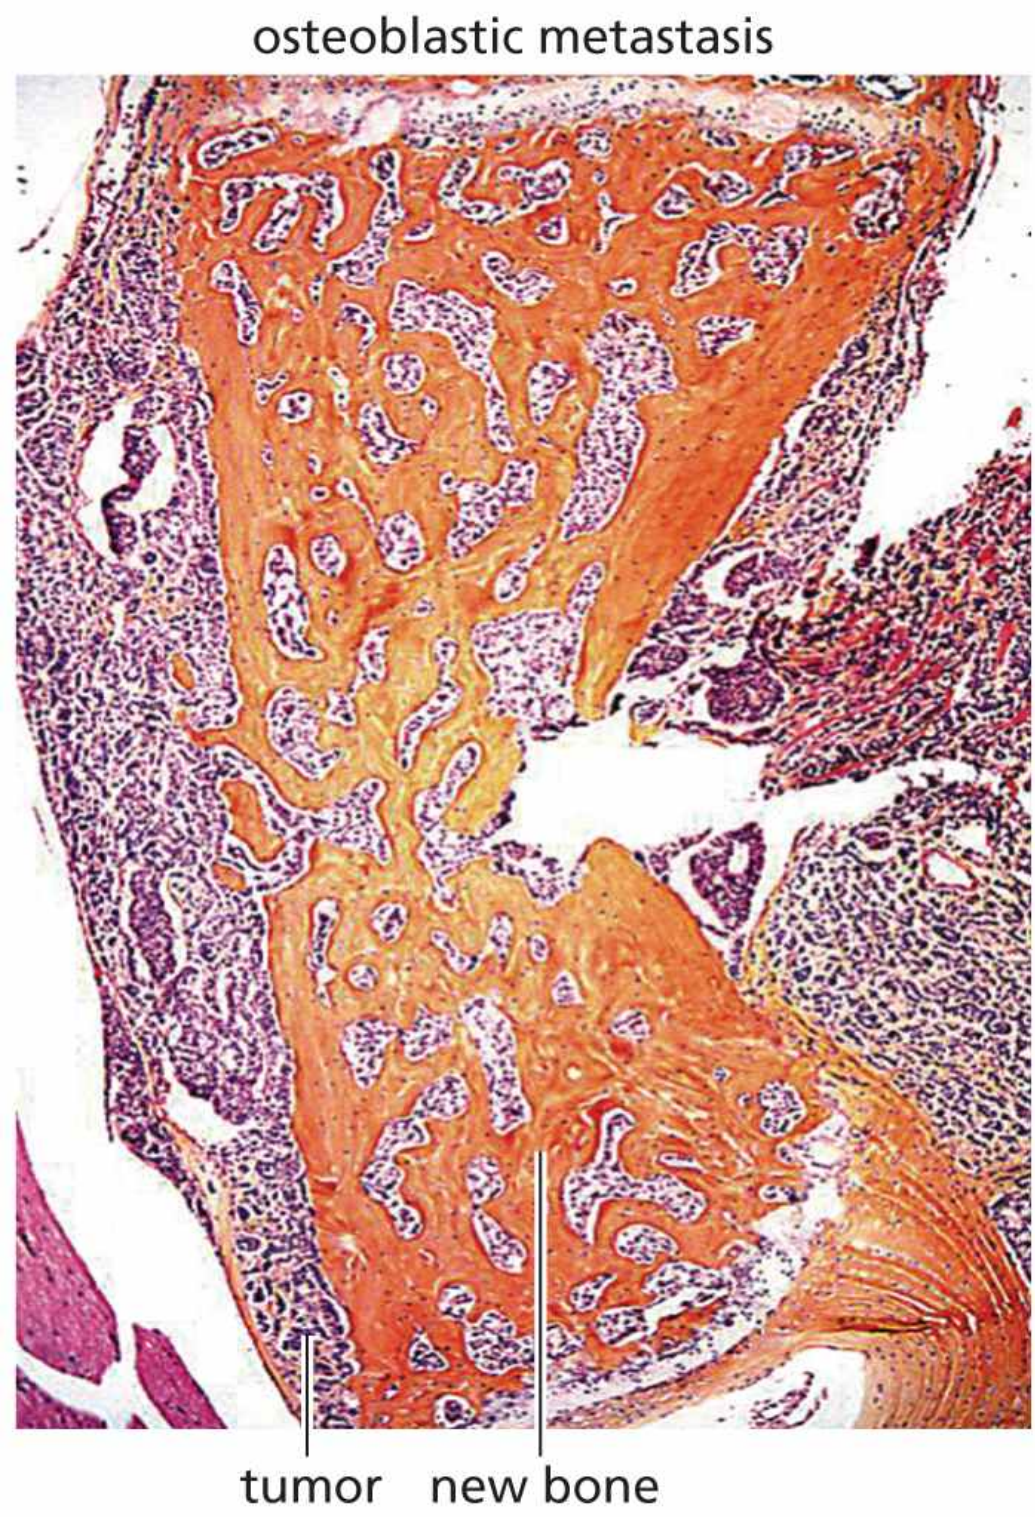
A color micrograph of normal bone in cross section. On the left, muscle tissue appears as pink. In the middle, bone marrow appears a purple, with a spongy texture. Veins of mineralized bone, appearing as orange, surround the marrow and run through it.

(A)



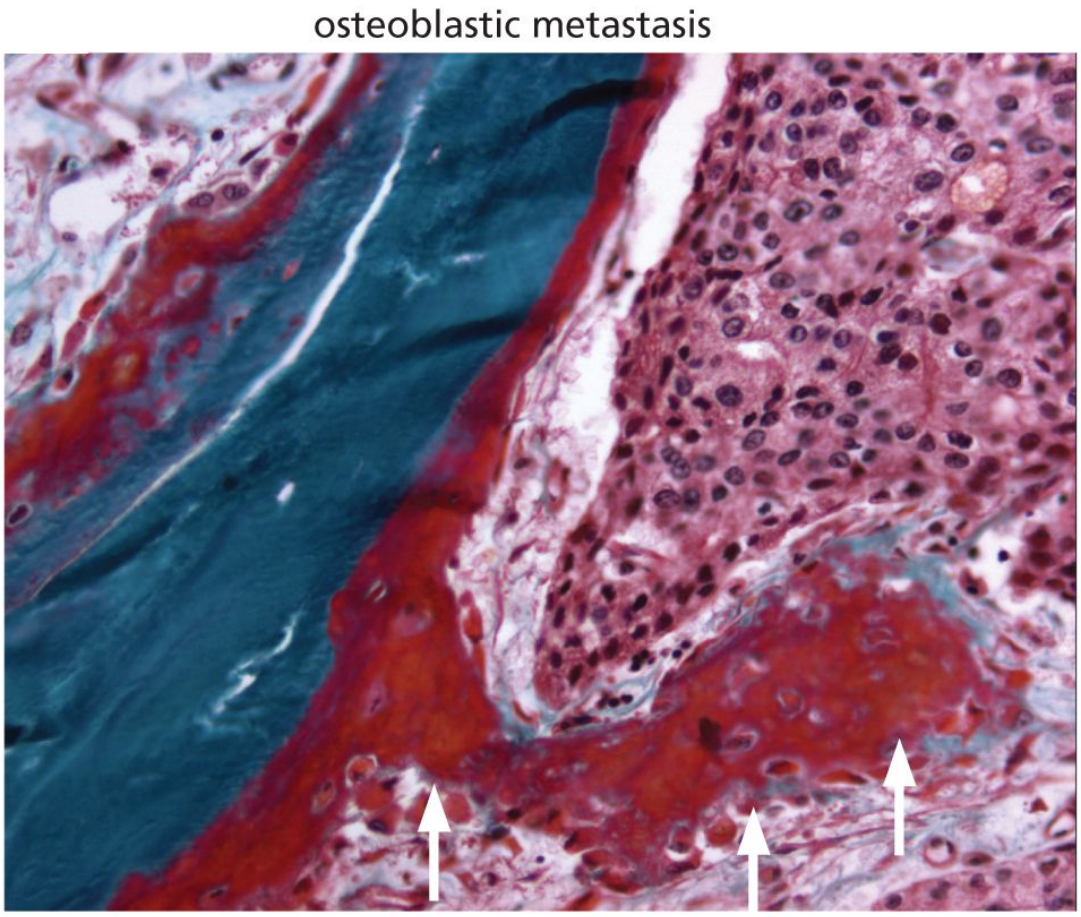
A color micrograph of bone with osteolytic metastasis. There is more marrow-like tissue, except that a large portion of it, labeled tumor, is dense and lighter

in color. This tissue and the darker marrow tissue are still partly surrounded by orange mineralized bone, but in the left part of the image, the tumor appears to have eroded the bone and broken through it.
(B)



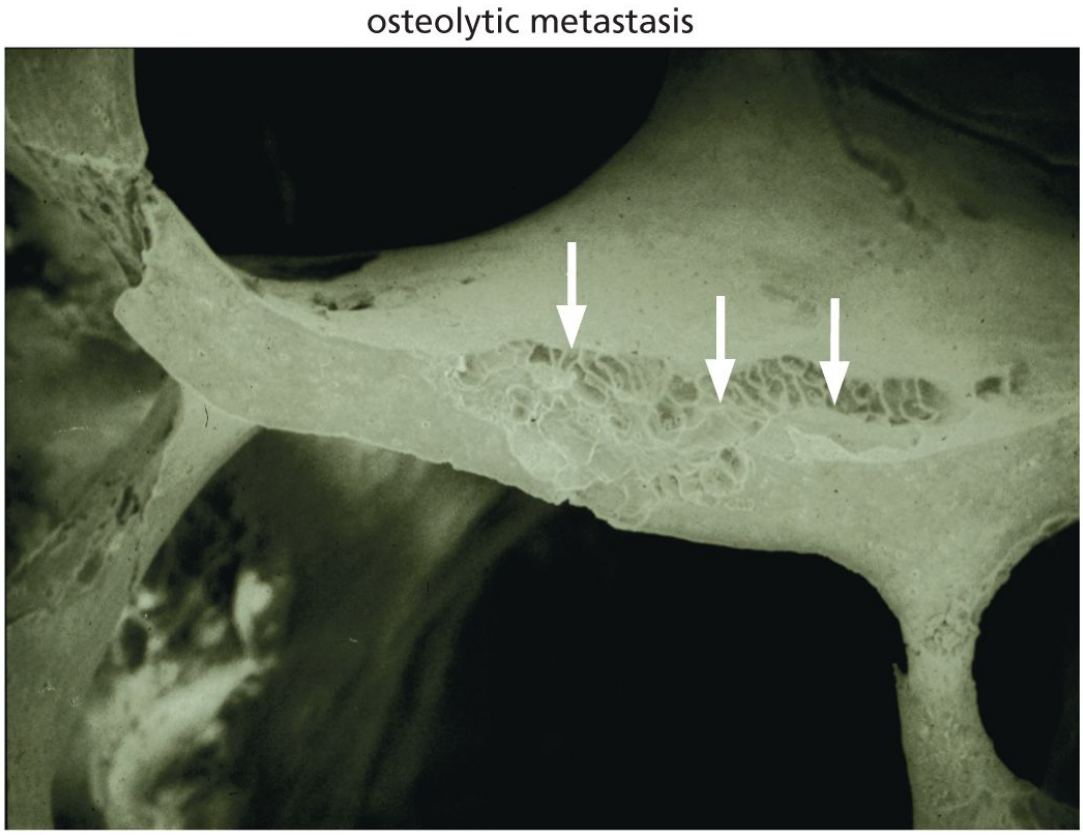
A color micrograph of bone with osteoblastic metastasis. Down the middle of the image is a wide, orange band of thick, porous mineralized bone. Spongy purple tissue on either side represents tumor.

(C)



A histology stain image in which normal bone appears as dark teal green and surrounding prostate cancer tissue appears as pink with dark purple nuclei. Surrounding the teal bone is a sheath of reddish purple that has grown a hornlike protrusion, which has pushed rightward into the prostate cancer tissue.

(D)



A scanning electron micrograph showing a location where healthy bone has been made thin and porous by something eating away at the bone matrix.

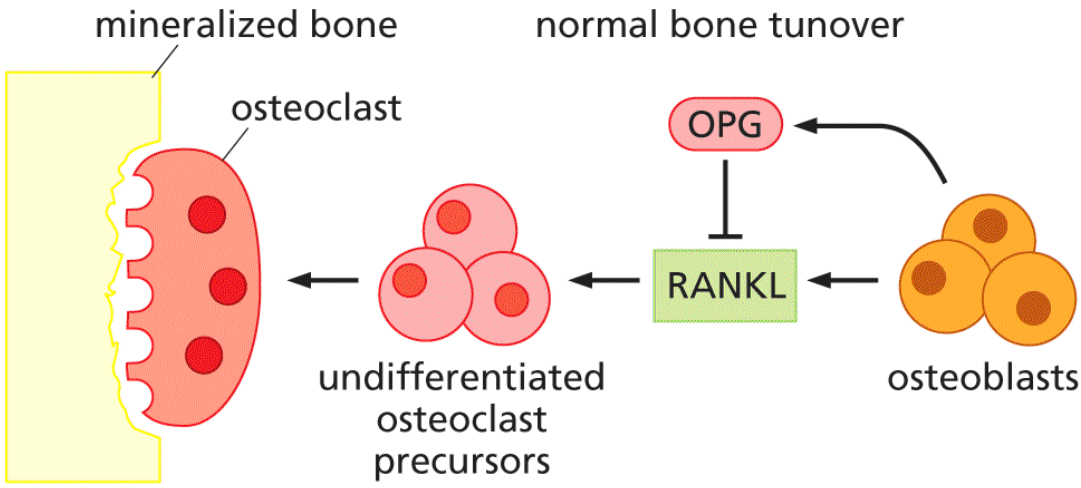
(E)

Figure 14.46 Osteolytic and osteoblastic metastases The first three of these micrographs present sections of mouse vertebrae and femurs in which the mineralized bone (*orange*), surrounding muscle (*bright red*), and bone marrow (*dark purple*) are clearly delineated. (A) This vertebra of a control mouse injected only with buffer is seen to be composed of extensive marrow with ribbons of mineralized bone running through the marrow. (B) In a mouse bearing a human breast cancer cell line (MDA-MB-231) that creates osteolytic lesions, much of the mineralized bone is seen to be missing, and the marrow has been displaced by tumor cells (*dark red*). (C) In a mouse bearing a human breast cancer cell line (ZR-75-1) that creates osteoblastic lesions, much of the marrow space is now filled with mineralized bone (*orange*) with tumor masses evident to the *left* and *right.* (D) In the iliac crest of the pelvis of a prostate cancer patient, the native bone (*dark green-blue*) can be readily resolved from the newly synthesized, still-poorly mineralized osteoblastic lesion (*purple*), which is sometimes termed osteoid. The osteoid is protruding into a mass of metastatic prostate cancer cells (*dark purple nuclei*). (E) A scanning electron micrograph reveals how devastating

the osteolytic lesions (*arrows*) can be in terms of compromising bone structure in a patient with metastatic osteolytic lesions created by osteoclasts. (A–C, from J.J. Yin, K.S. Mohammad, S.M. Käkonen et al., *Proc. Natl. Acad. Sci. USA* 100:10954–10959, 2003. With permission from National Academy of Sciences, U.S.A. D, courtesy of C. Morrissey and R.L.Vessella. E, courtesy of G.R. Mundy.)

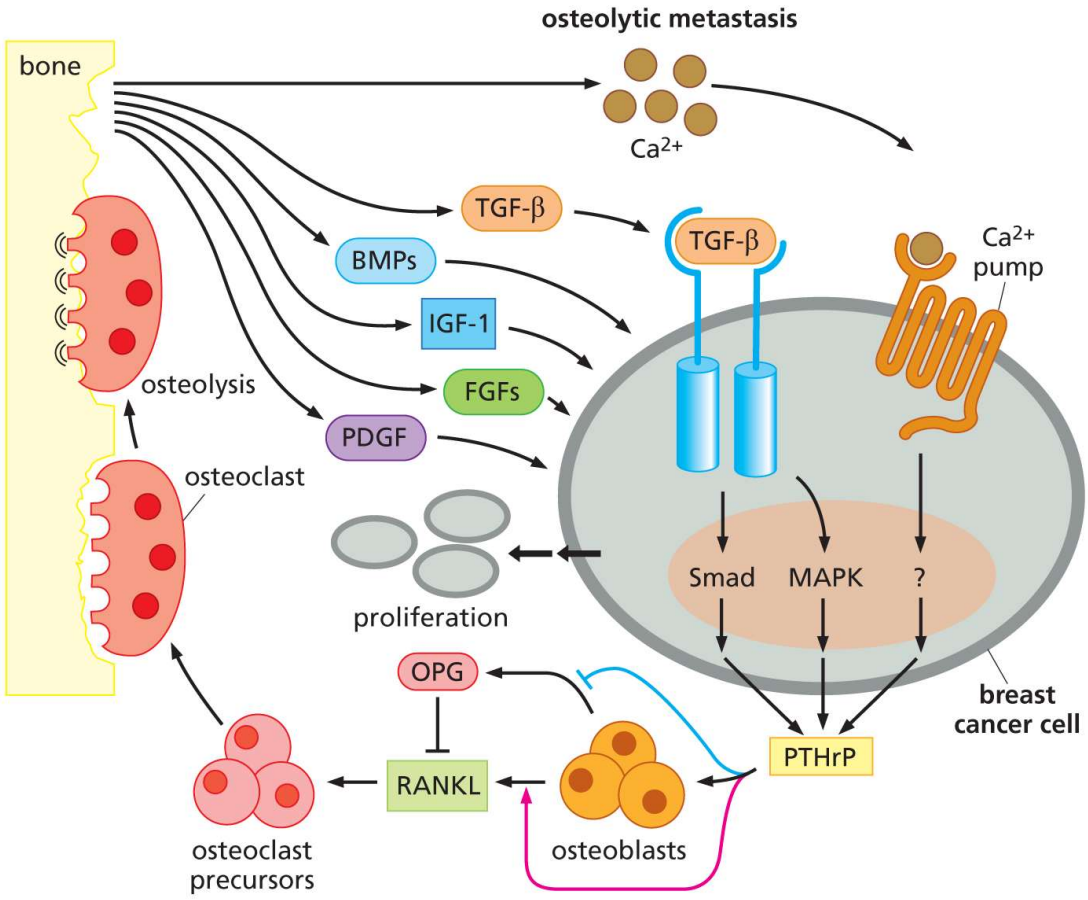
In fact, these two behaviors represent the extremes of a continuum, since both types of cancers activate both osteoblasts and osteoclasts to a greater or lesser extent. For example, while osteolytic metastases predominate in advanced breast cancer patients, as many as one-quarter of these women also have clearly defined osteoblastic lesions in their bones. Similarly, prostate carcinomas also generate occasional osteolytic metastases scattered among the many osteoblastic growths spawned by these tumors. One exception to this rule of a mingling of both types of bone metastases is provided by myeloma cells (tumors of the B-cell, antibody-secreting lineage), which create exclusively osteolytic lesions.

The normally operative close coordination between osteoblasts and osteoclasts is mediated, at least in part, by the exchange of growth factor signals. An important inducer of osteoclast differentiation is RANK (receptor activator of NF-κB) ligand, or simply RANKL. RANKL is produced by and displayed on the surface of osteoblasts. When an osteoclast precursor displaying the RANK receptor comes into contact with an osteoblast and its cell surface RANKL molecules, this results in activation of the RANK receptors of the osteoclast precursor and its maturation into a functional osteoclast (**Figure 14.47A**). At the same time, osteoblasts produce a soluble decoy receptor, termed osteoprotegerin (OPG), which can bind RANKL and ambush it before it succeeds in activating the RANK receptor on the surface of osteoclast precursors. The result is a blockage of the RANKL–RANK signaling and the inhibition of osteoclast maturation. Hence, the balance between the RANKL (stimulatory) and OPG (inhibitory) signals displayed by osteoblasts determines the state of activation of osteoclasts (Figure 14.47A and B). This dynamic interaction of osteoblasts and osteoclasts provides the background for the actions of cancer cells that metastasize to bones. Their attraction to the bone derives ultimately from the collagenous extracellular matrix that forms the organic scaffolding in which calcium phosphate crystals are deposited (see Figure 14.45B). As it happens, bone ECM is an unusually rich source of the mitogenic and trophic factors that allow several types of carcinoma cells to thrive. Consequently, by provoking the demineralization of bone, cancer cells gain access to the storehouse of factors sequestered in the bone ECM and use them to support their own proliferation and survival.



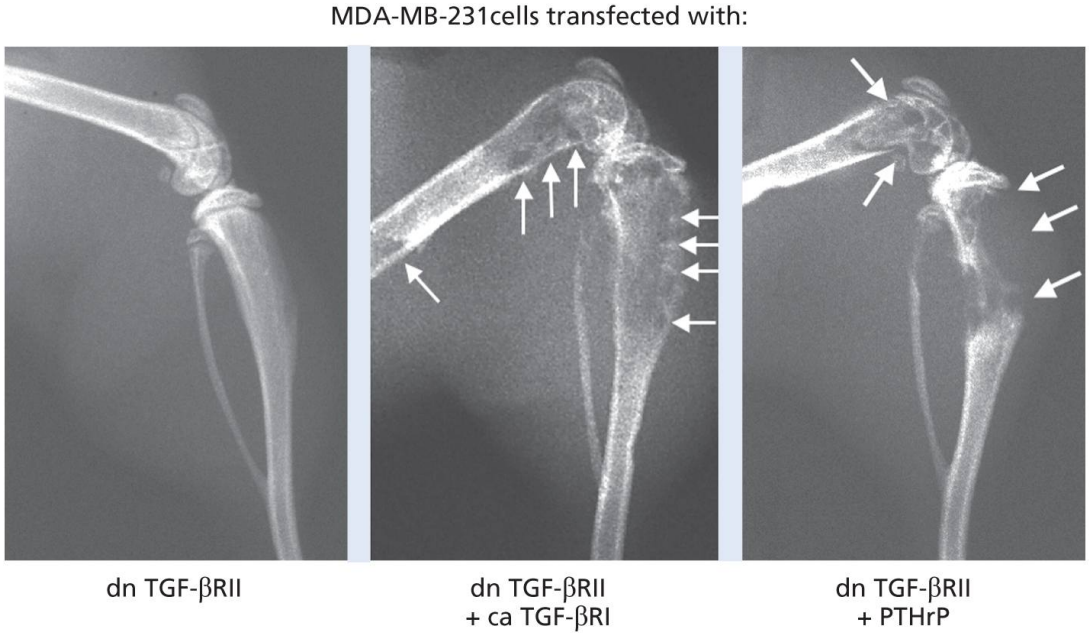
Normal bone turnover. An osteoblast secretes RANKEL, which stimulates undifferentiated osteoclast precursors to develop into osteoclasts, one of which is shown dissolving mineralized bone. The osteoblast also secretes O P G, which inhibits the osteoclast-promoting action of RANKEL.

(A)



A breast cancer cell’s manipulation of the balance of RANKEL and O P G produced by osteoblasts. The cancer cell releases P T H r P, which amplifies an osteoblast’s RANKEL production and inhibits its O P G production, causing increased production of osteoclasts that dissolve bone. The dissolved bone release calcium ions and various proteins that stimulate the cancer cells to release more P T H r P and also to proliferate.

(B)



A series of three X-rays of mice limbs in which M D A-M B-2 3 1 cells have been transfected with, respectively, d n T G F-beta R 2, dn T G F-beta R 2 plus c a T G F-beta R 1, and d n T G F-beta R 2 plus P T H r P. In the first image, no bone damage is visible, in the second, some erosion is visible, and in the third, dramatic erosion is visible.

(C)

Figure 14.47 Osteoblasts vs. osteoclasts (A) The physiological balance between normal bone formation and resorption is created by signaling between osteoblasts, which assemble bone, and osteoclasts, which dissolve it. In an ongoing cycle, osteoclasts remove mineralized bone by covering and sealing off a section of bone and secreting digestive acid into the bone below them (see Figure 14.45C); this is followed by osteoblastic filling of resulting cavities with new bone. The osteoblasts release RANKL, which acts via the RANK receptor (*not shown*) displayed by osteoclast precursors to induce the latter to mature into functional osteoclasts. The osteoblasts may also secrete osteoprotegerin (OPG), which acts as

a *decoy receptor* to ambush RANKL before it has had a chance to activate osteoclast precursors. Hence, the balance between RANKL and OPG determines the net rate of bone growth or loss. (B) Release by a breast cancer cell (*right, gray*) of PTHrP (parathyroid hormone–related peptide, *below*) causes nearby osteoblasts to change the mix of signals that they release: they increase RANKL synthesis (*red arrow*) and decrease OPG synthesis (*blue line*), the result being RANKL-induced maturation of osteoclast precursors into functional osteoclasts. The latter undertake osteolysis, which causes bone demineralization, exposes the extracellular matrix within the bone (see Figure 14.45B), and results in liberation of TGF-β, Ca^{2+}, BMPs, PDGF, FGFs, and IGF-1 (*upper left and middle*). IGF-1 and Ca^{2+} enable cancer cell proliferation and survival, and the additional presence of TGF-β induces the cancer cell to release more PTHrP, resulting in a self-sustaining positive-feedback loop that has been termed the “vicious cycle” of osteolytic metastasis. (C) Evidence supporting the vicious cycle model of osteolytic metastasis comes in part from experiments involving the use of MDA-MB-231 cells, a line of human breast cancer cells that show a high tendency to produce osteolytic metastases (see Figure 14.46B). The ability of these cells to do so is gauged here by X-ray analyses of the hind limbs of mice that have borne MDA-MB-231 tumor xenografts. When a dominant-negative type II TGF-β receptor (dn TGF-βRII) expression construct is introduced into these cancer cells, this mutant protein blocks their ability to respond to TGF-β, specifically the TGF-β that would otherwise be liberated from the extracellular matrix of the osteolytic lesions that they may have created. Without TGF-β stimulation, these cancer cells fail to form osteolytic metastases (*left panel*). However, if this inability to respond to TGF-β is overridden by introducing additionally into these cells an expression construct specifying a constitutively active type I TGF-β receptor (ca TGF-βRI), then the powers of these breast cancer cells to induce osteolytic lesions are restored (*arrows, center panel*). This observation, on its own, does not indicate precisely how the ca TGF-βRI succeeds in restoring the osteolytic activity to these cells. An explanation comes from an experiment in which a vector causing PTHrP expression (instead of ca TGF-βRI expression) is introduced into the cells expressing the dn TGF-βRII, causing them to regain the ability to form osteolytic metastases (*arrows, right panel*). This is compatible with the notion that PTHrP functions downstream of TGF-β signaling and that the latter is no longer important for osteolysis if PTHrP is expressed constitutively, i.e., is no longer under the control of TGF-β. (B, from G.R. Mundy, *Nat. Rev. Cancer* 2:584–593, 2002. With permission from Nature. C, from J.J. Yin, K. Selander, J.M. Chirgwin et al., *J. Clin. Invest*. 103:197–206, 1999. With permission from American Society for Clinical Investigation.)

Metastasizing cancer cells reach the bone through the vessels feeding the marrow. Once there, they adhere to specialized stromal cells coating the surfaces of the bone facing the marrow. Metastasizing breast cancer cells, upon arrival in bone, revert to a behavior characteristic of their normal precursors (mammary epithelial cells, MECs). During lactation, when producing milk, MECs forming the small sacs (alveoli) of the mammary gland release parathyroid hormone–related peptide (PTHrP). PTHrP then travels from the breast through the circulation to the bones, where it triggers a chain of events that encourages the dissolution of bone minerals by osteoclasts. This results in the mobilization of calcium ions, which travel back via the circulation to the mammary gland, where they are incorporated into the milk by the MECs.

This normal calcium-mobilizing mechanism is subverted by metastasizing breast cancer cells that become established in bones (see Figure 14.47B). Having attached to the stromal cells covering the surfaces of mineralized bone, the breast cancer cells, reverting to the habit of normal MECs, release PTHrP. The PTHrP, in turn, impinges directly on its receptors displayed by osteoblasts, causing these cells to release RANKL. RANKL then induces the differentiation of osteoclast precursors into active osteoclasts. The activated osteoclasts degrade nearby mineralized bone, thereby liberating calcium ions together with the rich supply of growth factors attached to the ECM of the bone.

The growth factors liberated from the bone ECM, including PDGF, bone morphogenetic proteins (BMPs), fibroblast growth factors (FGFs), insulin-like growth factor-1 (IGF-1), and TGF-β, fuel the further growth of the breast cancer cells, inducing them to secrete more PTHrP. This PTHrP engenders more osteolysis by the osteoclasts, leading to a self-perpetuating signaling system that has been called a "vicious cycle" (see Figure 14.47B) in which TGF-β also plays a key role (**Sidebar 14.10**).

Sidebar 14.10 TGF-β and PTHrP play pivotal roles in the vicious cycle of breast cancer osteolytic metastases

Breast cancer cells that have metastasized to the bone produce far more parathyroid hormone-related peptide (PTHrP) than do others in the same animal that have not because certain growth factors liberated from the bone ECM stimulate PTHrP production by the metastatic cancer cells. The most important of these bone-derived factors is TGF-β, as illustrated by some simple experiments. In one of these, a dominant-negative TGF-β receptor (which blocks a cell's ability to respond to TGF-β) is expressed in the cancer cells; this blocks the ability of these cells to drive osteolytic metastases in the bone; forced expression of PTHrP in these cancer cells reverses this effect (see Figure 14.47C).

In another experiment, breast cancer cells that usually lack the ability to metastasize to bone and fail to secrete TGF-β can be forced (through the use of an expression vector) to secrete TGF-β. The latter then acts in an autocrine fashion to stimulate these cells to produce their own PTHrP, allowing them to form large numbers of bone metastases. Finally, antibodies that bind and neutralize PTHrP are able to block the ability of human breast cancer cells to generate osteolytic lesions in mice. These are some of the disparate observations that have inspired the "vicious cycle" model depicted in Figure 14.47B.

The central role of osteoclasts in this cycle suggests possible points of therapeutic intervention. One highly effective strategy depends on drugs belonging to the class of bisphosphonates, which are taken orally and become adsorbed to the apatite crystals that constitute the mineral portion of bone; the drug molecules can persist there for extended periods of time, as long as a decade or more. When bisphosphonate-containing bone is eventually dissolved by osteoclasts, the latter are poisoned by the liberated bisphosphonates, leading to their apoptosis. Hence, bisphosphonates are useful for reducing the burden of osteolytic lesions in patients with various types of metastatic cancer.

When immunocompromised mice carrying human breast cancer cells are treated with bisphosphonates, the number of osteolytic lesions is reduced and, at the same time, the total burden of tumor cells in these animals is decreased. This observation provides additional indication that late in tumor progression, the proliferation of these breast cancer cells depends greatly on osteolysis and the resulting liberation of growth factors from dissolved bone; similar observations have been made in human breast cancer patients treated with bisphosphonates. For example, a clinical study reported in 2011 that premenopausal women who developed breast cancer and were treated with zoledronic acid—a bisphosphonate—experienced a 37% increase in overall survival (relative to those who did not receive this treatment) over a period of seven years. Such clinical responses further reinforce the notion that many breast cancer relapses in patients (1) derive from metastatic deposits in the marrow and (2) depend on the ability of disseminated metastatic cells to generate mitogens by dissolving bone. Moreover, bisphosphonate therapy can provide additional benefits to patients suffering from metastatic breast cancer by reducing the hypercalcemia—pathologically high concentration of calcium in the circulation—stemming from the large-scale resorption of mineralized bone. Hypercalcemia usually signals the final stages of malignant disease and causes gastrointestinal, urinary tract, cardiovascular, and neuropsychiatric problems.

Figure 14.47B predicts that the vicious cycle driving osteolytic metastases should be slowed down or even blocked by therapeutic treatment with osteoprotegerin (OPG). In fact, a derivative of OPG has been found to be as effective as a widely used

bisphosphonate in slowing down bone resorption in patients with metastatic breast cancer. However, clinical development of this OPG derivative was eventually discontinued, having been displaced by a slightly more effective treatment—a monoclonal antibody (denosumab) that binds and neutralizes RANKL. A phase III clinical trial revealed that denosumab was more effective than bisphosphonates in delaying the onset of serious skeletal-related events in patients with metastatic breast disease, while having comparable efficacy in delaying disease progression.

Glossary

osteoclast
: Cell type of monocyte origin that functions to degrade and demineralize already-assembled bone.

osteoblast
: Mesenchymal cell type related to fibroblasts that constructs mineralized bone through the deposition of a collagenous matrix and apatite crystals.

demineralize
: To dissolve the inorganic apatite (i.e., calcium phosphate) component, notably of bone.

resorption
: The osteoclast-mediated process of dissolving mineralized bone with attendant mobilization of calcium into the circulation.

osteolytic
: Referring to a bone lesion that involves localized dissolution of mineralized bone usually driven by the localized actions of osteoclasts. *See also* **osteoblastic**.

osteoblastic
: Referring to a class of bone lesions that involve localized increases in the amount of mineralized bone. *See also* **osteolytic**.

osteoid
: The extracellular matrix that forms during bone formation prior to mineralization.

decoy receptor
: A nonsignaling protein that binds and sequesters a ligand (e.g., a growth factor), thereby diverting the ligand from binding and activating its functional cognate signaling receptor.

vicious cycle
: Term used to describe the self-perpetuating, complex interactions between disseminated cancer cells, osteoclasts, and osteoblasts that has been used to explain the mechanisms underlying osteolytic metastases.

bisphosphonates
: Class of drugs, characterized by a chemical backbone with the structure P–C–P, that are incorporated into bone apatite and

subsequently become available to poison osteoclasts that may later undertake to dissolve the bone, thereby liberating the previously incorporated toxic bisphosphonates.

hypercalcemia

Presence of elevated concentrations of calcium ions in the blood.

phase III

A clinical trial in which very large numbers (e.g., hundreds to thousands) of patients are exposed to a new drug, given in a randomized fashion with placebo controls, and tested for its efficacy relative to existing approved therapeutic modalities, with the intent of demonstrating statistically significant clinical benefit, usually one greater than existing approved therapies. *Compare* **phase I**, **phase II**.

osteotropism

The trait of cells, notably metastasizing cancer cells, to migrate to and colonize the bone marrow.

alveolus (pl., alveoli)

A small sac within a tissue that is connected to a duct, such as the sacs seen in the lung and in the mammary gland during pregnancy.

14.14 Occult micrometastases threaten the long-term survival of many cancer patients

Throughout this chapter, we have read repeatedly about the extraordinary inefficiency with which metastases are produced. Some of this metastatic inefficiency is created by the profound difficulties that cancer cells experience as they undertake the initial steps of the invasion–metastasis cascade. Most of those that do manage to reach distant sites and survive in their newfound homes fail to form clinically detectable metastases. The result is the presence of myriad dormant micrometastases seeded throughout the tissues of many cancer patients.

While micrometastases are, with rare exception, unable to expand to form clinically detectable metastases, they do provide clear indication that a primary tumor has seeded cells throughout the body. These micrometastases represent a threat to the long-term survival of cancer patients, if only because some of them may erupt into full-fledged, clinically significant macroscopic metastases years after they become implanted in some distant tissue site. Breast cancers are notorious for yielding relapses one and even two decades after the primary tumor has been removed and the patient has been declared to be free of cancer.

In one study of breast cancer patients, micrometastases were detected by sampling the bone marrow of the iliac crest of the pelvis. About 1% of a population of patients suffering from nonmalignant conditions showed cytokeratin-positive cells (that is, epithelial cells) in their marrow. In contrast, 36% of breast cancer patients carrying tumors of stages I, II, or III had such micrometastases in their marrow. The presence of these micrometastases in the marrow proved to be a highly useful prognostic marker for the risk of relapsing with clinically detectable metastasis (see also Figure 14.42D). Thus, within four years, one-quarter of the marrow-positive patients had died from cancer, whereas only 6% of those lacking

cancer cells in their marrow had died from this disease. Another study found a more than tenfold increased risk of death from breast cancer among those whose marrow carried micrometastases composed of single cells or small clumps of cancer cells.

Colon cancer patients who have undergone resection (surgical excision) of their primary tumor will often appear in the cancer clinic a year or two later with a small number of metastases in their liver but none elsewhere; these can then be removed surgically, often with significant clinical benefit. Once again, micrometastases in the marrow of the pelvis can be scored. About 90% of those who lack these micrometastases are still alive 15 months later, whereas only 60% of those who carry such micrometastases survive to this point.

A procedure used to treat cancer of the esophagus provides yet another insight into metastatic spread. These tumors are often treated surgically, which necessitates the removal of one or more rib segments, from which marrow can be easily flushed. Two independent studies reported that 79% and 88% of these patients, respectively, harbored carcinoma micrometastases in their rib marrow at the time of their surgery. These numbers, which contrast with the approximately 30% of initially diagnosed breast cancer patients bearing micrometastases, correlated with a far grimmer prognosis for patients suffering this type of cancer, with less than half of them surviving more than three years after diagnosis.

The melanoma literature provides equally dramatic testimony of the long-term dangers posed by occult, dormant micrometastases (that is, those that are latent and apparently not growing). In one particularly well-documented case, kidneys were prepared for organ transplantation from the cadaver of a patient who had undergone resection of a small melanoma 16 years earlier. The patient had been followed closely for 15 years after removal of this small primary tumor and had remained symptom-free. However, soon after transplantation, the two recipients of his kidneys (who were immunosuppressed to accommodate the allogeneic kidney grafts) developed aggressive melanomas that were directly traceable to this donor (see **Supplementary Sidebar 14.11**).

We still understand relatively little about the mechanisms that prevent dormant micrometastases from erupting into clinically threatening growths long after primary tumor removal. In some instances, one can observe micrometastases growing as cuffs around small vessels; this suggests that they lack their own angiogenic capabilities but are nonetheless able to take limited advantage of host capillaries that happen to be nearby. In most micrometastases found in the marrow, the involved cells lack any indication of cell proliferation markers and thus are in a nongrowing, G_0-like state for extended periods of time (see Figure 14.43), perhaps for months and even years (consider, however, **Sidebar 14.11**). (Because such cells are not proliferating, they may be especially resistant to chemotherapeutic treatment designed to eliminate the residual disease that persists following surgical removal of a primary tumor.)

Sidebar 14.11 Are all micrometastases truly dormant?

The cancer cells borne by many patients with “minimal residual disease” occasionally acquire the ability to colonize a site of dissemination, creating a clinically apparent metastasis and, in turn, a new site from which carcinoma cells can further disseminate. How this occurs depends critically on the state of the disseminated tumor cells (DTCs) in patients with this condition.

The state of metastatic dormancy might be interpreted as one in which the cells are residing in a state of quiescence, that is, out of the active growth-and-division cycle that we encountered in Chapter 8. The alternative is that the cells in such growths are actually in a state of active proliferation, but are unable to drive increases in the size of the micrometastatic deposits, simply because the growth of such deposits is counterbalanced by an equal rate of attrition.

Importantly, a major shift in cell phenotype that is associated with the “awakening” of dormant micrometastases has a low probability of occurring in populations of quiescent cells. Instead, extensive observations made over many years’ time indicate that such major changes happen spontaneously only in *proliferating* cell populations. Hence, in many

patients with minimal residual disease, some clones of micrometastatic cancer cells are likely to be passing through repeated growth-and-division cycles and occasionally spawning variants that have, through some random accident, acquired colonizing ability.

Immune mechanisms may also contribute to suppressing the growth of micrometastases, thereby preventing metastatic disease relapse. This is suggested by the occasionally observed explosive growth of aggressive metastatic tumors in immunosuppressed organ transplant recipients such as the two kidney graft recipients described above. Moreover, the wound-healing response following primary tumor resection may transiently liberate nearby DTCs from immune control, once again enabling their eruption. There is also evidence that localized inflammation in the tissue harboring dormant micrometastases can provoke their awakening and the eruption of rapidly growing metastases. Finally, the possibly critical role of tumor stem cells as founders of macrometastatic colonies may help to explain the inability of most of initially seeded DTCs to generate macroscopic outgrowths (**Supplementary Sidebar 14.14**). Beyond this, relatively little is known about the details of the mechanisms that preclude most micrometastases from successfully colonizing the tissues in which they have landed.

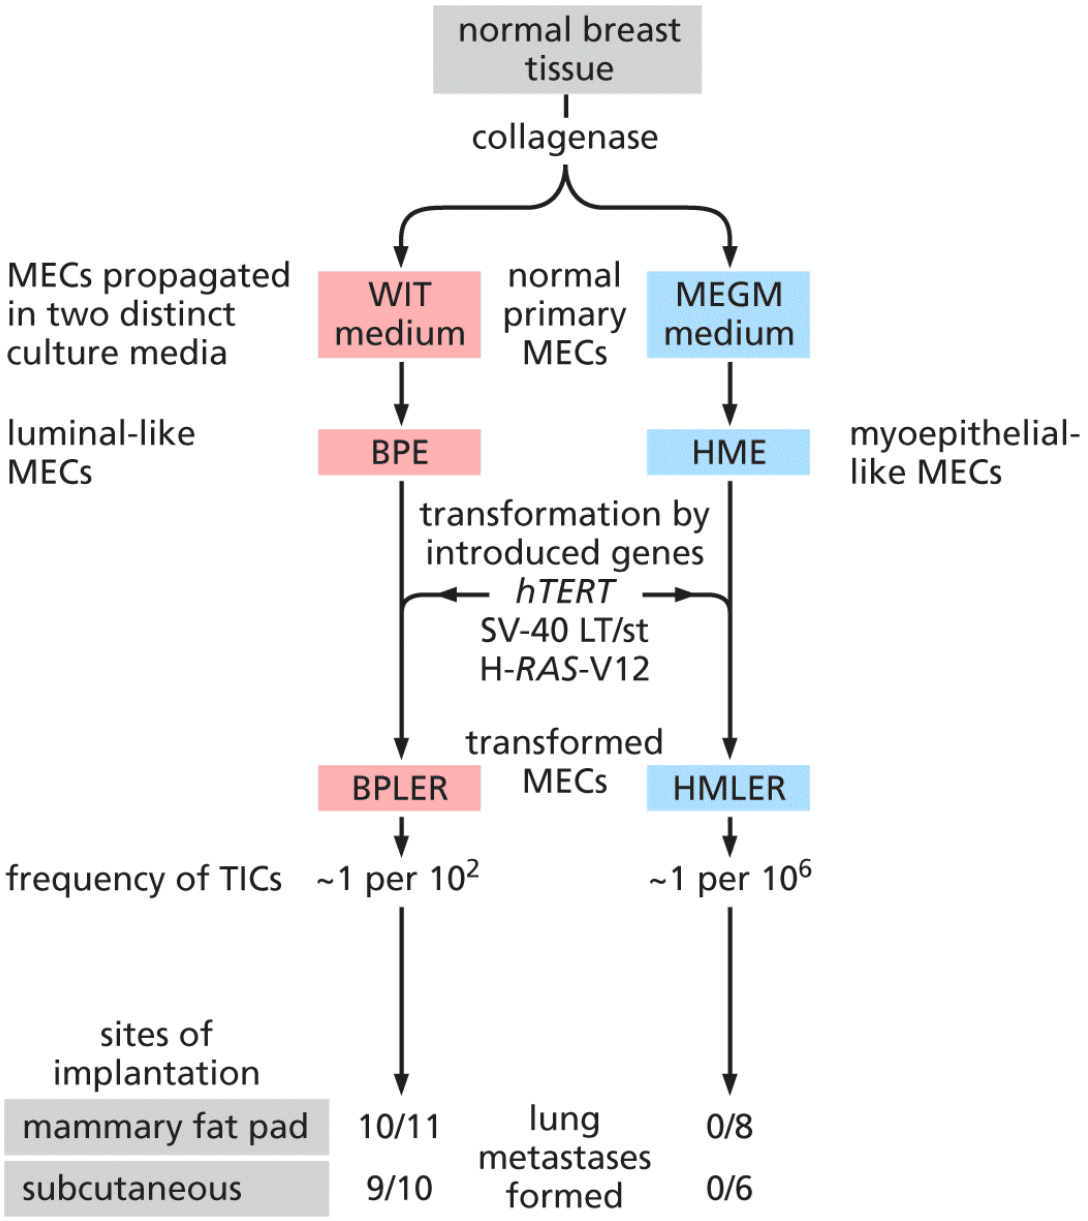
14.15 Synopsis and prospects

Several major issues have complicated the search for the genetic determinants of aggressive phenotypes of cancer: Are these phenotypes programmed by a small number of pleiotropically acting, master control genes, or do the actions of multiple, independently regulated genes collaborate to create each of these phenotypes? Do these genes undergo mutation during tumor progression, or do they become involved in the late steps of tumor progression through nongenetic, that is, epigenetic mechanisms that control their expression? And how do familiar oncogenes and tumor suppressor genes contribute to invasion and metastasis?

Although many of the genetic elements governing metastasis remain unclear, significant progress is being made in solving another puzzle: Are the cells within a primary human tumor that undertake invasion and metastasis rare variants (among the larger population of tumor cells) that have, through some genetic or epigenetic accident, acquired the ability to execute these steps? Or are all the cancer cells within certain primary tumors equally capable *a priori* of invading and metastasizing (albeit with extraordinarily low efficiency), whereas the great majority of the cancer cells in other tumors lack these abilities?

In fact, such differences in the eventual metastatic behavior of various tumor cell populations may be determined extremely early, even *before* multi-step tumor progression has begun in a tissue: thus, as **Figure 14.48** indicates, the differentiation programs of the normal cells-of-origin can strongly influence the biological behaviors of derived neoplastic descendants and indeed can dominate the actions of any somatically sustained oncogenic alleles. This would suggest that a tendency to eventually metastasize or not is a trait that is shared in common by the neoplastic cells within a primary tumor.

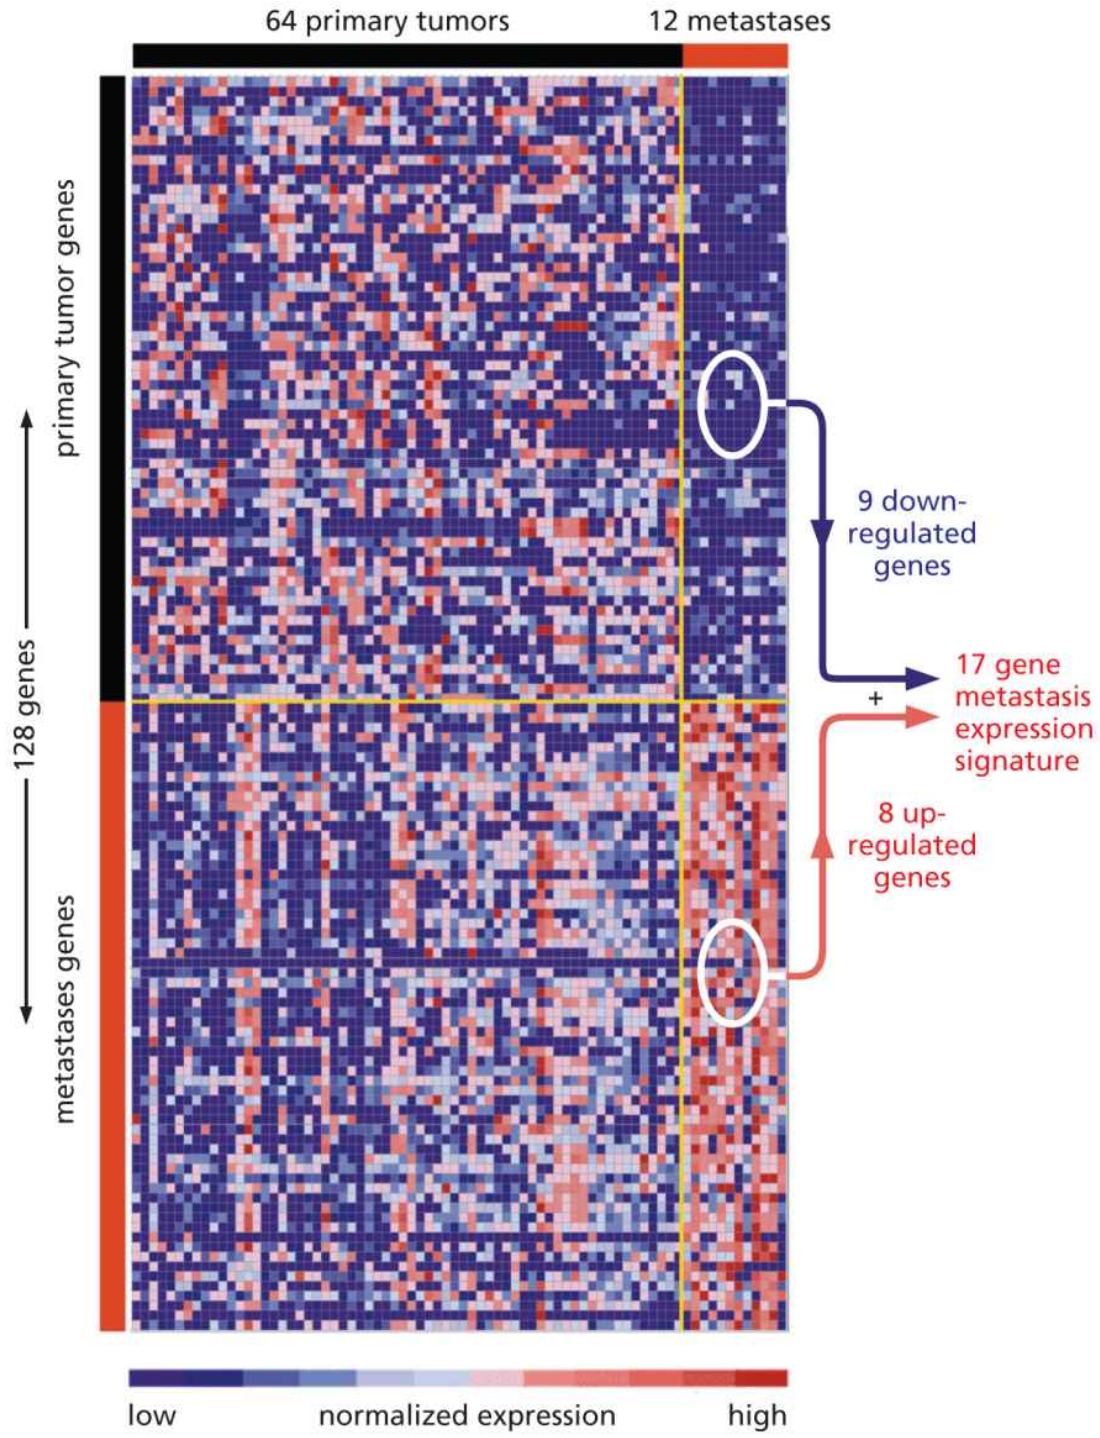


A flowchart showing the course of an experiment. Normal breast tissue is exposed to collagenase to obtain mammary epithelial cells. These are then cultured either in W I T medium to obtain luminal-like cells that express B P E, or myoepithelial-like cells that express H M E. The two types of cells are transformed, respectively, by introduced genes into B P L E R or H M L E R. The frequency of tumor initiating cells is about 1 per 100 in B P L E R and about 1 per 1 million in H M L E R. When these are implanted into mammary fat pads or subcutaneously, the B P L E R cells reliably produced lung metastases whereas the H M L E R cells did not.

Figure 14.48 Influence of cell-of-origin on metastatic propensity The observations to be presented in Figure 14.49 indicate that a substantial proportion of the cells in a primary tumor share a gene expression signature that was acquired relatively early in the course of tumor progression and is coupled with the propensity of the tumor to eventually metastasize. Such acquisition may have derived from the initial somatic mutations that triggered multi-step tumor progression or, even earlier, in the gene expression signature of the preexisting normal cell-of-origin, the latter reflecting its program of differentiation. In the experiment described here, a heterogeneous population of normal human mammary epithelial cells (MECs) explanted directly from a normal mammary gland were propagated *in vitro* in two alternative tissue culture media, which selected for the outgrowth of MEC populations that expressed either a more luminal (BPE) or a more myoepithelial (HME) gene expression pattern and therefore originated from two distinct differentiation lineages in the mammary gland. These cells were then transformed through the successive introduction of an hTERT gene, the SV40 early region (expressing small and large T antigens), and a RAS oncogene (see Figure 11.28), resulting in BPLER and HMLER tumorigenic cells. Although the introduced transforming genes were expressed at comparable levels in the two cell populations, these transformed cells behaved very differently. The concentration of tumor-initiating cells (TICs), also known as cancer stem cells, in the BPLER cell population was 10^4 times higher than in the HMLER cell population. The BPLER cells formed lung metastases following orthotopic implantation (into mammary stromal fat pads; see Figure 14.25C) or implantation into subcutaneous sites (in 10 of 11 and in 9 of 10 implanted mice, respectively), whereas the HMLER cells, implanted in equal numbers in these sites, failed to do so. Because the two cell populations acquired identical sets of oncogenes that were expressed at very similar levels, the only source of their dramatically different behaviors must be associated with the differentiation programs of the normal MECs in each population prior to experimental transformation. By extension, this implies that the differentiation programs of normal cells-of-origin continue to imprint themselves on the behavior of their neoplastic progeny. (From T.A. Ince, A.L. Richardson, G.W. Bell et al., *Cancer Cell* 12:160–170, 2007. With permission from Elsevier.)

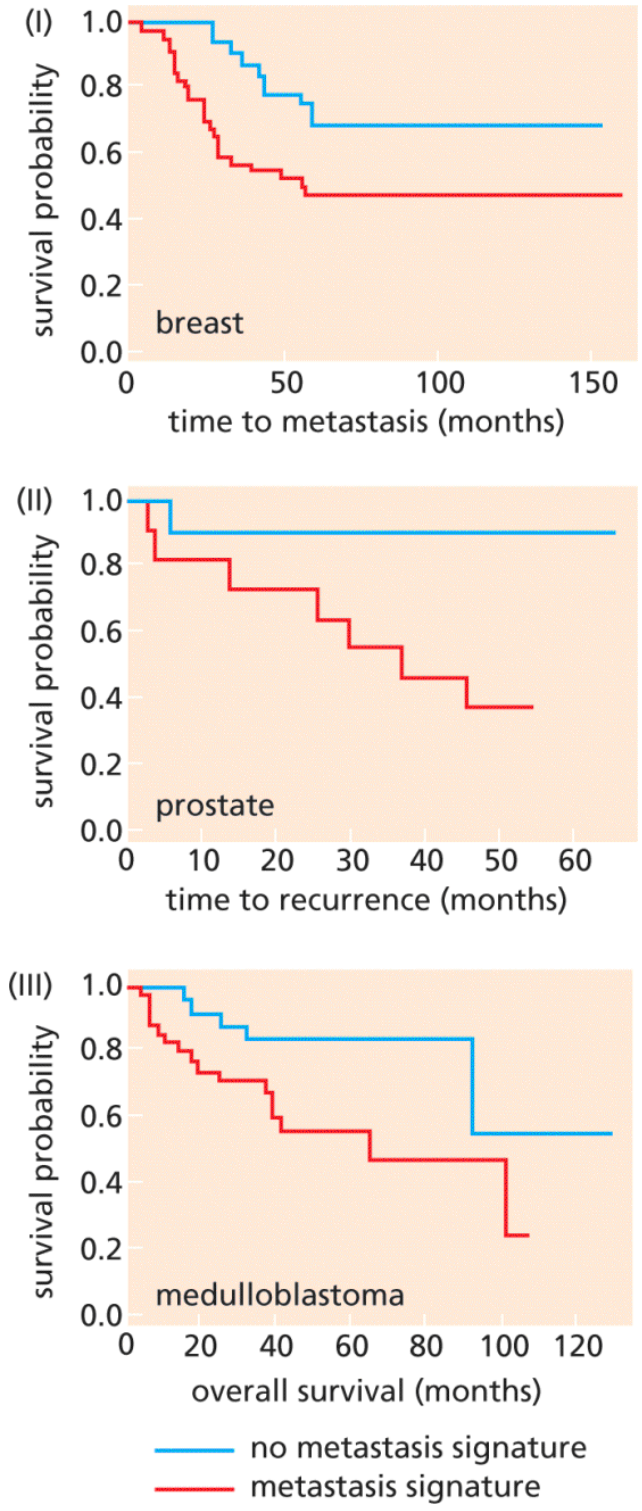
More direct evidence for this scheme (of widespread metastatic competence shared among the cells within a primary tumor) can be found in attempts to predict the metastatic tendencies of primary tumors. Thus, there are multiple examples of cancer types in which the transcriptomes of primary tumor cells can be used as prognostic indicators of eventual tendency to metastasize. By necessity, because the transcriptomes are determined in each case by extracting RNA from large numbers of pooled primary tumor cells, these transcriptomes are reflective of a widely shared state

of expression rather than one that is characteristic of a small minority of primary tumor cells. As seen in **Figure 14.49**, an effort to distill the complex transcriptomes of primary tumors and their association with metastases yielded a signature of 17 genes that could be used to predict the likelihood of patients bearing three types of primary tumors to progress to various clinical end points. Observations like these suggest that metastatic cells are drawn from the general population of cells in a primary tumor rather than from small, specialized, genetically unrepresentative subclones of cells.



A Gene expression microarray with 128 rows for different genes, half of them primary tumor genes and the other half metastases genes. There are columns for 64 primary tumors and 12 metastases. The array reveals that in primary tumors, primary tumor genes tend to be somewhat more commonly expressed than metastases genes, whereas in metastases, metastases genes are much more strongly expressed than primary tumor genes. In metastases, a

combination of 9 downregulated primary tumor genes and 8 upregulated metastases genes constitutes a 17 gene metastasis expression signature. (A)



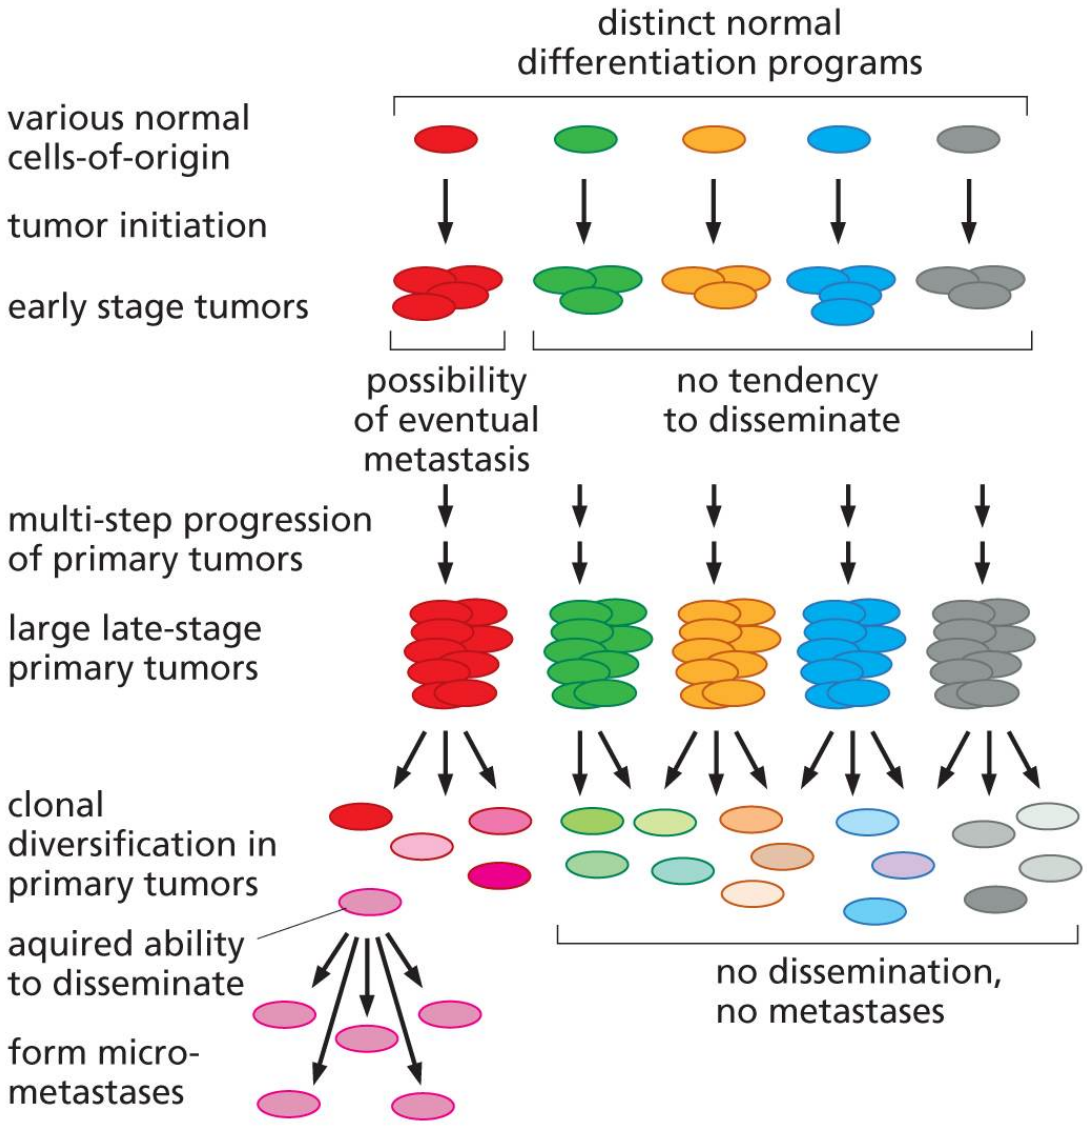
Three line graphs describing survival probability as a function of time for three types of cancer, with and without a metastasis signature. The first line graph shows that about 30 percent of primary breast tumors without the metastasis signature metastasized in just over 50 months, and slightly over 50 percent of tumors with the signature did so. The second line graph shows that only about 10 percent of primary prostate tumors without the metastasis signature recurred, and over 60 percent of tumors with the signature did so, within 50 months. The third line graph shows that slightly over 80 percent of medulloblastoma patients whose primary tumor did not have the metastasis signature survived out to 50 months, and less than 60 percent of patients whose primary tumor did have the metastasis signature survived out to 50 months.

(B)

Figure 14.49 Schedule of acquiring metastatic propensity The process of metastasis is the endpoint of multi-step tumor progression for many human tumors. This raises the issue of whether the tendency to metastasize is acquired late in tumor progression by a small subpopulation of cells or relatively early. (A) Gene expression microarrays make possible the simultaneous monitoring of the expression of thousands of genes to determine a specific pattern or expression signature that is correlated with a specific phenotype or set of phenotypes. In the expression array analysis seen here, genes that are expressed at high levels are in *red* and those expressed at low levels are in *blue*. RNAs prepared from 64 primary adenocarcinomas (from various tissues) and 12 metastatic nodules of adenocarcinomas (*arrayed across the top*) were analyzed (*horizontal black, red bars*, respectively). Of the thousands of genes analyzed in an initial gene expression array (*not shown*), 128 genes (*arrayed vertically*) were found to be associated—because of over- or underexpression—with metastases and metastatic progression (*vertical red, black bars, respectively*). Further distillation of the data yielded a set of 17 genes whose expression was as useful as that of the 128-gene set in predicting eventual metastases from primary tumors. (B) When researchers used the metastasis expression signature of panel A to analyze the gene expression patterns of other types of primary tumors, they were able to separate the patients bearing tumors of the breast (I), prostate (II), as well as (III) medulloblastomas into two groups (*blue, red lines*) having markedly different times to clinical progression or relapse following initial surgery. Most cells in certain primary tumors expressed a gene expression signature associated with metastasis, suggesting that this signature was acquired relatively early in primary tumor progression, possibly even before the initiating somatic mutation, and it became widespread in such tumors, being inherited by the great majority of descendants of early founders of the tumor cell population. (A and B, from S. Ramaswamy, K.N.

Ross, E.S. Lander et al., *Nat. Genet*. 33:49–54, 2003. With permission from Nature.)

However, DNA sequencing studies of the genomes of metastases and corresponding primary tumors suggest an apparently opposite conclusion: that primary tumors are genetically heterogeneous, and that metastases arise from genetically specialized subpopulations within primary tumors. An eventual reconciliation of these two portrayals of metastatic progression may be as follows (**Figure 14.50**): the differentiation program of a normal cell-of-origin is an important determinant of whether a primary tumor will ever have the potential to spawn metastasis-competent subpopulations. In those tumors that happen to inherit a differentiation program that favors eventual metastasis, diverse, specialized subclones may subsequently arise through somatic mutations or other stochastically acquired cell-heritable changes. Among these subclones will be those that have actually acquired metastatic powers. These subclones will then become the major sources of metastatic dissemination. Some speculations about the evolution of metastatic competence extend and reinforce this model (**Supplementary Sidebar 14.15**).



A diagram starts with five different normal cells-of-origin, each with a distinct normal differentiation program. Each cell undergoes tumor initiation, followed by the formation of an early-stage tumor. In one of the tumors, there is the possibility of eventual metastasis. In the other four tumors, there is no tendency to disseminate. All five tumors then go through multi-step progression of primary tumors to form large late-stage primary tumors, followed by clonal diversification in primary tumors. The same four tumors display no dissemination and no metastases. The one remaining tumor acquires the ability to disseminate and then forms microtumors.

Figure 14.50 Determinants of eventual metastatic dissemination. Observations like those presented in Figure 14.49 suggest that the differentiation programs of the normal cells-of-origin of a tumor continue to strongly influence the fully

transformed, tumorigenic descendants cells long after primary tumors are formed. As depicted here, most types of normal cells-of-origin, following neoplastic transformation, will generate primary tumors that have little tendency to disseminate even though the constituent cells are capable of robust proliferation in the context of the primary tumor. A subset of normal cells-of-origin (*left*, *red*) will, in contrast, yield primary tumors of comparable size and growth rates that contain cells that may well eventually metastasize. As the cells within a primary tumor undergo diversification during primary tumor progression, certain cells within the tumor will form small clonal populations that have acquired the ability, under appropriate circumstances, to disseminate and form micrometastases. Because this last step occurs at random times, most eventually formed metastases will represent the descendants of the clonal populations that were the first to develop the ability to disseminate.

As described here, EMT programs offer an attractive mechanistic solution to the problem of how carcinoma cells disseminate from primary tumors to distant tissues. Thus, the multiple distinct phenotypes conferred on neoplastic epithelial cells by this pleiotropically acting program may enable a primary tumor cell to physically translocate from the heart of a primary tumor to the parenchyma of a distant organ. Accordingly, a carcinoma cell that has activated an EMT program may be able to accomplish most of the steps of the invasion–metastasis cascade (see Figure 14.3) except the last one—colonization. If eventually proven, this model would represent a simplifying solution to a problem that has been viewed as one of endless complexity.

Of additional interest, and as illustrated in Figure 14.18, certain observations have demonstrated that once breast cancer cells have passed through an EMT in order to travel from the primary tumor to a foreign tissue compartment and found a new metastatic colony, many of the carcinoma cells in the resulting colony undergo an MET and thereby generate cells of a more epithelial phenotype. Thus, the presence of the resulting epithelial cells in such a metastasis seems to be critical to its robust outgrowth.

Our repeated reference to EMT programs in the context of carcinoma pathogenesis raises the question of whether there are alternative, equally important cell-biological programs that drive malignant progression. At present, it seems gratuitous to search for alternatives. Thus, in light of the detailed surveys of the traits of spontaneously arising, malignant carcinoma cells and the phenotypes of EMT-expressing cultured cells, it seems increasingly likely that EMTs play a central role in the malignant progression of most if not all carcinoma types and that the existence of alternative, equally important cell-biological programs is improbable.

Unanswered by our discussions are the associations of EMT programs with nonepithelial tumors, notably hematopoietic, connective tissue, and central nervous system (CNS) tumors, some of which are able to invade and occasionally metastasize. The origin of the CNS from an early embryonic epithelium—the neuroectoderm—offers the possibility that certain EMT-TFs that have been studied in the context of carcinoma progression may prove to be important actors for this class of tumors as well. Still, this uncertainty reminds us how little is understood at present about the malignancy programs of nonepithelial tumors.

Whether one or another model of metastasis is ultimately validated, it is clear that the identities of many of the genes that are specifically involved in programming metastasis have been elusive. Experimental resolution of these problems is confounded by complications at every level.

1. Experimental analyses are complicated by the inefficiencies of the metastatic process. Even when cancer cells have ostensibly acquired a genotype and phenotype enabling metastasis, they succeed in metastasizing with extraordinarily low efficiency. Such a weak connection between genotype and measurable phenotype derails most currently available experimental strategies.
2. A second dimension of complexity arises from the apparent collaboration of genetic and epigenetic factors in creating the metastatic trait. Recall, for example, that in certain experimental models of cancer, an EMT is achieved when *ras*-transformed cells are exposed to TGF-β (see Section 14.3). This transition, which is likely to operate in many human carcinomas and enable their invasiveness, can be triggered by specific signals that somatically mutated cells encounter in certain tissue microenvironments but not in others. Hence, at least in these cases, invasion and subsequent metastasis can hardly be portrayed as genetically templated traits and, for this reason, cannot be readily studied by many commonly used experimental techniques that focus on cancer cell genetics and cancer genome sequencing.
3. In many tumors, the genes and proteins that participate directly in programming invasion and metastasis may be expressed only at the invasive edges of primary tumors (see Figure 14.14), and the cancer cells in these invasive edges may represent only a minor fraction of the total neoplastic cell populations in these tumors. This organization greatly complicates experiments designed to reveal the biochemical and genetic bases of invasiveness and metastatic ability, which often rely on analyzing bulk populations of cancer cells prepared from large chunks of surgically resected tumors.
4. Carcinomas constitute the most common class of human cancers, and the neoplastic epithelial cells within these tumors may need to undergo an EMT in order to become invasive and metastatic. However, if invading carcinoma cells occasionally advance far through an EMT program and shed almost all epithelial traits, they become the proverbial “wolves in sheep’s clothing,” because most

commonly used histological analyses are unable to distinguish these cells from the non-neoplastic mesenchymal cells of the tumor-associated stroma. (Indeed, this difficulty explains why many tumor pathologists deny the very existence of the EMT as a key process in the development of carcinoma invasiveness.)

5. Metastatic dormancy creates another experimental problem. In breast cancer patients, for example, metastases may suddenly appear as long as 20 years after the initial primary tumor has been removed. Because of this long latency period and the sheer number of micrometastases carried by many patients, it has been difficult to learn how and why only a few of them suddenly acquire the ability to mushroom into macroscopic, life-threatening tumors.

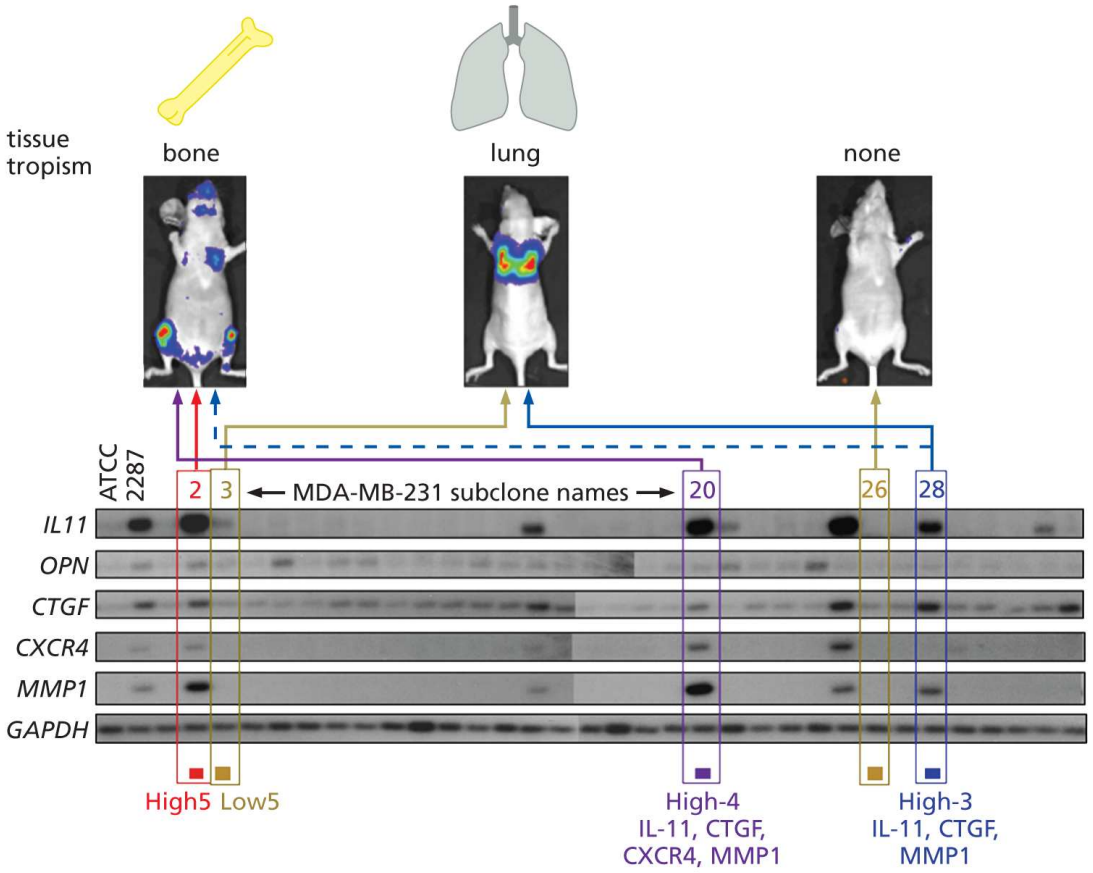
These experimental difficulties have greatly held back the progress of metastasis research, leaving many simple yet fundamental questions unanswered. For example, are there really genes that are specialized to impart an invasive or metastatic phenotype to cancer cells? And in the same vein, are there specialized metastasis suppressor genes that must be inactivated before a population of tumor cells can acquire invasive or metastatic ability? Or do the genes and proteins that affect metastasis operate as components of the regulatory circuits that we have repeatedly encountered throughout this book, namely, the circuits governed by the products of oncogenes and tumor suppressor genes?

The tissue tropisms of metastasizing cancer cells—their tendencies to colonize some but not other organs—represent the major challenge for cancer biologists studying metastasis. Figure 14.41B only begins to suggest the daunting complexity of the colonization problem. There, the tendencies of only four common cancers (those arising in the prostate, pancreas, breast, and colon) are illustrated in terms of their tendencies to form metastases in four organ sites (brain, lungs, liver, and bone marrow). In principle, each type of primary tumor cell depicted in Figure 14.41B must develop a distinct set of adaptations for each organ microenvironment in which it lands, yielding 16 distinct adaptive programs. Of course, there are far more primary tumor types that can metastasize to distant organs, and there are yet other alternative organ sites in which these tumors can found metastatic colonies; in addition, the various subtypes of primary tumors arising in an organ (for example, different subtypes of breast or lung carcinomas) may differ in their requirements for adaptation to different sites of metastatic colonization. In aggregate, these combinatorial interactions suggest the existence of many dozens, likely hundreds of distinct adaptive programs, each composed, in turn, of multiple genetic and epigenetic changes that enable one specific subtype of disseminating primary tumor cell to colonize a certain target organ.

This uncertainty is beginning to change. A powerful strategy for discovering the genes and proteins responsible for specific metastatic tropisms involves the isolation of tumor cells that show preference for colonizing a specific target organ. By retrieving

already-metastasized cancer cells from that organ, propagating them *in vitro*, and injecting them into host mice, followed by another round of isolating metastatic cells from that organ, it is possible to select clones of cancer cells that stably express a highly specific tropism for that organ.

Alternatively, single-cell clones (that is, clonal cell populations, each of which is descended from a single isolated cell) can be prepared from a heterogeneous population of cells present in a human cancer cell line. The gene expression profile (see Figure 13.20A) of each clone can then be analyzed, and its tendency to form metastases in one or another target organ can be determined. This analysis can lead to the identification of genes whose expression in a cancer cell is correlated with the metastatic tropism of that cell and may even contribute causally to this behavior (**Figure 14.51**). Indeed, ectopic expression of a group of such genes in otherwise-poorly metastatic clonal cell populations can induce these cells to exhibit potent osteotropic metastasis. Such experiments also indicate that within a heterogeneous tumor cell population, various preexisting gene expression patterns can strongly influence the ability of individual cells to exhibit a variety of metastatic behaviors.



A figure related to Gene expression patterns and metastatic tropism. 33 breast cancer cell lines, plus comparison lines A T C C and 2287 are analyzed for the

strength of expression of five genes, these being I L 11, O P N, C T G F, C X C R 4, and M M P 1, with G A P D H as a control. Cell line 2, in which all five test genes were strongly expressed, formed osteotropic metastases in mice. The same thing happened with cell line 20, in which all genes except O P N were strongly expressed. Cell line 3, in which all five test genes were weakly expressed, formed metastases in the lungs instead. Cell line 26, in which none of the five test genes were expressed, did not form metastases. Cell line 28, in which I L-11, C T G F, M M P 1 were strongly expressed, formed metastases in the lungs and, to a lesser degree, in bone.

Figure 14.51 Gene expression patterns and metastatic tropism Thirty-three cells from a large population of human MDA-MB-231 breast cancer cells were each expanded into a clonal population in culture. The mRNA expression pattern of each subclone was analyzed (*columns*, *arrayed left to right*) using probes for the mRNAs of five genes—IL11 (interleukin-11), OPN (osteopontin), CTGF (connective tissue growth factor), CXCR4 (chemokine receptor 4), and MMP1 (matrix metalloproteinase-1)—and, as loading control, a probe for GAPDH (glyceraldehyde-3-phosphate dehydrogenase) mRNA. In addition, the expression patterns of the original tumor cell population (ATCC, *left column*) and a subcloned cancer cell population termed 2287 (which was selected for its ability to generate osteolytic metastases; *second column*) were analyzed. The five experimental genes were chosen because of their overexpression in osteotropic metastatic cells and their known biological properties in promoting osteolytic metastases. Clone 2 cells (*red box*), when injected into the arterial circulation of mice, showed a tendency to produce osteotropic metastases, as indicated by *in vivo* imaging; these cells expressed high levels of all five experimental mRNAs. Clone 3 cells (*yellow box*), in contrast, expressed low levels of all five mRNAs and preferentially formed lung metastases. And clone 26 genes (*yellow box*), which expressed essentially none of these mRNAs, formed no metastases at all. Moreover, when otherwise poorly metastatic cells were forced to express combinations of three of these genes, they acquired the ability to form bone metastases efficiently (*not shown*), pointing to the causal role of these genes in forming these metastases. Metastases were visualized through the presence of a luciferase gene in the tumor cells, which causes cells to release a bioluminescent signal. (Top, from J. Massagué. Bottom, from Y. Kang, P.M. Siegel, W. Shu et al., *Cancer Cell* 3:537–549, 2003. With permission from Elsevier.)

Such research does not address the clinical challenges associated with metastasis, which remain daunting. The existence of micrometastases represents a major challenge for oncologists who would like to prevent disease relapse years after the primary tumor has been eliminated. Micrometastases of less than 0.2 mm diameter may carry several hundred to several thousand cells, and their detection in an organism carrying

approximately 5×10^{13} cells represents, at least at present, an almost-impossible undertaking. These micrometastases represent an ongoing threat because some of them may erupt into lethal outgrowths at an unpredictable future time.

This issue leads directly to another: Can the therapies used to treat primary tumors also be used to treat their metastatic derivatives? Or are metastatic cells so different from their progenitors in the primary tumor that they require their own customized therapies? In fact, expression array analyses indicating substantial similarity between the gene expression profiles of primary tumors and their metastatic offshoots provide some hope that metastatic cells may respond to the same therapies that succeed in destroying the primary tumors from which they derive.

To conclude, we go back to the beginning of this chapter: if, as experimental evidence increasingly shows, the epithelial–mesenchymal transition is a critical event in the acquisition of invasiveness and metastatic dissemination, and if cancer cells resurrect embryonic transcription factors to acquire malignant traits, then Lewis Wolpert's statement might require revision, in that gastrulation (and the associated EMT) might well loom as one of the most *dangerous* events in our lives!

OceanofPDF.com

Key concepts

- Invasion and metastasis are responsible for 90% of cancer-associated mortality, and the majority of cancer cells at the time of death may often be found in metastases rather than the primary tumor.
- The invasion–metastasis cascade involves local invasion, intravasation, transport, extravasation, formation of micrometastases, and colonization.
- The sequence of steps in this cascade is completed only infrequently, resulting in metastatic inefficiency. The least efficient of these steps appears to be colonization.
- Many of these steps can be executed by carcinoma cells that activate a cell-biological program called the epithelial–mesenchymal transition (EMT), which is normally used by cells during embryonic morphogenesis and wound healing.
- An EMT can be programmed by pleiotropically acting transcription factors that are normally involved in organizing various steps of early embryogenesis.
- Signals released by the stromal microenvironment of a cancer cell, operating together with genetic and epigenetic alterations of the cancer cell genome, are often responsible for inducing expression of the EMT-inducing transcription factors in the cancer cell and thus the EMT.
- The EMT involves loss of an epithelial cell gene expression program and acquisition of mesenchymal gene expression. The latter enables cells to acquire invasiveness, motility, and a heightened resistance to apoptosis.
- Passage through an EMT places carcinoma cells in a state from which they can progress further to become cancer stem cells, which in turn confers on them powers that are essential for the seeding of new tumor colonies.
- Cell invasiveness is enabled by various matrix metalloproteinases (MMPs) that function to degrade components of the extracellular matrix. These enzymes are often manufactured by inflammatory cells within the tumor-associated stroma.

- Metastatic cancer cells may travel via the lymph ducts to nodes. However, their spread via the blood circulation is responsible for most distant metastases.
- Many cancer cells that are carried through the circulation form microthrombi that lodge in the arterioles and capillaries of various tissues.
- The ability of cancer cells to extravasate may depend on many of the same activities that were used earlier to execute invasiveness and intravasation.
- Although the earlier steps of the invasion–metastasis cascade are likely to be similar in various types of human tumors, the last step—colonization—is likely to depend on complex interactions that are specific to the particular type of metastasizing cells and the microenvironments of the host tissues in which they land.
- The details of colonization mechanisms are best understood in the context of osteotropic metastases, especially the osteolytic metastases initiated by breast cancer cells.
- In some cases, the metastatic tropisms of cancer cells can be explained by the organization of the circulation between the primary tumor site and the target site of metastasis. In many other cases, the reasons that cancer cells metastasize from primary tumors to certain target organs are poorly understood.
- The acquisition of invasive and metastatic powers does not appear to involve major changes in the genotype of cancer cells within the primary tumor.

Thought questions

1. What arguments can be mustered for or against the notion that invasion and metastasis are likely to be orchestrated by specific mutant alleles that are acquired by cancer cells late in tumor progression?
2. What explanations can be offered for the inefficiency of colonization by the cells within micrometastases?
3. What arguments suggest that the ability to metastasize is expressed either by the bulk of cancer cells in a primary tumor or only by a minority of cells that are specialized to do so?
4. What evidence suggests that genetic and phenotypic evolution of cancer cells can occur in sites within the body that are far removed from the primary tumor?
5. What specific types of physiological support might be supplied by tissues that are frequently sites of successful metastasis formation? In what way do these supports affect the ultimate success of the colonization process?
6. How might primary tumors exhibit metastatic powers as soon as they form?
7. Would the ability to prevent metastasis have demonstrable effects on the clinical course of some human tumors but not others?
8. What evidence supports the involvement of an EMT in human tumor pathogenesis, and what evidence argues against it?
9. How might the ability to accurately determine the prognosis of a diagnosed prostate or mammary tumor lead to dramatic changes in the practice of clinical oncology?
10. What mechanisms might be invoked to explain why large primary tumor size is often correlated with a poor prognosis of metastasis?

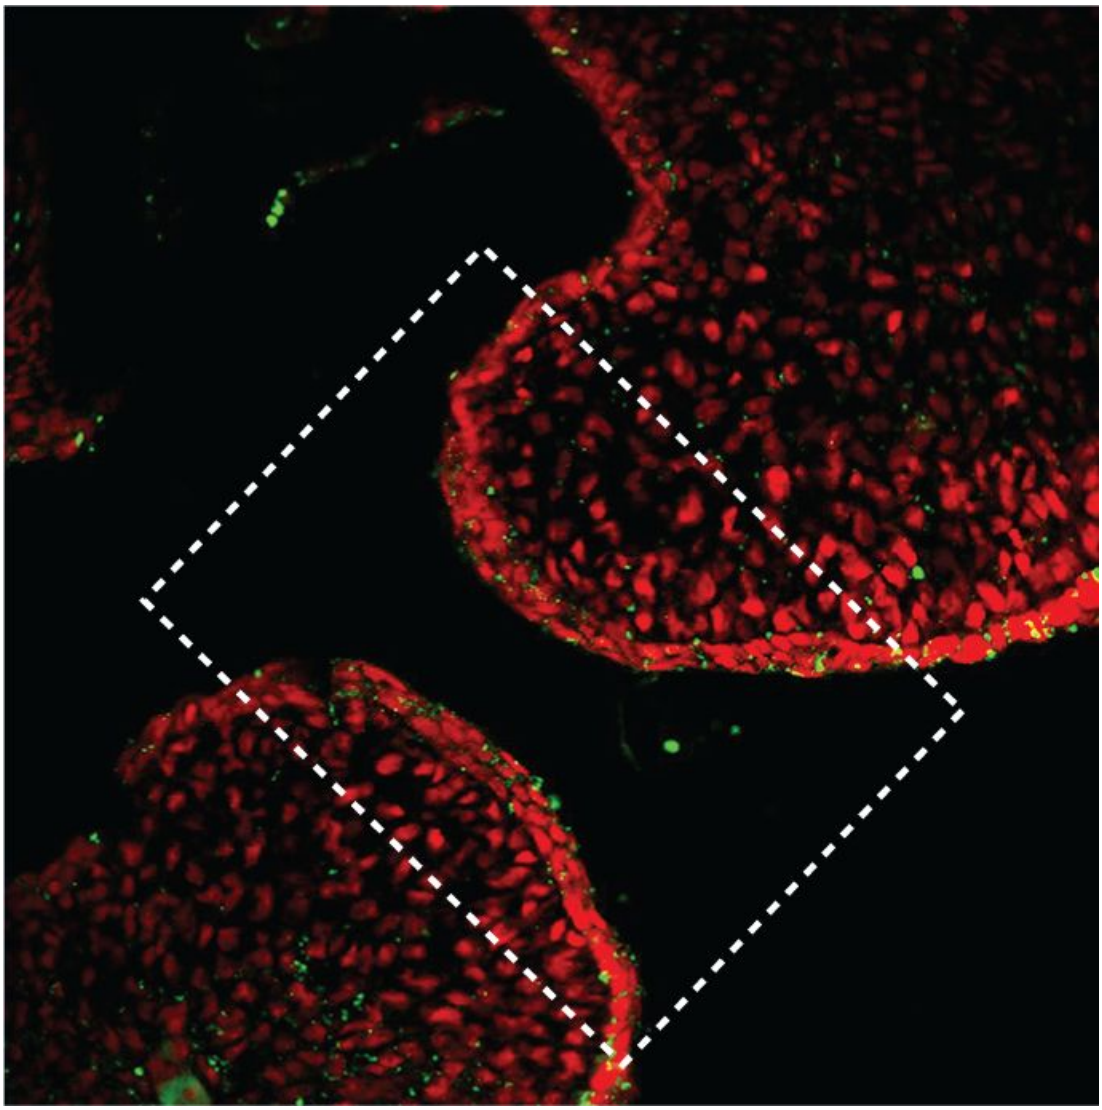
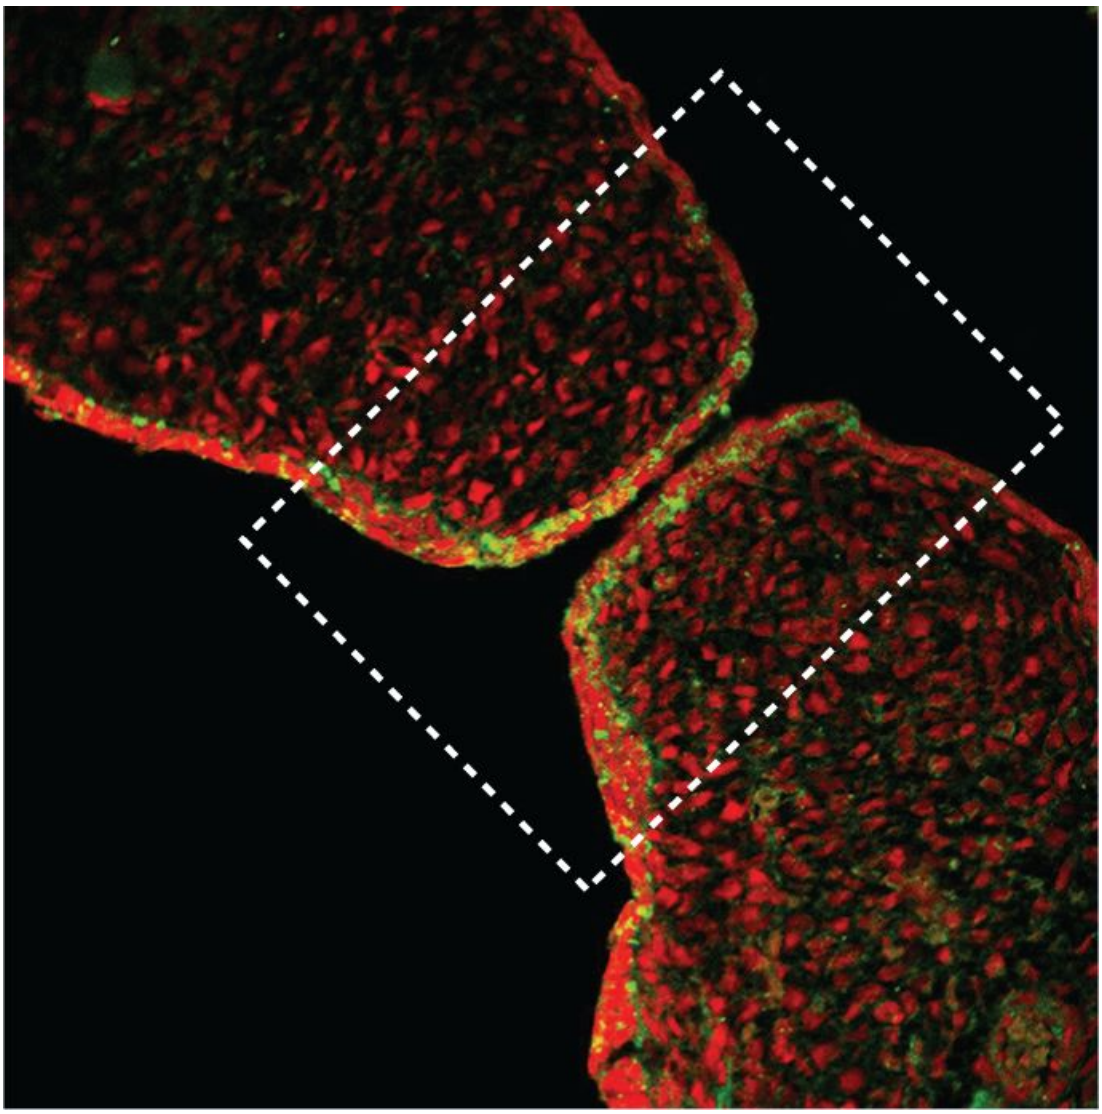
Supplementary Sidebars

Supplementary Sidebar 14.1 An example of an EMT relatively late in embryonic development

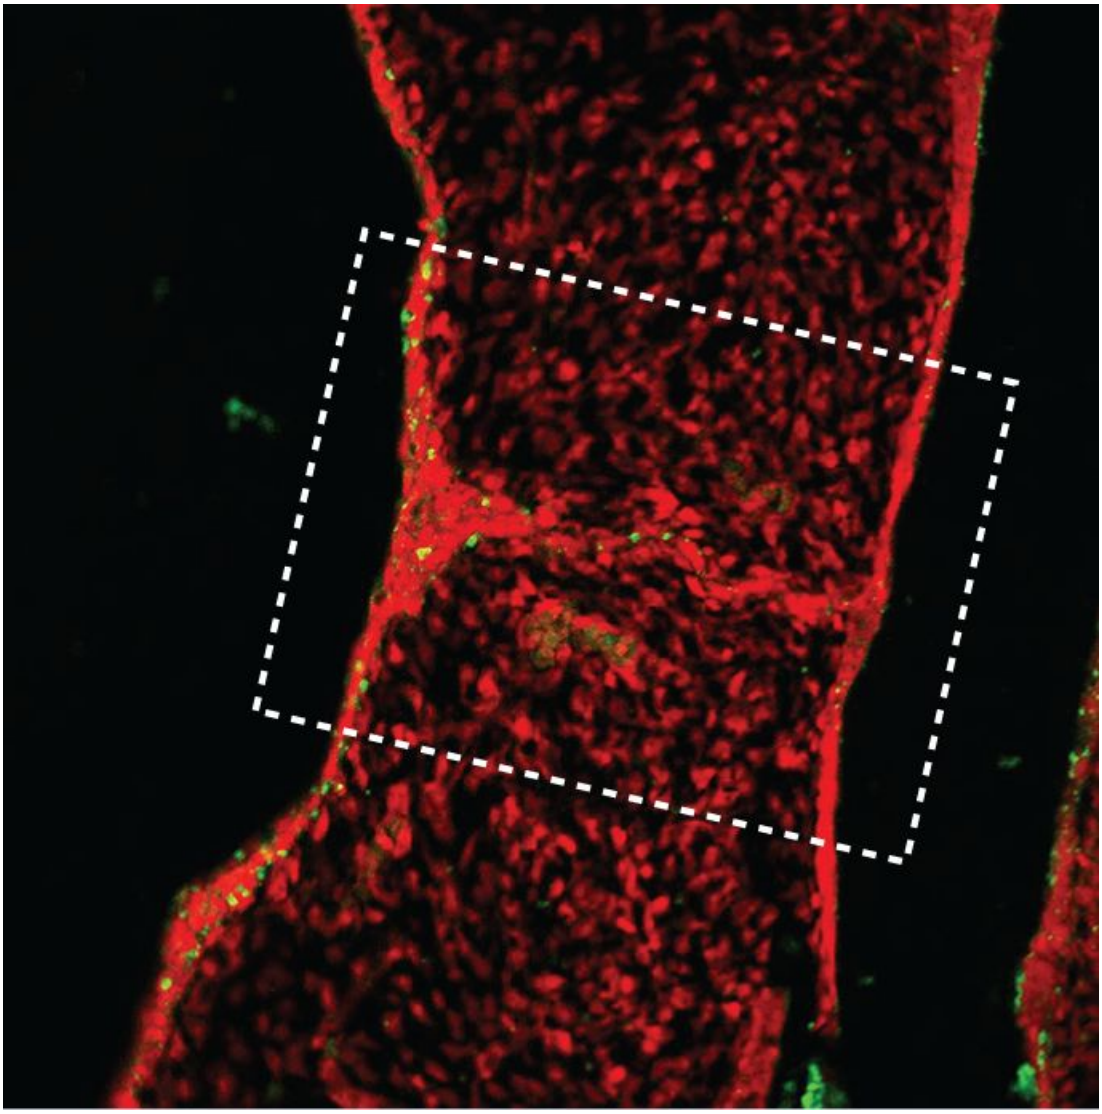
A variety of morphogenetic steps occurring long after the earliest processes, such as gastrulation and neural crest migration, continue to depend on EMTs and the transcription factors that orchestrate them. One graphic example is the formation of the palate (**Figure S14.1**), which requires the fusion of embryonic cell layers converging from both sides of the roof of the embryonic oral cavity to form a single tissue—a process that occasionally occurs incompletely and thereby generates the condition of cleft palate.



(A)



(B)



(C)

Figure S14.1Palatal morphogenesis and Twist The process of palate formation that generates the roof of the oral cavity in a mouse embryo depends on the fusion of two palatal “shelves” that are initially formed on opposite sides of the future oral cavity, grow toward one another, and then fuse. This fusion process depends on an EMT in the epithelial cells at the point of initial contact; as illustrated in this series of micrographs, at the point of fusion the epithelial cells have acquired expression of the Twist EMT-inducing transcription factor, which is detected here by immunofluorescence (*green*). (Because the growth factor TGF-β is known to induce Twist expression in cultured cells, the fusion of the palatal shelves can be prevented by the application of anti-TGF-β antibody.) Cell nuclei were stained with ToPro dye (*red*). (A) Before fusion, Twist is detected in scattered cells in both the outer epithelium and the underlying mesenchymal tissue. (B) As the two

palatal shelves converge, intense Twist expression is induced (*green*), largely at the point of future fusion. (C) Once fusion has occurred, Twist expression declines dramatically and the fusion point (still apparent here) will eventually be healed completely, erasing all vestiges of the fusion process (*not shown*). It remains unclear whether this EMT program enables epithelial cells to migrate bidirectionally out from the point of fusion toward the nasal and oral cavities (above and below the recently formed palate, respectively) or whether it generates large populations of mesenchymal cells that will form the future mesenchyme of the palate. (From W. Yu, H. Kamara and K.H. Svoboda, *Dev. Dyn.* 237:2716–2725, 2008. With permission from John Wiley & Sons.)

Supplementary Sidebar 14.2 TGF-β works in conflicting ways during tumor progression

The powers of TGF-β to affect tumor development both positively and negatively have been shown dramatically by experiments reported in 1996 using a transgenic mouse model of skin carcinogenesis. In this model, the development of squamous cell carcinoma was favored by the expression of a *ras* oncogene under the control of a transcriptional promoter that ensured its expression in keratinocytes of the skin. When a transgene favoring TGF-β expression in the skin was also installed in the germ line of these cancer-prone mice, the absolute number of skin tumors that formed was decreased, ostensibly because of the anti-proliferative effects of TGF-β. However, those few tumors that did arise showed the phenotype of aggressive spindle-cell carcinomas (formed from cells that have undergone an EMT) rather than the more benign squamous cell carcinomas that are usually seen in such transgenic, tumor-prone mice. Consequently, once transformed epithelial cells have developed a resistance to TGF-β's cytostatic effects (for example, through inactivation of the pRb pathway; see Section 8.10), this factor can collaborate with oncogenes residing in the carcinoma cells to trigger an EMT and attendant high-grade malignancy.

To summarize these and other observations, TGF-β can contribute to cancer cell malignant phenotypes through at least four mechanisms. First, most human carcinomas retain at least some functional TGF-β receptor signaling, allowing them to continue to respond to TGF-β during the entire course of tumor progression. (This contrasts with the situation observed in a subset of colon carcinomas in which receptor function may be lost entirely through mutations in the receptor-encoding genes; see Figure 12.26.) Second, the inactivation of the pRb pathway, which occurs in most if not all human cancers, causes malignant cells to lose their responsiveness to the cytostatic effects of TGF-β; this loss, however, does not affect the responses to other downstream signals that are released by ligand-activated TGF-β receptors, specifically the signals that trigger induction of EMT programs. Third, in the absence of the cytostatic effects of

TGF-β, exposure of certain kinds of cancer cells to this factor may actually *favor* their proliferation. For example, glioblastoma and osteosarcoma cells that are treated with TGF-β respond by producing and secreting PDGF; once released, the latter acts in an autocrine fashion to stimulate the proliferation of these cancer cells via the PDGF receptors that they also display. Finally, exposure of breast cancer cells to TGF-β causes them to release other factors that accelerate the breakdown of mineralized bone—a critical step in the formation of *osteolytic* metastases; as we will learn later (Section 14.13), this breakdown liberates additional mitogens that drive cancer cell proliferation.

Supplementary Sidebar 14.3 Signals operate in various combinations during embryogenesis

The EMT program involves at least three dimensions of complexity—the multiple discrete manifestations of the cell-biological program, the multiple transcription factors that can orchestrate it singly or in combination, and the multiple distinct afferent signals that function combinatorially to activate it. Focusing on the latter, we can refer to the two major normal functions that this program was evolved to accomplish, specifically wound healing and developmental morphogenesis. The former, although having its own internal complexity (see Section 13.3), pales in comparison with the myriad biological programs that allow the morphogenesis associated with organismic development to proceed properly.

The master programs of development ensure that cells in certain specific locations within an embryo activate EMT programs at certain times, whereas cells located in other locations do not. The location of each of the cells within an embryo is determined and defines its immediate surroundings, specifically by the identities of its immediate neighbors and the diverse paracrine signals that they release. These multiple requirements for proper morphogenesis demand that EMT-activating signals function combinatorially, that is, a cell in a defined position in an embryo will receive one combination of afferent signals flowing from its own particular set of close neighbors; their identities define its unique location and dictate its future fate and that of its descendants. Cells located elsewhere in the embryo will experience their own combinations of afferent signals released by their own respective neighbors. This logic provides the biological rationale that seems to explain the selective forces that drove the development of the EMT machinery (and its regulation) during a period in the pre-Cambrian era—by some accounts as long as 750 million years ago—when the complexity of metazoan morphogenesis was being invented.

Supplementary Sidebar 14.4 The epithelial versus mesenchymal status of carcinoma cells appears to be influenced by cell-intrinsic responses

We read throughout this chapter about the importance of contextual signals originating in the tumor microenvironment that function in various combinations to induce activation of EMT programs in nearby carcinoma cells (see **Supplementary Sidebar 14.3**). Not discussed in these accounts is the influence of the *responsiveness* of the carcinoma cell to these signals. Thus, this responsiveness may be influenced by the nature of the somatic mutations that these cells have acquired en route to full-fledged malignancy. In addition, the differentiation program of the tissue in which cancer cells have arisen may exert strong influences on their ultimate positions along the epithelial–mesenchymal spectrum of phenotypes.

This notion has been studied in part by creating an "EMT score" that quantifies the extent to which the program has been activated in a cell of a certain origin, using a variety of markers to calculate this score. Having done so, one can measure the EMT score of samples of carcinoma cells prepared directly from patients' tumors and compare these with the behavior of carcinoma cell lines that are propagated in culture. In the former case, the EMT status of the carcinoma cells is the product of the various contextual, heterotypic signals that the carcinomas cells have experienced while growing within histologically complex tumors. In the latter case, the carcinoma cells proliferate in the absence of any contextual signals except those that they generate on their own. As seen in **Figure S14.2**, there is a striking similarity when comparing these two EMT measurements (that is, phenotypes exhibited by cancer cells present in spontaneously arising human tumors versus phenotypes of cancer cell lines derived from the same tumor subtypes) in a survey of a broad range of carcinoma cell types. This similarity, on its own, suggests that the carcinoma cells exhibit an *intrinsic responsiveness* to EMT-inducing signals that operates independently of the signals that they happen to encounter *in vivo*. Such responsiveness may be influenced by the ongoing expression of differentiation programs that these cells inherit from their respective normal cells-of-origin operating together with the spectrum of autocrine signals that they happen to generate and experience, the latter once again being influenced by their differentiation programs.

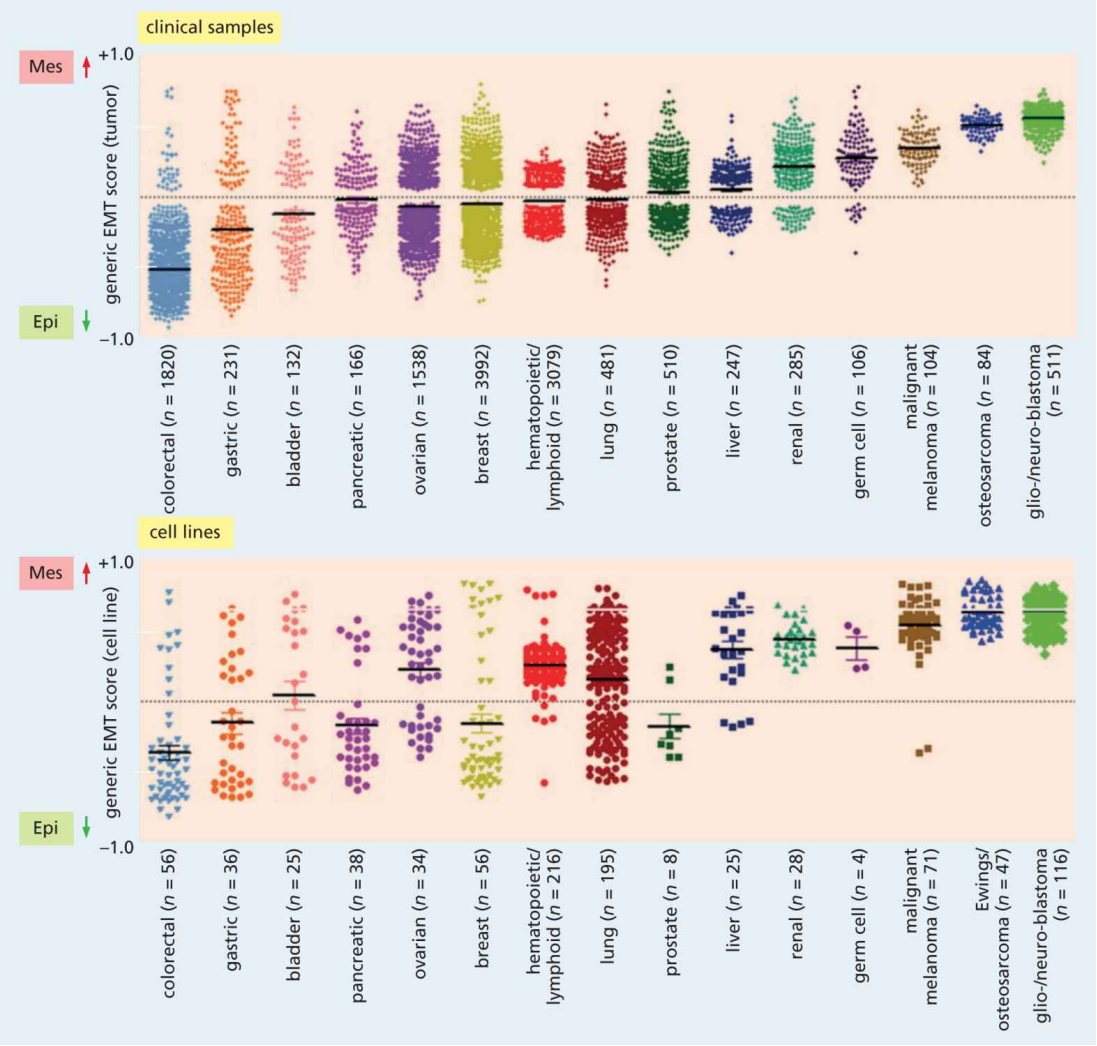


Figure S14.2 EMT Score and the natural set points of human cancer cells A quantitative measure of the extent of EMT activation was devised by creating an algorithm that measured the weighted sum of a series of EMT-related markers in cancer tumor cells. The resulting "generic EMT scores" (*ordinates*) were than derived for a series of clinical samples (*upper panel*) and human cancer cell lines propagated in culture (*lower panel*). Cells residing in a more mesenchymal phenotypic state received EMT scores closer to +1, whereas cells residing in a more epithelial state received EMT scores closer to –1. The numbers of samples evaluated are indicated in the parentheses in each case. The striking similarities between these two independently measured sets of human cancer cell collections suggested that the lower cell lines, which were propagated in culture in the absence of any stromal support, naturally seek and enter into a certain E vs. M phenotypic state along the E-to-M spectrum, even in the absence of the stromal signals that must be experienced by corresponding tumor cells residing in

naturally arising human tumors. (From T.Z. Tan, Q.H. Miow, Y. Miki et al., *EMBO Mol. Med*. 6:1279–1293, 2014. With permission from John Wiley & Sons.)

Supplementary Sidebar 14.5 Metastasizing cancer cells often take on hitchhikers while traveling through the blood

Repeated reports over the course of the last century have documented the presence of metastasizing cancer cells within small clots, termed variously microthrombi, microemboli, or thromboemboli. These consist of multiple platelets and red blood cells adsorbed to the surface of individual tumor cells or clumps of tumor cells within blood vessels (**Figure S14.3A**). (The process of forming these microthrombi is sometimes termed embolization.) In fact, the direct contact of cancer cell surfaces with blood plasma tends to provoke localized clotting. In experimental mouse models of human cancer development, the formation of these microthrombi can already be observed within two minutes of the entrance of cancer cells into the circulation.

Figure S14.3 Contribution of platelets to the formation of metastases The initial adhesion of platelets to intravasated cancer cells is triggered by Tissue Factor (TF), a glycoprotein that is expressed on the surfaces of most cell types outside of the circulatory system. This binding seems to be reinforced by receptors —L-selectin and P-selectin—that are expressed on the cell surface of platelets. Both selectins appear to recognize and bind mucins on the surface of cancer cells. (A) Green fluorescent protein (GFP)–labeled cells from a human colon cancer cell line were injected intravenously into mice, and 30 minutes later, frozen sections were prepared from the lungs of these mice and immunostained with an antibody that recognizes platelets (*red*). When this experiment was performed in mice that are wild type at the locus for P-selectin (*left*), a cloud of platelets was apparent; however the same experiment performed in P-selectin–negative cells (*right*) failed to demonstrate platelet aggregation, indicating the key role of P-selectin in forging links between platelets and intravasated cancer cells. Similar clouds of platelets can be found at even shorter times after introduction of other cell types, such as

melanoma cells, into the general circulation. (B) The attachment of platelets to cancer cells is triggered by the actions of Tissue Factor, whose ectodomain is seen here. Exposure of plasma to Tissue Factor, which occurs following wounding, results in a 10^5-fold up-regulation of plasma-associated FVIIa; activated FVIIa then initiates the clotting cascade that results in the conversion of fibrinogen to fibrin and the adsorption of platelets to the surfaces of cancer cells. (C) Mouse B16 melanoma cells, which express the melanin pigment (*black*), were injected into the tail vein of either wild-type mice or *Nf-E2*$^{-/-}$ mice; the latter have virtually no platelets. As seen here, the mutant mice (*left*) developed very few melanoma metastases (*black spots*) in their lungs, whereas most of the wild-type mice (*right*) injected with an equal number of melanoma cells developed large numbers of metastases in their lungs. Hence, platelets provided a critical contribution to metastasis formation. (D) The counts of metastases visible on the surfaces of the lungs in panel C vary dramatically from mouse to mouse. Note that the ordinate is a logarithmic scale. (E) In wild-type mice (*left panel*), a cloak of platelets (*blue*) is present 30 minutes after human colon carcinoma cells (*green*) have been introduced into the circulation. P-selectin is required for the firm attachment of platelets to cancer cells. In mice unable to make P-selectin (*middle panel*), the cloak of platelets is substantially reduced, and now immune cells, including macrophages and monocytes (*red*), are able to approach closely to the cancer cells. Similarly, when wild-type mice are injected with heparin (an anti-coagulant that prevents platelet aggregation; *right panel*) prior to introducing the cancer cells, the platelets are absent and immune cells are present in abundance immediately around a cancer cell. (F) L-selectin plays a similarly important role in forming these microemboli. Human colon carcinoma cells were injected intravenously via the tail vein into immunocompromised mouse hosts and the numbers of metastasized human cancer cells were determined by measuring the amount of human DNA (represented here as densitometry units) in the lungs of these animals 6 weeks later. Mice whose platelets expressed normal levels of L-selectin ($L^{+/+}$) showed significant amounts of human DNA and thus metastases in their lungs, whereas those whose platelets lacked L-selectin ($L^{-/-}$) showed few if any lung metastases. (A and E, from L. Borsig et al., *Proc. Natl. Acad. Sci. USA* 98:3352–3357, 2001. With permission from National Academy of Sciences, U.S.A. B, from Y.A. Muller, R.F. Kelley and A.M. deVos, *Protein Sci.* 7:1106–1115, 1998. With permission from John Wiley & Sons. C and D, from E. Camerer et al., *Blood* 104:397–401, 2004. With permission from American Society for Hematology. F, from L. Borsig et al., *Proc. Natl. Acad. Sci. USA* 99:2193–2198, 2002. With permission from National Academy of Sciences, U.S.A.)

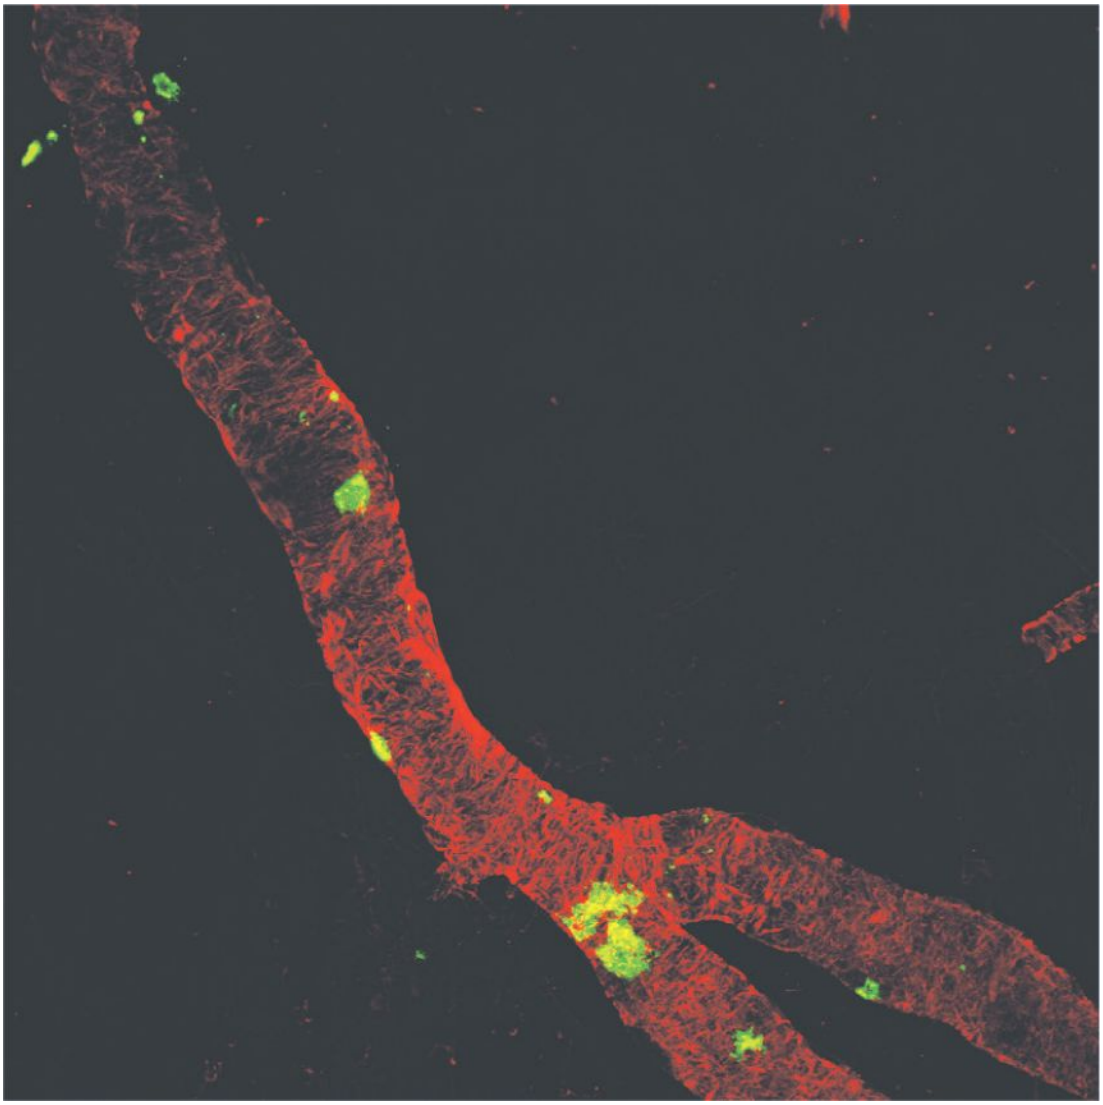
These localized clots are likely to be triggered largely by Tissue Factor (Figure S14.3B), a protein that is expressed on the surface of malignant carcinoma cells and

much less so by benign carcinoma cells and normal epithelial cells. Tissue Factor interacts with proteins in the plasma to initiate the clotting cascade: it activates thrombin, which in turn converts fibrinogen to fibrin (which binds the cells in clots together) and activates platelets (see Figure 13.12).

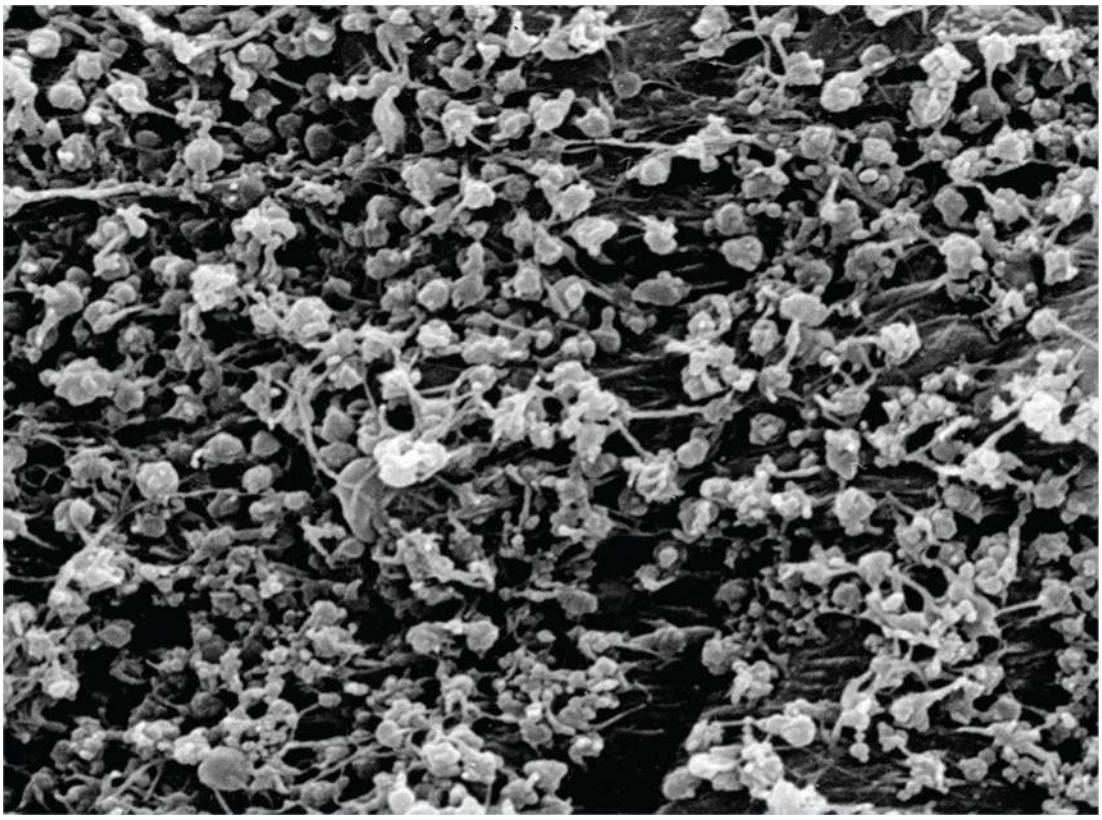
The importance of these microthrombi as vehicles for metastasizing cancer cells is indicated by studies using genetically altered mice that lack various components of the platelet-clotting machinery, including fibrinogen and components of platelets essential for their activation. Thus, melanoma cells were introduced via injection into the tail veins of these mice, and the numbers of subsequently arising lung metastases were determined. Mice lacking platelets showed a metastatic tumor burden that was only 4% of that seen in comparable wild-type mice (Figure S14.3C and D). Similarly, mutant mice carrying platelets that were unresponsive to activation by thrombin showed a metastatic burden that was only 9% of the burden seen in wild-type mice. And mice lacking the ability to form fibrin—the critical structural component of clots—exhibited lung metastases that totaled only 3% of the number counted in wild-type mice. In addition, two cell surface proteins, P- and L-selectin, seem to reinforce the adhesion of the platelets to intravasated cancer cells (Figure S14.3E and F).

Precisely how microthrombi facilitate metastasis remains a matter of conjecture. Some experiments indicate clearly that a coating of platelets protects cancer cells from various types of injury while they are traveling through the blood and are lodged in microvessels. This protection may include shielding these circulating cancer cells from attacks by natural killer (NK) cells (lymphocytes that have an intrinsic ability to recognize and kill many types of cancer cells; see Chapter 15) as well as from monocytes and macrophages. For example, the loss of metastatic ability resulting from the absence of fibrinogen is almost completely reversed if host mice are also unable to make NK cells. Presumably NK cells represent the major threat to metastasizing cancer cells in the circulation, and cancer cell survival seems to depend on the ability to hide behind cloaks formed by adsorbed platelets.

Platelets may also expedite metastasis through their ability to strongly adhere to the surfaces of injured blood vessels, specifically those in which the localized loss of the endothelial cell lining exposes the underlying vascular basement membrane and associated collagen IV (**Figure S14.4**). This binding may facilitate the attachment of entire microthrombi to the walls of larger vessels and thereby enable metastasizing cancer cells within these clumps to gain their first firm foothold in a tissue. Once physically stabilized in this way, cancer cells may begin to proliferate within microthrombi, penetrate through the vessel wall (that is, extravasate), and eventually establish a new metastatic colony in the parenchyma of a tissue.



(A)



(B)

Figure S14.4 Adhesion of microthrombi to vessel walls Microthrombi carrying cancer cells and attached platelets may occasionally adhere to the walls of larger vessels. (A) One highly plausible mechanism of attachment depends on the presence of patches of vascular basement membrane that are not covered by a continuous coating of endothelial cells and are therefore directly exposed to the lumen of a blood vessel. In this fluorescence micrograph, the outline of a blood vessel in a mouse is indicated by the configuration of the pericytes and smooth muscle cells around its exterior that have been immunostained with an antibody reactive with α-smooth muscle actin (*red*). Patches of basement membrane exposed to the lumen of this vessel have been stained through use of a lectin that specifically sticks to the basement membrane (*green*). (B) The endothelial cells lining the lumen of a rabbit carotid artery have been removed through the procedure of balloon angioplasty, exposing underlying basement membrane. Subsequently, as seen in this scanning electron micrograph, hundreds of platelets, which have a strong affinity for the collagen IV of the basement membrane, adhered to this basement membrane. This behavior suggests how microthrombi may attach to exposed patches of basement membrane through their halo of platelets. (A, courtesy of J.H.C. Chen and L. Coussens. B, from M.R. Miller et al.,

Cardiovasc. Res. 57:853–860, 2003. Republished with permission of Oxford University Press-Journals.)

In addition, as first reported in 2011, adhered platelets may help to induce components of the EMT program via the secretion of molecules like TGF-β. Indeed, this interaction, which is likely to occur after cancer cells have become trapped in distant microvessels, can perpetuate and thereby maintain expression of an EMT program that was initially activated within the confines of a primary tumor, and may thus confer the invasive traits that cancer cells require in order to extravasate by invading through the walls of these microvessels into the nearby tissue parenchyma.

Supplementary Sidebar 14.6 Metastatic dissemination of advanced primary tumor cells occurs relatively rapidly

A study published in 2008 attempted to measure the time periods that typically elapsed between distinct stages of colorectal carcinoma progression. This multi-step process was first linked to the genetic evolution of carcinoma cells in 1989 (see Figure 11.9), but the early research did not reveal the time elapsed between the successive steps. The advent of large-scale sequencing of cancer cell genomes, however, allowed calculations of the rate at which random, unselected point mutations accumulate with time, a rate found to be ~4.6×10^{-10} per base pair per cell generation. This number, taken together with the known rate of doubling of colorectal cells at various stages of tumor progression, allowed a rough calculation of the time required for the major steps of multi-step tumor progression to reach completion.

These calculations predict (**Figure S14.5**) that ~17 years is required for a primary, high-grade carcinoma to develop (via genetic and epigenetic mechanisms) from a relatively large, benign, adenomatous polyp. However, once this high-grade carcinoma forms in the gut, less than 2 years are required for metastases to the liver to arise.

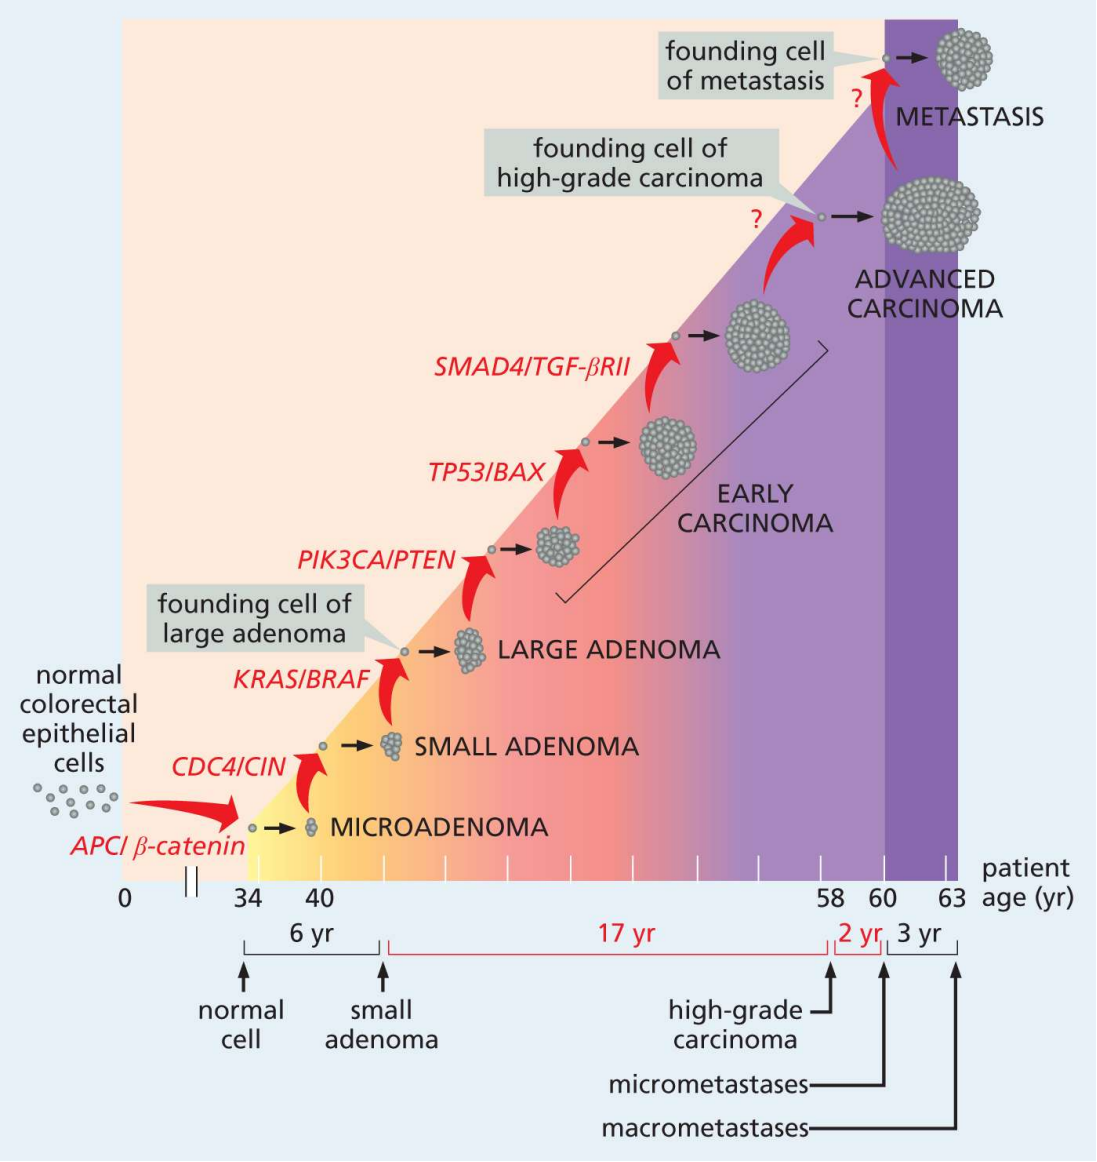


Figure S14.5 Timetable of colorectal tumor progression This scheme illustrates the time spans that have been associated with various discrete stages of colorectal tumor progression based on the somatic mutations that have been acquired in the genomes of colorectal epithelial cells at various stages of multi-step tumor progression. The age of the average patient at each stage of colorectal cancer (CRC) progression is indicated *below* the drawing, as are the time spans required to progress from a fully normal intestinal enterocyte to the formation of a small adenoma (6 yr), from this stage to a high-grade primary carcinoma (17 yr), from this stage to a micrometastasis (2 yr), and from the latter to the formation of a clinically detectable macroscopic metastasis (3 yr), this last step representing the process of colonization. The time of appearance of the founding cells of several of these clonally expanding populations is indicated. Mutant oncogenes and tumor

suppressor genes that are found typically in various stages of CRC tumor progression and are responsible hypothetically for driving these clonal expansions are given in *red*. (From S. Jones et al., *Proc. Natl. Acad. Sci. USA* 105:4283–4288, 2008. With permission from National Academy of Sciences, U.S.A.)

The rapidity with which such high-grade primary carcinoma cells disseminate seems to be incompatible with a requirement for additional rare genetic events to occur and become well represented in the genomes of evolving pre-metastatic tumor cell populations. This suggests instead that the heritable genetic changes that were selected during primary tumor formation and were required for its outgrowth were already *sufficient* to enable metastatic dissemination to take place. Stated differently, high-grade primary carcinoma cells may already be genetically equipped to disseminate. Accordingly, epigenetic changes acquired by these high-grade primary carcinoma cells —specifically those acquired during passage through an EMT—may suffice to enable these genetically altered cells to disseminate.

In light of the information presented in Section 14.7, the process of multi-step tumor progression can be depicted in a new way: primary tumor formation depends on the acquisition of a number of critical gene mutations (and hypermethylated transcriptional promoters). In many tumors, once these changes have been acquired, expression of one or several EMT-TFs in these cells may enable them to complete the remaining steps of the invasion–metastasis cascade (up to the stage of colonization) without the need for additional genetic alterations.

These considerations have additional implications for the overall process of tumor pathogenesis and metastasis. They suggest three major phases of this process: (1) primary tumor formation through heritable genetic and epigenetic somatic alterations (the latter via promoter methylation); (2) activation of an EMT program in cells and their physical dissemination leading to the formation of micrometastases; and (3) colonization, which demands that disseminated micrometastatic cells undergo a series of adaptations to an unfamiliar tissue microenvironment by still-unknown changes, perhaps largely nongenetic.

The subsequent outgrowth of a macroscopic metastasis—the product of successful colonization—may then allow a repetition of steps 2 and 3, in this case involving the newly formed macrometastasis rather than the primary tumor as the source of the disseminating cancer cells.

Supplementary Sidebar 14.7 Our cells devote an enormous number of genes to regulating protein degradation

Surveys of the human genome sequence have yielded a repertoire of protease-encoding genes that is vastly larger than previously anticipated. These enzymes degrade protein substrates both inside and outside of cells. They can be placed into five major functional classes, depending on the identity of the critical functional group in the catalytic sites of these enzymes. Thus, in addition to the metalloproteinases, serine, cysteine, aspartyl, and threonine proteases have been characterized.

A 2003 detailed analysis of the human genome identified 553 genes that encode proteases, some which, based on their sequence, appeared to be catalytically inactive but nonetheless subserving some still-unknown function. (For comparison, recall that the entire human kinome contains 518 protein kinases, compared to the 553 proteins that together compose the "degradome.") Of these proteases, 125 appeared to be membrane bound, although the location of the membrane (i.e., cell surface versus intracellular membrane) was not revealed by this analysis. Most of these 553 proteins are likely to be secreted proteins or cell surface proteins, highlighting the complex regulatory interactions that are mediated by proteases and operate in the extracellular space, about which we know almost nothing.

The large super-family of proteases could be grouped into 63 distinct gene families based on their amino acid sequences. This echoes the explosive growth of another group of enzymes known to be involved in protein degradation—the ubiquitylating enzymes. Some surveys have enumerated as many as 527 of these enzymes that are encoded by the human genome (see **Supplementary Sidebar 7.5**). The actions of the ubiquitylating enzymes are countered by as many as 110 distinct de-ubiquitylating enzymes (DUBs), most of which are cysteine proteases. Altogether, about 5% of the genes in our genome are devoted to one or another aspect of protein degradation. Only a tiny fraction of these genes and their protein products have been studied to date; many are likely to control the concentrations of important cellular growth-regulating proteins. It is inevitable, therefore, that a significant cohort of these regulators will eventually be discovered to play key roles in neoplastic growth control and tumor invasiveness.

Supplementary Sidebar 14.8 Complex subcellular structures enable cell motility

The process of cellular movement can be broken down into several distinct steps. To begin, a cell will extend its cytoplasm in the direction of intended movement. This extension involves the protrusion from the cell surface of lamellipodia—broad, flat, sheetlike structures that may be tens of microns in width but only 0.1 to 0.2 μm thick (**Figure S14.6**; see also Figure 14.35). At the same time, cell surface proteases, such as those cited in **Supplementary Sidebar 14.7**, are used to selectively degrade ECM proteins that stand in the way of the "leading edge" of the migrating cell. While this is going on, the cell deploys integrins to construct new points of attachment between the

lamellipodia and the ECM at its leading edge and, at the same time, breaks such adhesions at its “lagging edge,” thereby liberating components of its cytoplasm and plasma membrane for redeployment to the leading edge (see Figure 14.33).

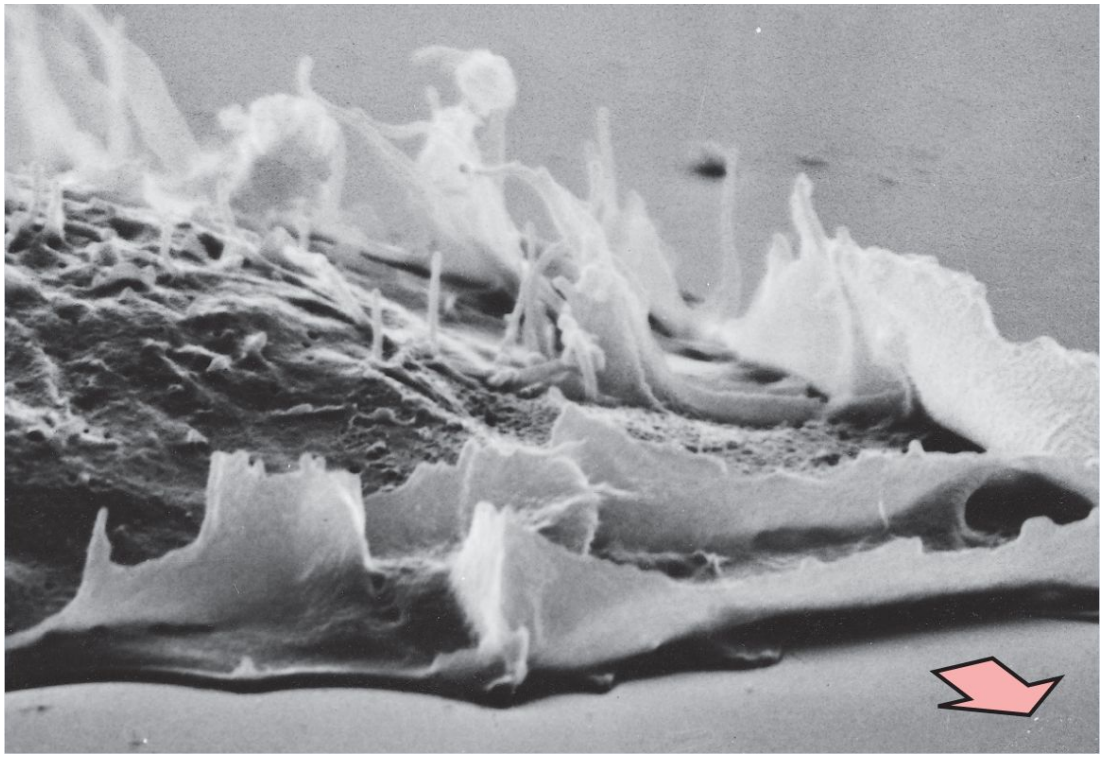

Figure S14.6 Lamellipodia and filopodia This scanning electron micrograph (SEM) of a spontaneously transformed rat liver cell shows the elaborate ruffles—lamellipodia—that migrating cells extend at their leading edge during locomotion in the indicated direction (*pink arrow*). Lamellipodia are presumed to play a key role in the advance of invasive cancer cells *in vivo*, but this has not yet been directly demonstrated. Lamellipodia that fail to attach to the substrate seem to be swept back as ruffles along the dorsal (top) side of the cell; their component parts are then reintegrated into the larger plasma membrane and cytoskeleton. Not shown here are the filopodia—the small fingerlike protrusions that are extended from the leading edges of lamellipodia and are seen in abundance in Figure S14.7D. (Courtesy of Julian Heath.)

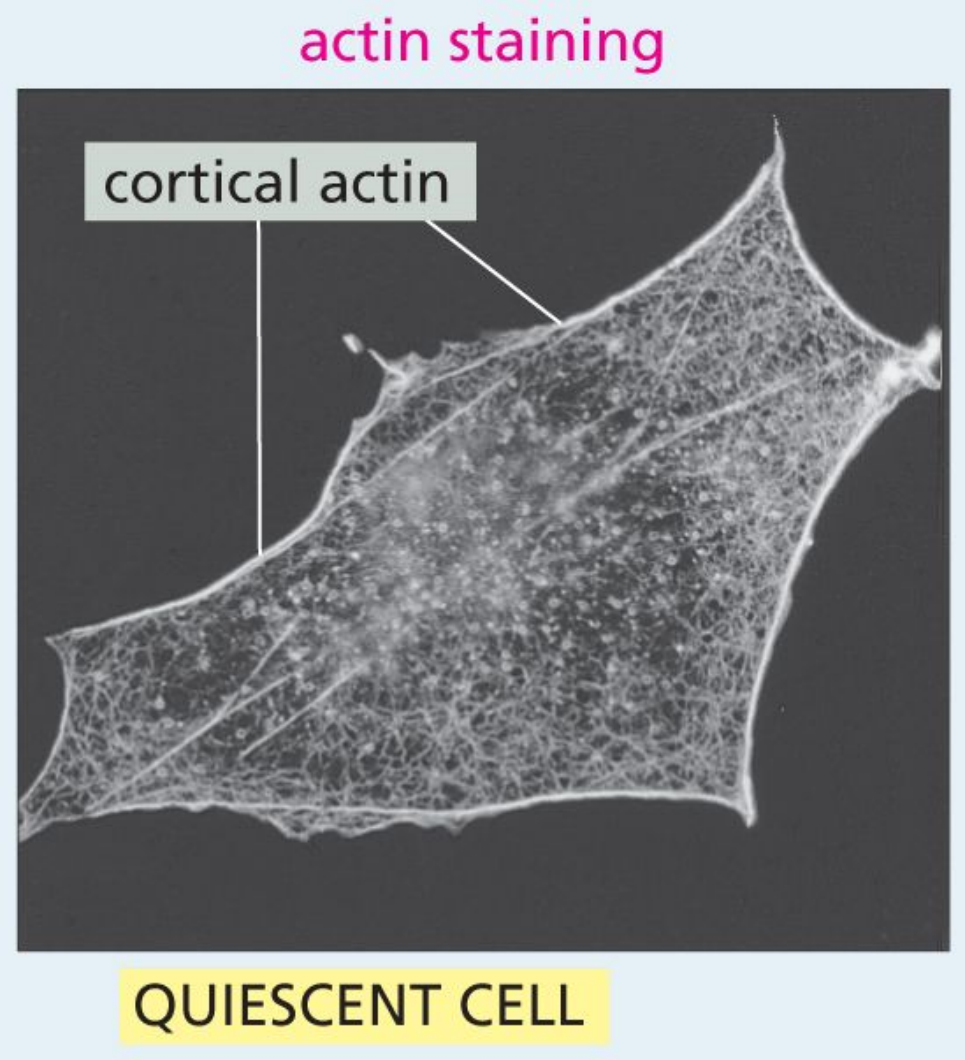
Protruding from the lamellipodia are spikelike structures termed filopodia that are thought to enable an advancing cell to explore the territory that lies ahead and initiate the formation of focal adhesions by integrins (see Figure 14.35); once formed, these adhesions provide cells with survival signals and, at the same time, allow them to gain traction through firm physical connections with the adjacent ECM. There are also indications that filopodia play a key role in the initial formation of micrometastases,

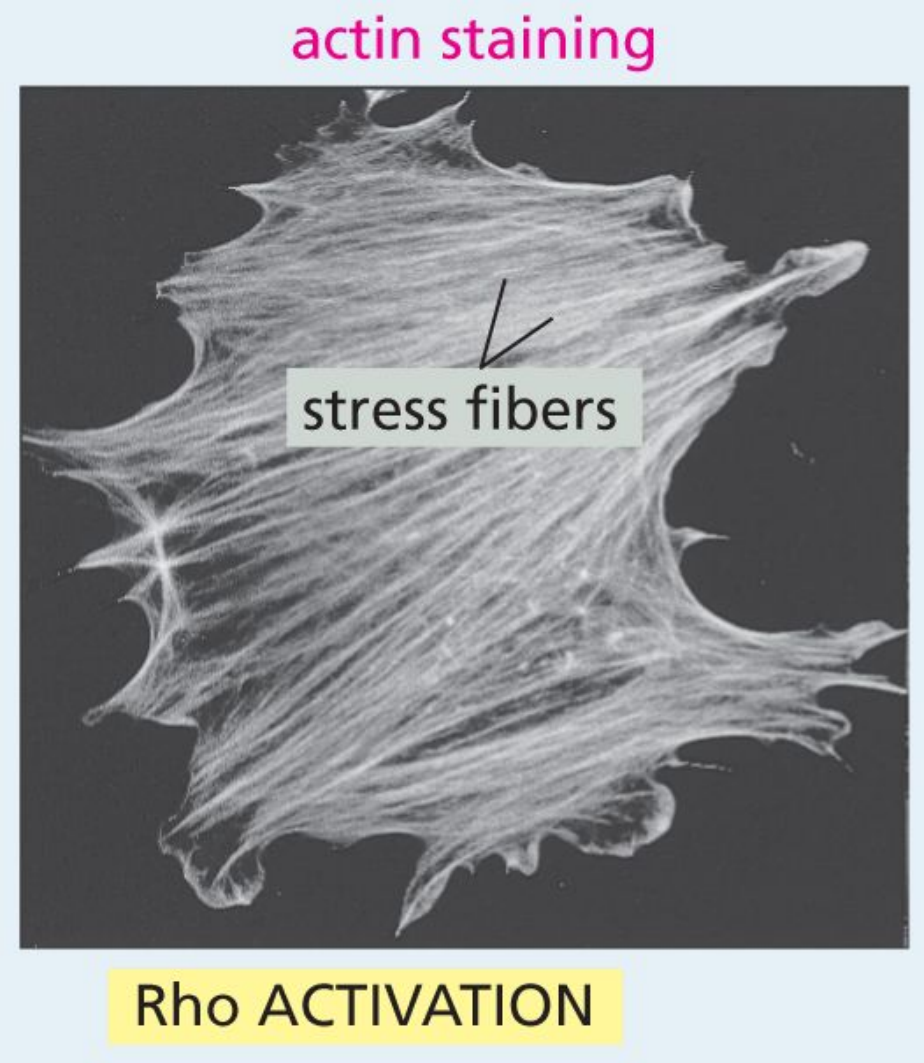
doing so by enabling extravasated cancer cells to form focal adhesions with the ECM of the surrounding tissue. Like lamellipodia, filopodia are assembled through the reorganization of actin fibers, in this case the fibers that are tightly bundled together beneath the plasma membrane of each filopodium (see Figure 14.35B). All these changes are organized by the actions of Ras-like small G proteins, as described in **Supplementary Sidebar 14.9**.

Supplementary Sidebar 14.9 Small G proteins govern cell motility

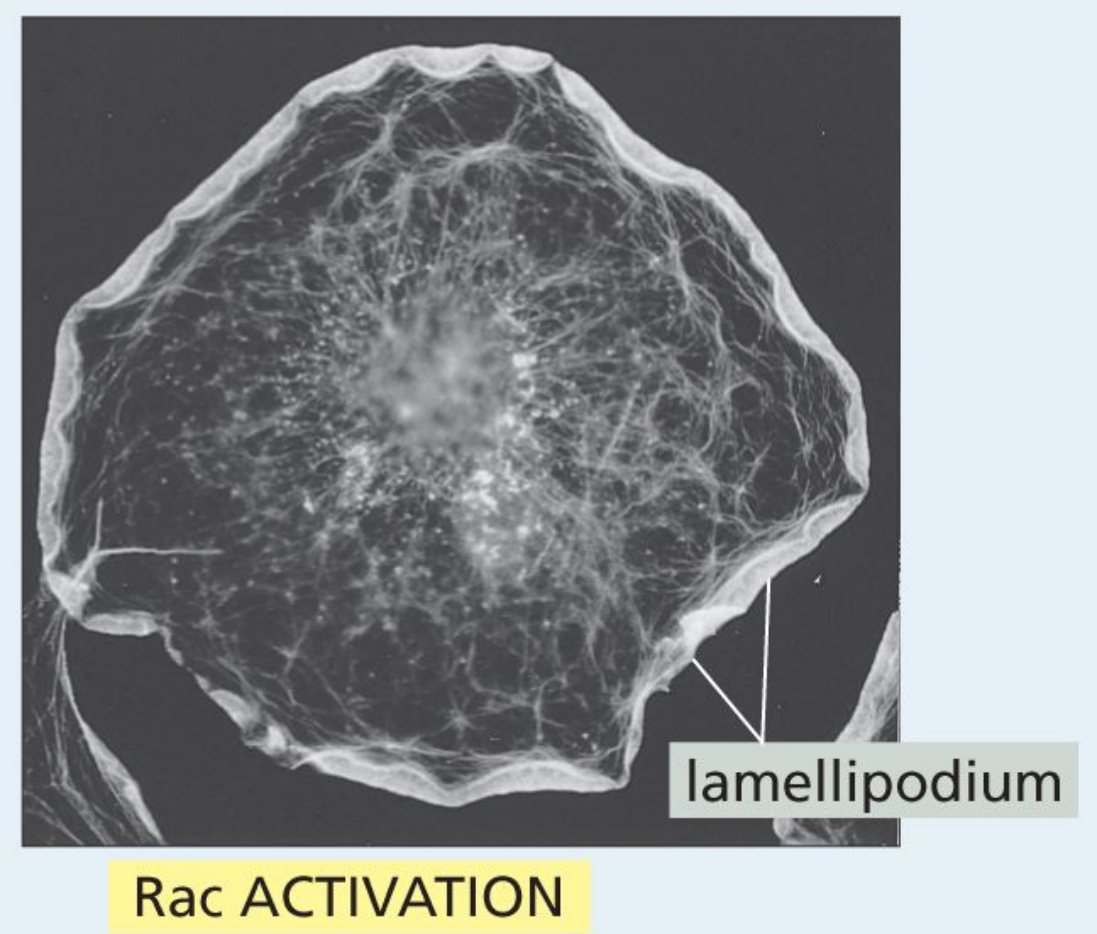
The management of the details of cell shape and motility is under the control of members of a group of Ras-related proteins belonging to the Rho family. As discussed briefly in Chapter 6, the Rho proteins, like Ras, operate as binary switches, being in a functionally active state while binding GTP and in an inactive state once they hydrolyze their bound GTP to GDP. More than 20 members of the Rho family of proteins have been discovered in human cells. They are divided into three subfamilies —the Rho proteins proper, the Rac proteins, and Cdc42. Like the Ras proteins, most members of the Rho protein family bear lipid groups at their C-termini that enable anchoring to intracellular membranes. Each of these has specialized functions in reorganizing cell shape and enabling cell motility (**Figure S14.7**).



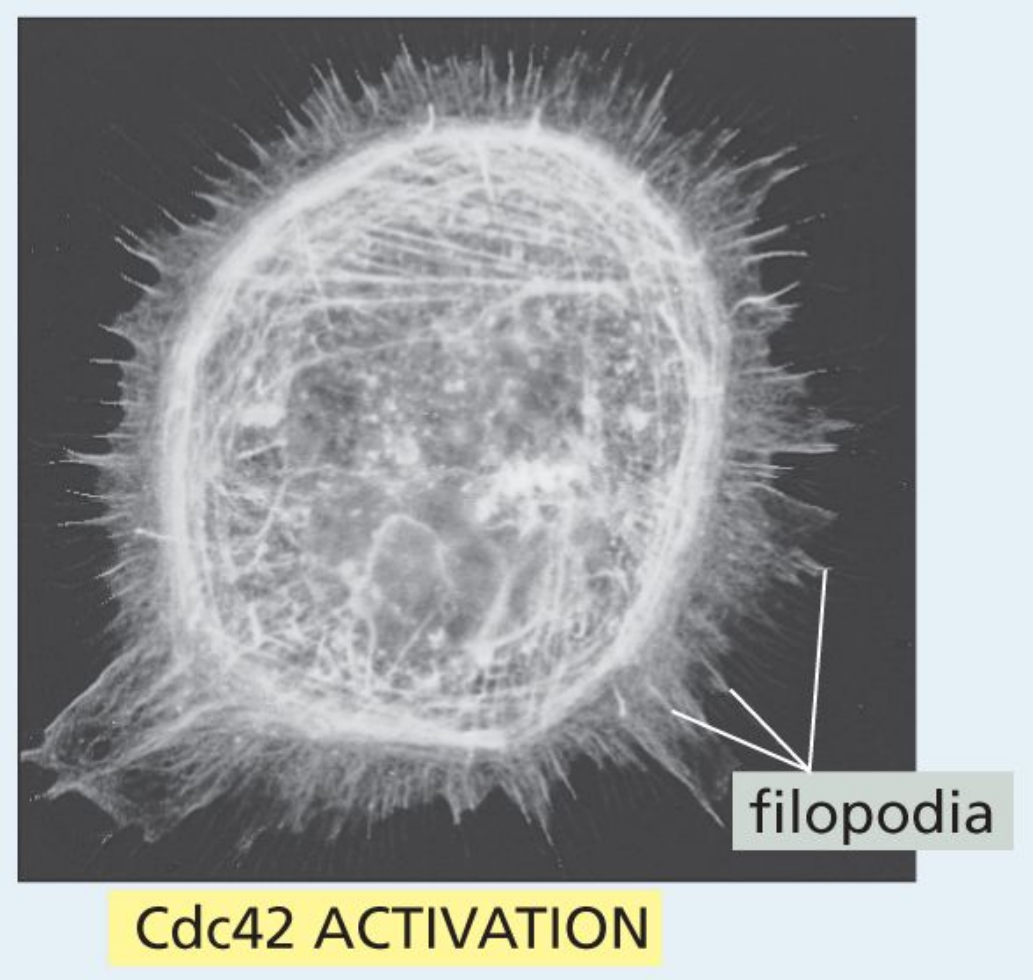
(A)



(B)



(C)



(D)

Figure S14.7 Effects of Rho-like proteins on the actin cytoskeleton and cell adhesion Members of the Rho family of small GTPases, which consists of Rho, Rac, and Cdc42 subfamilies, control both the actin cytoskeleton and the formation of focal adhesions (see Figure 5.22A). The actin fibers were labeled in all cases with fluorescent phalloidin. (A) Quiescent, serum-starved 3T3 fibroblasts serve as the controls for the panels that follow; note the cortical actin beneath the plasma membrane of this cell. (B) Exposure of cells to lysophosphatidic acid, which specifically activates Rho subfamily proteins, causes the cell to assemble large numbers of focal adhesions (*not shown*), which in turn enable the assembly of actin stress fibers. (C) Micro-injection of a constitutively activate form of a Rac protein into a cell causes it to construct a single enormous lamellipodium around its entire circumference. (In contrast, a focal source of a Rac-activating signal is likely to induce a lamellipodium only on the side facing this source.) (D) Micro-injection of a guanine nucleotide exchange factor (GEF) of Cdc42 into a cell causes it to extend hundreds of filopodia in all directions, which fails to reflect the

usual focal localization of these extensions on one or another side of a cell. (Courtesy of Kate Nobes; from A. Hall, *Science* 279:509–514, 1998.)

Figure S14.7 actually misrepresents the actions of these various Rho-like proteins in one important respect: it implies that each of them acts globally throughout the cell to organize certain changes in the configuration of the actin cytoskeleton. In reality, the complex program of cell motility depends on the *localized* activation of each of these proteins in very small domains of the cytoplasm, which in turn enables the cell as a whole to move in one direction or another. This focal activation seems to depend, in turn, on the subcellular localization of specialized Rho GEFs (guanine nucleotide exchange factors), which, like Sos (see Section 6.2), operate to convert Rho proteins from their inactive GDP-bound form to their active GTP-bound form; there are about 80 Rho GEFs in mammalian cells, few of which have been studied in any detail. The alternative to localized activation—global activation throughout a cell—would lead to attempts by a cell to move simultaneously in all directions, a scenario suggested by the lamellipodia of Figure S14.7C, which form a continuous ring around the entire perimeter of the cytoplasm. (The global activation of Rac function in the cell depicted in Figure S14.7C is an artifact of introducing mutant, constitutively activated Rac protein into the cell by micro-injection.)

Growth factor activation of tyrosine kinase receptors leads to the activation of many members of the Rho family of G proteins (**Figure S14.8**). For example, treatment of cultured fibroblasts with platelet-derived growth factor (PDGF), a potent mitogen for these cells, activates a number of Rho proteins and stimulates these fibroblasts to move across the bottom of a Petri dish. Alternatively, when fibroblasts are placed in three-dimensional culture by being suspended in a collagen gel, PDGF induces them to invade through this gel. All three subfamilies of Rho proteins appear to contribute to this invasion, whereas only Rac may be needed for the movement of fibroblasts across a solid substrate in culture. These various behaviors also illustrate an important distinction between the Ras proteins and their distant Rho family cousins: in cancer cells, Ras proteins are often activated by alterations in their structure (more specifically, amino acid substitutions), whereas the various Rho proteins are functionally activated by their upstream physiological regulators.

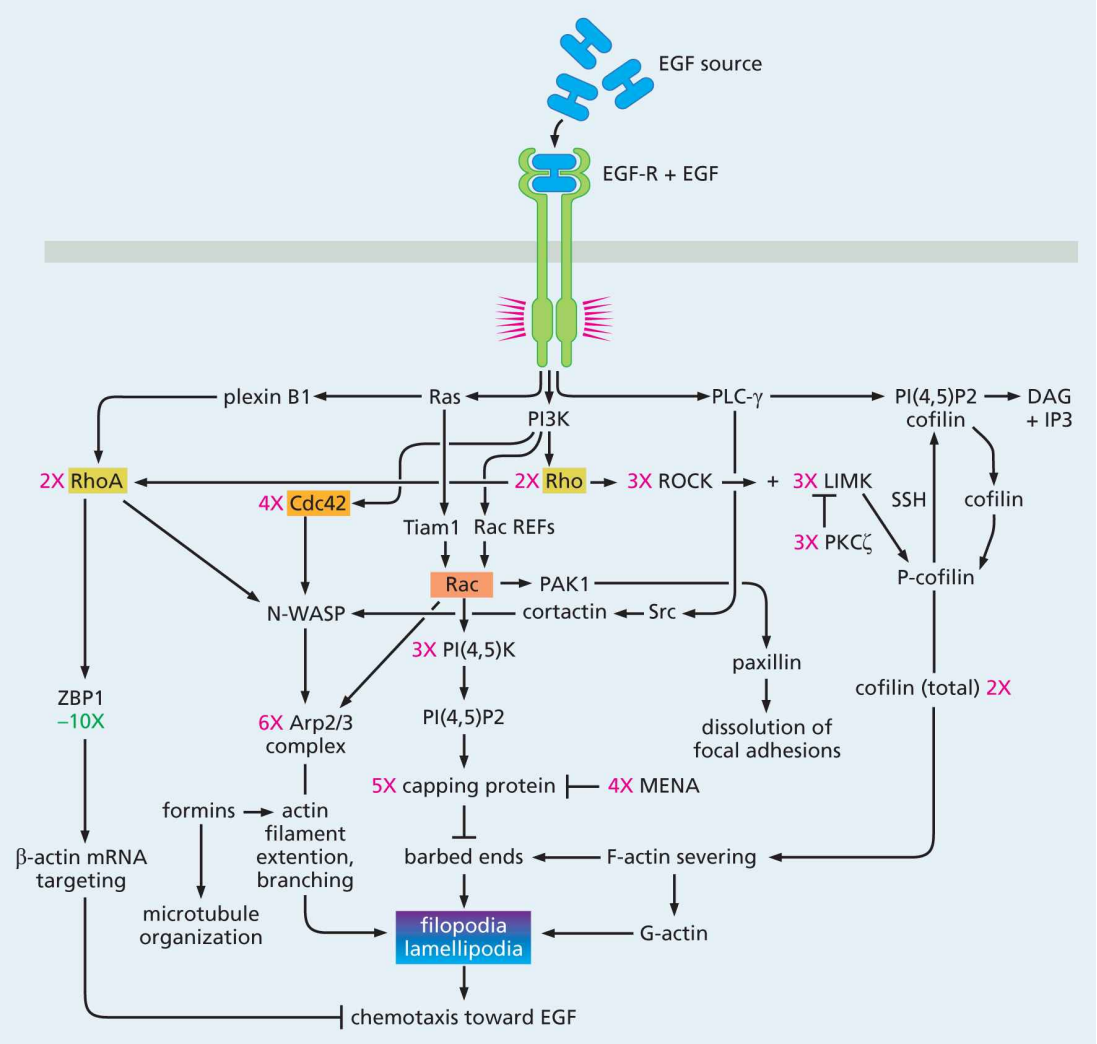


Figure S14.8 The circuitry mediating EGF-induced cell motility Many of the signal-transducing proteins that lie downstream of the EGF receptor and are responsible for mediating EGF-induced cell motility are indicated here. These act in large part through their ability to assemble and dissolve components of the actin cytoskeleton, which in turn create the filopodia and lamellipodia at the cell surface that enable motility and invasiveness; reconfigurations of the microtubule cytoskeleton also contribute to motility. The relative proportions of these proteins change as breast cancer cells acquire increased motility and invasiveness; the extent of overexpression of mRNAs encoding a number of these proteins in the cancer cells is indicated by the *pink* numbers, and the extent of reduced expression is indicated by the *green* number. Together these changes in expression have been termed the “invasion signature.” Some proteins, such as cofilin, sever existing actin fibers in certain localized regions of the cell, while capping protein prevents further extension of existing fibers (see Figures 14.34 and 14.35). Cortactin is associated with cortical actin and is responsible for organizing the invasive edges

of lamellipodia. Members of the Rho family of GTPases are indicated in *yellow* and *orange;* major cellular structures are indicated in *blue/purple*. This "wiring diagram" continues to undergo revisions as new component signaling proteins and interconnections between them are delineated. (Adapted from W. Wang et al., *Trends Cell Biol.* 15:138–145, 2005. With permission from Elsevier.)

All of the signaling connections between the tyrosine kinase receptors, such as the PDGF and EGF receptors, and these Rho family proteins are not known. We do know, however, that these receptors, by activating Ras, stimulate at least three downstream signaling pathways involving the Raf, PI3K (phosphatidylinositol-3 kinase), and Ral-GEF effectors (see Sections 6.5–6.7); a subset of these may, in turn, influence cell motility via regulation of the Rho proteins. In addition, activated Ras binds and appears to activate Tiam1, which functions as a guanine nucleotide exchange factor for Rac. (Recall that GEFs are responsible for causing small G proteins, such as Ras and Rho, to jettison bound GDP and take on GTP, thereby activating signaling by these G proteins.) Hence, Tiam1 and Rac should also be considered to be downstream effectors of Ras that affect cell motility, ostensibly by regulating the formation of lamellipodia.

Actually, from the perspective of cell motility, PI3K is clearly the most important of the well-characterized Ras effectors. By generating PIP3 [phosphatidylinositol (3,4,5)-triphosphate], the PI3K enzyme creates a chemical structure on the cytoplasmic face of the plasma membrane to which a variety of cytosolic proteins can attach via their PH domains (see Section 6.6). Among these tethered proteins are several GEFs that are responsible for activating members of the Rho family of G proteins. These Rho GEFs become activated following their tethering to the plasma membrane.

(The overarching role of PI3K and PIP3 in choreographing cell motility is illustrated by studies of the motility of the slime mold *Dictyostelium discoideum*. PI3K, and thus its product, PIP3, is localized at the leading edge of an advancing slime mold cell. Conversely, PTEN, the enzyme that dephosphorylates PIP3 and thereby antagonizes PI3K, is localized to the sides and to the rear, lagging edge of such a cell. This introduces another element into our thinking: although growth factor receptors, such as the PDGF-R, might in principle release signals encouraging PI3K activation throughout a cell, the actual signaling by this enzyme may also be influenced by its localization and the localizations of its activating GF receptor and antagonist within the cell.)

Tiam1 was originally identified as the product of a **T**-cell lymphoma **i**nvasion **a**nd **m**etastasis gene, indicating the importance of its encoded protein to these late steps of tumor progression. Tiam1 function appears to be stimulated both by its association with GTP-bound, active Ras (see Figure S14.8) and by its binding to PIP3. By activating Rac proteins, the Tiam1 GEF encourages the localized polymerization of

actin at the leading edge of migrating cells, thereby yielding the lamellipodia that are so critical to cell locomotion (see Figure S14.6).

The other Rho-like proteins that are activated by Rho GEFs are responsible for other parts of the cell motility program (see Figure S14.7B). For example, Rho proteins like RhoA and RhoB, acting in concert with Rac proteins, promote the establishment of new points of adhesion between the leading edge of the cell and the extracellular matrix. The reverse is also true: the forging of new focal adhesions also encourages Rac activation (see Figure S14.7C), suggesting the operation of some self-sustaining, positive-feedback loop that ensures the continuity of forward motion. Rac and Cdc42 proteins also appear able to induce expression of certain secreted proteases, notably the matrix metalloproteinases (MMPs) described in the last section. By doing so, they may coordinate localized remodeling of the extracellular matrix with extension of lamellipodia at the leading edge of a motile cell.

The contraction of the cell body (which helps to drag the lagging edge of the cell forward toward the leading edge; see Figure 14.33) is equally important for a cell's directed movement. This contraction is also governed largely by members of the Rho subfamily of proteins. By encouraging the formation of actin bundles in the cytoplasm, Rho proteins are able to create the structures known as "stress fibers" (see Figure S14.7B) and thereby contribute to the regulation of the contractility of the cytoplasm.

Cdc42, which represents the third subfamily of Rho-like proteins, has its own specialized function: it is able to induce the extension of the fingerlike filopodia (see Figures 14.35A and S14.7D). As mentioned in **Supplementary Sidebar 14.8**, filopodia contribute to cell motility by nucleating the formation of focal adhesions, which in turn allow advancing cells to establish a firm footing in the ECM. In addition, activated Cdc42 is able to stimulate generalized cell motility, independent of its specific effects on filopodia.

To complicate things even more, the actions of Rho, Rac, and Cdc42 differ in different cell types. For example, in normal epithelial cells (rather than the fibroblasts discussed above), the Rac and Rho subfamily proteins are responsible for maintaining the E-cadherin–dependent cell–cell adherens junctions; as we have read, these junctions are vital for preserving the epithelial cell sheet and therefore immobilize participating epithelial cells. However, in transformed epithelial cells, such as colon carcinoma cells that have undergone a partial or complete EMT, Rac clearly contributes to increased motility. In nonmotile cells, Tiam1 (the Rac exchange factor) is found in these adherens junctions, whereas in migrating cells, Tiam1 localizes to lamellipodia and related membrane ruffles.

The task of integrating these disparate observations into a single scheme has only begun. An early attempt to do so, seen in Figure S14.8, will surely be followed by

dozens of revisions. Virtually all the subcircuits depicted in this scheme of EGF-induced motility are likely to participate in organizing the motility stimulated by other motogenic growth factors, such as HGF and PDGF, as well.

The relevance of the Rho family proteins to cancer metastasis has been highlighted by searches for genes that are specifically expressed in metastatic cells but are expressed to a much lesser extent in nonmetastatic cells. In one set of experiments, strongly metastatic variants of mouse and human melanoma tumor cell lines were selected and the gene expression patterns of the cell lines were compared with those of weakly metastatic cells. Prominent among the genes whose expression was elevated in the metastatic variants was the gene encoding the RhoC protein (one of the Rho subfamily). Indeed, introduction of a RhoC-expression vector into poorly metastatic melanoma cells caused them to become highly metastatic, while ectopic expression of a dominant-interfering form of RhoC reduced the metastatic powers of usually metastatic cells. RhoC has also been found to be strongly expressed in cells of inflammatory breast cancers, a particularly aggressive form of this disease, and in pancreatic carcinomas, which are almost always highly aggressive.

Our rapidly expanding understanding of the molecular mechanisms underlying cell motility and invasiveness has converged on studies of the EMT program. In particular, these mechanisms provide insights into how some of the key changes occurring during an EMT are actually accomplished by various effectors regulating the cytoskeleton, protease synthesis, and thus cancer cell motility. Here, much interest has focused on the Mena protein, also called ENAH (see Figure 14.34).

Supplementary Sidebar 14.10 Specially designed instruments can be used to detect circulating tumor cells

Devices have been developed that allow the isolation of circulating tumor cells (CTCs) from the blood of cancer patients; these instruments are currently in a state of rapid further development. Some of these devices rely on the immobilization of monoclonal antibody molecules on the solid surfaces on the sides of channels through which blood is then forced. These microfluidic devices come in various configurations, two examples of which are provided here (**Figure S14.9A** and **B**). Application of such microfluidic devices to the analysis of the blood of normal controls and prostate cancer patients is seen in Figure S14.9C–E.

Figure S14.9 Microfluidic devices for capturing circulating tumor cells (CTCs) from the blood of cancer patients Two examples of a variety of microfluidic devices ("chips") are shown. By coating the surfaces of these devices with monoclonal antibody molecules that recognize cell-surface antigens displayed by cancer cells, CTCs from a variety of tumors can be trapped. Although early versions of such chips did not allow intact cells to be readily isolated, more recent versions do indeed permit the isolation of intact, even viable cells. An alternative means of isolating CTCs, not shown here, involves the coupling of monoclonal antibodies to iron particles, allowing the coupled antibodies to bind to the surfaces of CTCs, and isolating the resulting antibody–CTC complexes with a magnetic field. (A) This chip contained 78,000 cylindrical microposts coated with a monoclonal antibody reactive with EpCam, a cell surface antigen expressed by many carcinoma cells and normal epithelial cell types but not expressed by hematopoietic cells. In the chip visualized here by scanning electron microscopy, human lung cancer cells added to normal human blood were passed through the microfluidic chamber. A captured lung cancer cell, colorized *red*, is also seen at higher magnification in the inset at the *top right*. In

blood samples from patients with a variety of metastatic cancers (lung, prostate, pancreatic, breast, and colon carcinomas), 99% yielded CTCs immobilized on this chip. (B) Shown is a microfluidic chip of the herringbone configuration, which allows more efficient capture of CTCs. Moreover, because of the decreased turbulence within the channels, larger aggregates composed of multiple CTCs can be captured. This device, like the one described in panel A, depends on coating the surfaces with a monoclonal antibody directed against EpCam. (C) Here, a microfluidic chip of the type described in panel A was used to screen the blood of patients with metastatic prostate cancer and, as a control, of normal male and female volunteers for the presence of CTCs. In this case, an antibody against PSA (prostate-specific antigen) was used to trap PSA^+ prostate cells on the microposts within the chip; hematopoietic cells expressing the CD45 cell surface antigens were excluded from this analysis. The concentration of CTCs per ml is plotted on a logarithmic scale (*ordinate*). Normal men exhibited between ~0.5 and 10 CTCs per ml (*red circles*), whereas the prostate cancer patients, including those with both localized and metastatic disease, had from ~0.5 to ~3000 CTCs per ml of blood. (D) The changing levels of CTCs in response to anti-androgen therapy against metastatic prostate cancer were measured in a number of men, one of whose responses are plotted here. The man was first treated with leuprolide, which interferes with androgen biosynthesis by altering signaling in the pituitary gland and subsequently, toward the end of this course of treatment, with bicalutamide, an androgen receptor antagonist. This patient's levels of circulating PSA (*red curve*) dropped dramatically in response to initial treatment, in parallel with a decrease in the levels of PSA-positive CTCs (*green curve*), while his levels of cytokeratin-positive CTCs dropped more slowly. (E) The concentrations of CTCs from a group of 177 patients with metastatic breast cancer were monitored at intervals after initiation of a new course of therapy. The survival of two subgroups of patients with different concentrations of CTCs/7.5 ml of blood are shown. (A, from S. Nagrath et al., *Nature* 450:1235–1239, 2007. With permission from Nature. Supplementary Sidebar 14.11 Hidden micrometastases are revealed through organ transplantation

Organ transplantation first came into widespread use in the early 1960s. The procedure requires that the immune systems of organ recipients be suppressed in order to prevent immune rejection of implanted donor organs. Some of the organ donors at the time had

previously been treated, ostensibly successfully, for one or another type of cancer. Although gross examination of the donated organs indicated that they were healthy, cancer cells clearly contaminated these tissues, because the transplant recipients occasionally developed tumors of donor origin. These tumors thrived in the recipients and often became life-threatening, because the immunosuppressed state of the recipients prevented their immune systems from rejecting these foreign cancer cells—a theme that we will pursue further in Chapter 15.

Today, organ donors are screened far more thoroughly before their organs are transplanted into others. Even so, donors may harbor undetected micrometastases whose existence may be revealed only upon organ transplantation. In some cases, a misdiagnosis of an organ donor's cause of death results in unsuitable organs being made available for transplantation. For example, a diagnosis of death from a cerebral hemorrhage will obscure the real cause of death—a metastasis to the brain.

A worldwide registry of transplantation-associated malignancies, maintained in Cincinnati, Ohio, cataloged cases arising up to 1995 in which undetected cancer cells in the organs of 153 donors generated tumors in the recipients. (About 300,000 transplant procedures had been performed by that time.) In some cases, individual donors provided multiple organs, resulting in the development of identical cancers in several organ recipients. Some of the organ recipients exhibited widespread metastatic disease soon after transplantation; prominent among these were growths that could subsequently be identified as malignant melanoma and carcinomas of the kidney and lung. Because some types of tumors—notably primary brain tumors, squamous cell carcinomas of the skin, and localized (*in situ*) carcinomas of the cervix—almost never metastasize, organs from donors with histories of having borne these particular tumors are currently judged to be safe for transplantation.

Supplementary Sidebar 14.12 Peritoneovenous shunts provide dramatic support for the seed-and-soil hypothesis

The tendency of metastasizing cancer cells from certain types of primary tumors to establish themselves in specific target organs is amply borne out by repeated clinical observations of millions of cancer cases. Clinical observations of 14 cancer patients reported in 1984 revealed just how well adapted these cells must be in order to successfully colonize potential target organs. These cases involved patients with inoperable tumors (11 ovarian plus one each of stomach, pancreatic, and bronchial carcinomas) that were causing abdominal distension and associated discomfort because of the accumulation of large volumes of ascites. This fluid, which contains large numbers of cancer cells, accumulates in the peritoneal (abdominal) cavity, because (1) the lymphatic vessels draining this cavity become obstructed by cancer cells and (2) the cancer cells often release large amounts of VEGF (also known as

vascular permeability factor) into the ascitic fluid, causing microvessels in contact with this fluid to become highly permeable and leak plasma-like fluids into the abdominal cavity.

Surgeons have occasionally resorted to treating ascites by implanting a tube (termed a peritoneovenous shunt) that leads from the abdominal cavity into the subclavian vein near the heart; this tube permits the ascites and associated cancer cells to drain into the general circulation. When the circulation reaches the kidneys, the water from the ascitic fluid can be eliminated, while many important solutes are retained and recycled in the body (**Figure S14.10**). (The alternative—the direct removal of fluid from the abdominal cavity via a needle—can lead to severe depletion of ions and essential metabolites.) The ascitic fluid of ten of these patients was found to contain suspensions of between 10^5 and 10^6 viable cancer cells per milliliter. The 2 to 10 liters of ascitic fluid produced by the patients each week drained through these inserted tubes for their remaining lifetimes. The procedure yielded a great reduction in pain and discomfort and, in a number of cases, a clear extension of survival.

At the same time, this procedure also resulted in the continuous introduction, over months' to several years' time, of vast numbers of highly malignant cancer cells directly into the circulation. After passing through the heart, most of these cancer cells would be trapped in the capillary beds of the lung (see Figure 14.37D); some would pass through the lungs and become trapped in many other tissues throughout the body. However, in spite of billions of malignant cells being seeded in the lungs, these patients developed no macroscopic lung metastases; at most, only clinically insignificant, microscopic metastases were found upon autopsy. Hence, the highly malignant cancer cells clearly experienced a tissue microenvironment in the lung that was ill-suited to their continued survival and proliferation.

These observations provide dramatic testimony of the fact that the acquisition of a highly malignant growth phenotype does not, on its own, enable cancer cells to establish themselves in distant organ sites, and that additional cellular traits are required to allow them to colonize foreign tissue environments.

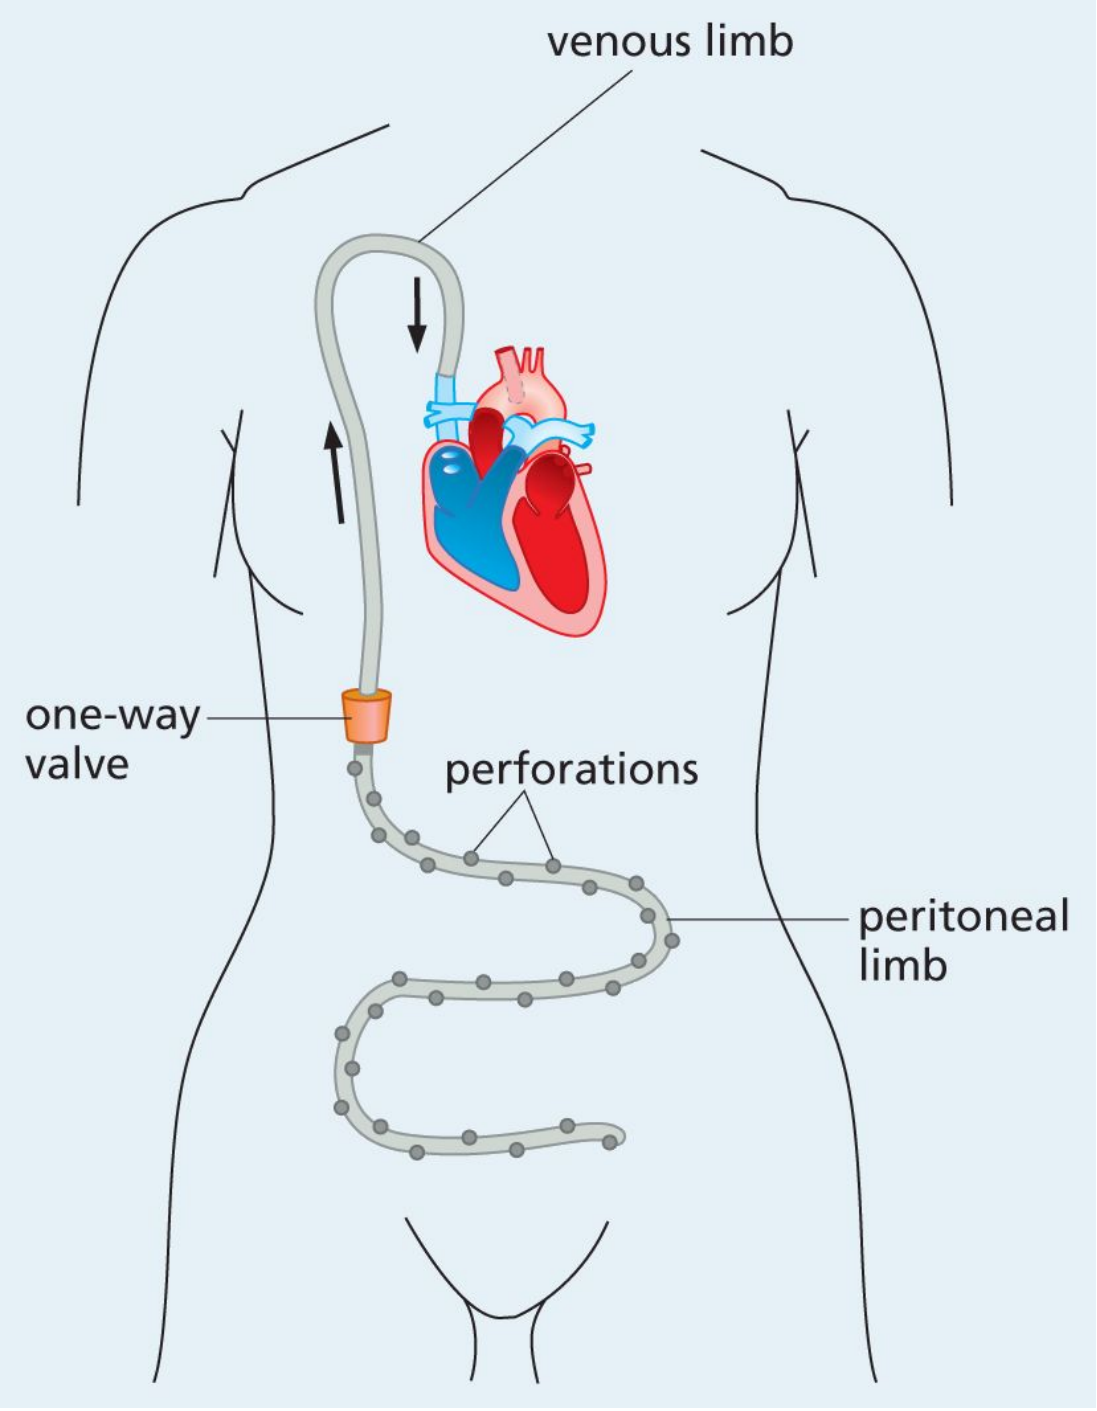

Figure S14.10 The peritoneovenous shunt and the seed-and-soil hypothesis
The peritoneovenous shunt (tube) is inserted into the intraperitoneal space in the abdomen (*below*), where it collects ascites fluid through perforations in the walls of the tube. The fluid is then drawn through a one-way valve and empties into the venous circulation near the heart (*above*). Although this shunt may transport billions of highly malignant cancer cells into the venous circulation and thus into

many parts of the body, few metastases are observed. (From V.T. de Vita, S. Hellman and S.A. Rosenberg, *Cancer: Principles and Practice of Oncology*, 6th ed. Philadelphia: Lippincott, 2001. With permission from Wolters Kluwer.)

Supplementary Sidebar 14.13 Tooth extractions may occasionally become exceedingly painful

A 1993 paper by a group of Israeli oral surgeons summarized 55 cases reported in the scientific literature, in which the extraction of a tooth was followed, within days, weeks, or several months, by the appearance of a metastatic growth at the site of the extraction. (The oral cavity is otherwise a rare site for the appearance of metastases.) In one-third of these cases, these metastases were the first indication of the existence of a cancer in a patient's body. Almost all of the responsible primary tumors were carcinomas arising in various internal organs. The time between the appearance of these oral lesions and the death of the patient was only four months on average, indicating that the disease was already highly advanced when the oral metastases were discovered.

These cases illustrate graphically that in some cancer patients, large numbers of metastatic cells are scattered throughout the body and that the cells' ability to found new tumor colonies at various sites depends strongly on the localized tissue environment. In a region of wound healing, such as a tooth extraction site, active inflammation and the remodeling of both bone and soft tissue occur. In such an environment, the tissue stroma provides many of the factors that create a hospitable site for wandering cancer cells to settle down and to proliferate rapidly. This echoes our discussion in Section 13.3, in which the activated, desmoplastic tumor stroma was described as a tissue having many of the attributes of a wound site.

Supplementary Sidebar 14.14 Tumor stem cells further complicate our understanding of the metastatic process

Earlier in this book (see Section 11.7), we encountered evidence that tumor cell populations arising in the breast and brain (and apparently in many other organs as well) are organized much like normal tissues, in which self-renewing stem cell populations are responsible for spawning the bulk of the cells. In the case of certain well-studied breast carcinomas, the bulk populations (>>95%) of tumor cells behave much like the actively dividing, more differentiated cells found in normal tissues. According to this conceptual model, the cancer stem cells (CSCs), also known as tumor-initiating cells (TICs), are tumorigenic, in that they can seed a new tumor mass

when implanted into a host, whereas the non-stem cells in the tumor mass are unable to do so because they lack self-renewal potential.

These observations, if extended and validated for a wide variety of tumor types, have important implications for the process of metastasis: if the non-stem cells in a primary tumor mass are truly non-tumorigenic then these cells may well succeed in leaving the primary tumor and lodging in distant tissue sites, but they will be unable to colonize these sites because of their limited self-renewal and thus limited long-term proliferative potential. Accordingly, the ability to create macroscopic metastases may be confined either to the relatively small number of CSCs that escape from the primary tumor or to cells that somehow enter into the CSC state after they have left the primary tumor. These cells are thought to have the ability to replicate to an unlimited extent and therefore are ideally suited to found new metastatic colonies that eventually expand to life-threatening sizes. Indeed, as described in Section 14.6, the same EMT program that allows primary carcinoma cells to physically disseminate from a primary tumor also endows many of them with the self-renewal potential of CSCs, which means that it is also likely to influence the fate of disseminated carcinoma cells. For example, those carcinoma cells that maintain their quasi-mesenchymal (and associated CSC) phenotype after dissemination are likely to be more qualified to colonize a site of dissemination, whereas those that rapidly shut down their EMT program, exit from the CSC state, and revert to a more epithelial state may lose colonization ability. These dynamics may well contribute to "metastatic inefficiency"—the failure of the vast majority of disseminated cancer cells to colonize the tissue sites in which they have landed (see Section 14.10).

Supplementary Sidebar 14.15 Does Darwinian evolution accommodate metastasis-specific alleles?

The conceptual model that was developed in Chapter 11 portrays multi-step tumorigenesis as a process formally akin to Darwinian evolution: a cell within a pre-neoplastic cell population acquires a particular mutant allele that confers additional proliferative advantage and, sooner or later, the descendants of this cell will predominate among the neoplastic cells in the primary tumor mass (see Figure 11.14).

As a logical extension of this thinking, the final steps of tumor progression would involve the acquisition of mutant alleles that enable the cells within benign tumors to evolve further toward the invasive and metastatic state. Inherent in this model, however, is a conceptual quandary: imagine that mutant alleles exist that confer metastatic ability but not replicative or survival advantage. The descendants of the rare tumor cell (for example, one in 10^6) that happens to acquire such a purely metastatic allele will, much later, continue to be equally rare among the population of cells in the

primary tumor mass (because this allele, by definition, does not confer proliferative or survival advantage in the primary tumor). Hence, given the scarcity of these cells, coupled with the inefficiency of the metastatic process, metastases originating from this small clonal population will rarely if ever form. This logic indicates that mutant alleles specialized to confer metastatic potential are unlikely to play a significant role in the last stages of primary tumor progression.

The simplest alternative to this model posits that certain mutant alleles arise during tumor progression that are advantageous for evolving, premalignant cancer cells and also *incidentally* confer increased metastatic ability. Cells carrying such multifunctional alleles may soon dominate the primary tumor mass, simply because of the proliferative advantage conferred by these alleles. This now-large mass of cells may then successfully seed metastases, because its constituent cells all happen to exhibit the additional, unselected trait of metastatic ability. (Implicit in this model is the notion that certain genes and proteins favoring aggressive proliferation within the primary tumor may also impart invasive and even metastatic phenotypes.)

A variant of this model involves a delayed phenotypic response to an initially sustained mutation. Imagine that at a certain step early in tumor progression, there are several alternative mutant alleles that can equally satisfy the proliferative needs of an evolving premalignant cell population. For example, relatively early in colon tumor progression, the K-*ras* oncogene is activated in almost half of all colon cancers; in many of the remaining ones, mutant B-*raf* genes (~15% of all tumors) or mutant PI3 kinase genes (~30% of all tumors) are often found (see Figure 11.11). Although these three alternative classes of alleles may function similarly early in multi-step tumor progression by promoting cell proliferation and survival, much later, in the context of subsequent mutational steps in tumor progression (for example, the mutation of a *p53* gene), the three genetic subtypes of colon tumors may elicit very different behaviors. Thus, speculatively, in the presence of a subsequently acquired mutant *p53* allele, the K-*ras* oncogene might portend the development of relatively benign tumors, whereas the mutant B-*raf* alleles may provoke an invasive outcome. If so, this would indicate that some tumors “start off on the wrong foot” because of the nature of the mutant genes that they happen to acquire early in multi-step tumor progression; years later, when tumor progression generates tumorigenic cells, these initially acquired alleles may strongly influence the invasive and metastatic behaviors of these cancer cells. In all these cases, other types of cell-heritable alterations, notably promoter methylation, may play roles similar to the genetic mutations discussed here.

The apparently important role played by the EMT program in invasion and metastasis by carcinoma must also be integrated into this thinking. Thus, if certain mutant alleles (and inherited epigenetic alterations) confer an acquired ability to metastasize, these alleles may not directly drive invasion and metastasis. Instead, they may act less

directly by conferring on primary tumor cells a heightened *responsiveness* to EMT-inducing signals, such as those originating in the tumor-associated stroma.

Glossary

embolization
: Process of forming an embolus. *See* **embolus**.

Tissue Factor
: A cell-surface glycoprotein expressed by many cell types in the body that interacts with clotting factors in the plasma, thereby triggering the coagulation cascade.

thrombin
: A plasma protease that is activated following wounding and triggers blood coagulation by activating platelets and cleaving fibrinogen to fibrin.

fibrinogen
: *See* **fibrin**.

fibrin
: Protein that is formed by the cleavage of plasma fibrinogen and assembles to form the fibers binding the platelets together in clots.

peritoneovenous shunt
: A tube that is inserted into the peritoneal space that allows the collection of cancer cells forming the ascites fluid in patients suffering high-grade cancers; the cancer cells, which enter through holes in the tube, are eventually emptied directly by the tube into the venous circulation, often via the vena cava.

microthrombus
: A blood clot or other solid body, such as a clump of cells, that can travel from one site in the body via the circulation to a second site in which it may become lodged within a blood vessel.

microembolus
: (pl., **microemboli**) Small body formed from cells or products of the clotting machinery that travels through the circulation and may be trapped in small vessels, often blocking further circulation through these vessels. *See also* **embolus**.

thromboembolus
: A blood clot or other solid body, such as a clump of cells, that can travel from one site in the body via the circulation to a second site in which it may become lodged within a blood vessel.

lamellipodium

(pl., **-ia**) A broad, sheetlike ruffle extending from the plasma membrane into the extracellular space that is typically found at the leading edge of a motile cell.

filopodium

Filamentous, spikelike protrusion from the surface of a cell, usually extending from the leading edge of a lamellipodium, that may be used by the cell to explore territory that lies ahead in its path and to forge focal adhesions with the extracellular matrix lying in this path. *See also* **lamellipodium**.

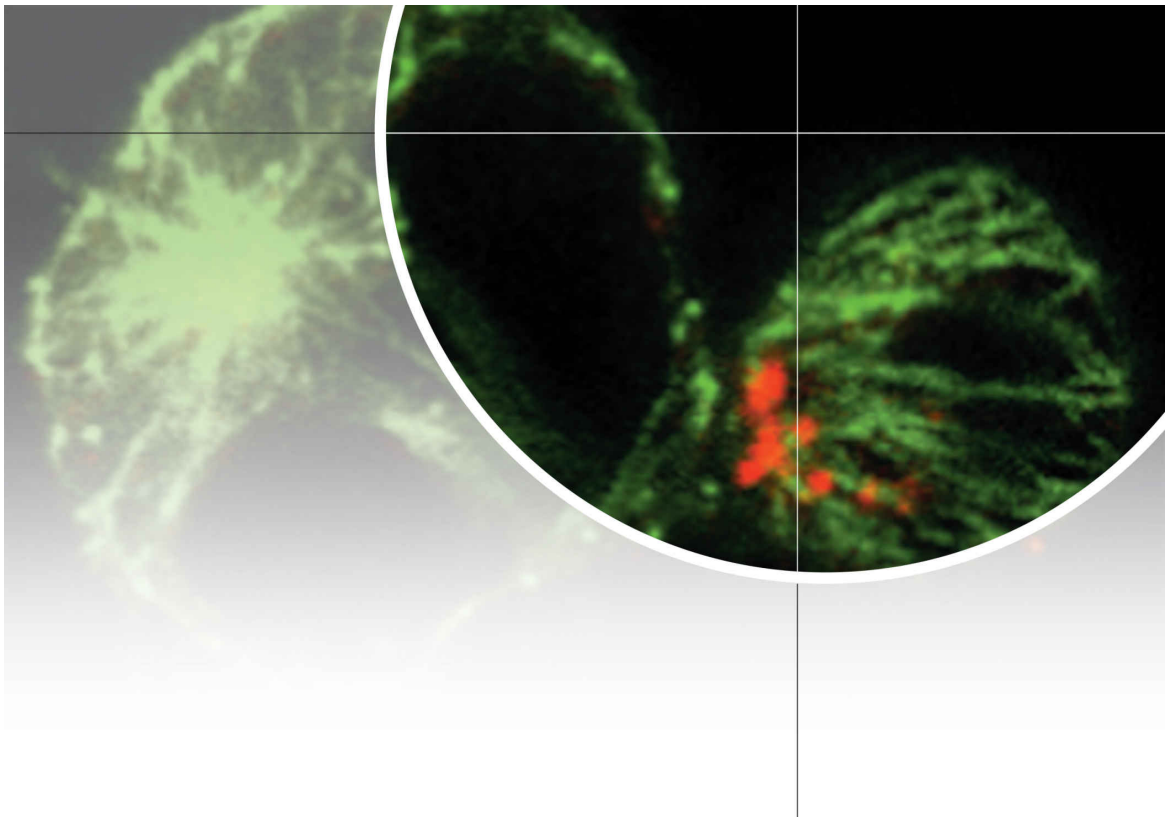
Chapter 15
Crowd Control: Tumor Immunology



A fluorescence microscopy image of a cytotoxic T lymphocyte attacking a larger target cell. The microtubular networks of both cells appear in green. The lymphocyte has bright red dots concentrated near the point of contact with the target cell.

It is by no means inconceivable that small accumulations of tumour cells may develop and, because of their possession of new antigenic potentialities, provoke an effective immunological reaction with regression of the tumour and no clinical hint of its existence.

Macfarlane Burnet, immunologist, 1957

Throughout this text, we have studied various defenses that the body erects against the appearance of cancerous growths. Many of these defenses are inherent in mammalian cells, more specifically in the hard-wired regulatory circuitry operating within individual human cells, and can influence the decision of a cancer cell to commit to division or even undergo programmed cell death. The most obvious of these are the controls imposed on cells by apoptosis or by the mechanisms of other death programs poised to trigger the death of cells that are misbehaving or, alternatively, suffering certain types of damage or physiological stress. Similarly, the pRb and p53 signaling circuits (see Chapters 8 and 9) are configured to impede the outgrowth of incipient cancer cells.

Even the organization of some tissues places constraints on how and where incipient cancer cells can proliferate. For example, normal epithelial cells that lose their tethering to the basement membrane activate the form of apoptosis called anoikis. This mechanism limits the ability of epithelial cells to stray from their normal locations within tissues and grow in ectopic (that is, abnormal) sites. Beyond these cell- and tissue-specific mechanisms, there is another line of defense: the immune system.

The powers of the immune system to detect and eliminate infectious agents have been known for well over a hundred years. In the 1950s, Macfarlane Burnet and Lewis Thomas independently speculated that the immune system can recognize tumor cells as altered forms of the normal cells in our tissues that, in the context of immunology, we hereafter will term self; having done so, the immune system would proceed to recognize and eliminate the tumor cells as foreign, unnatural entities that we will term non-self. This hypothesized process was codified as immunosurveillance, which implies that the immune system continuously monitors tissues for the presence of aberrant cells, including cancer cells, recognizes them, and quickly eliminates them. Subsequent work has confirmed the validity of this fertile but, until recently, speculative hypothesis. Indeed, it is now clear that the immune system can distinguish tumor cells from normal ones and can mount responses to eliminate them. This insight reveals why so many anti-cancer immune therapies have emerged in recent years from efforts to harness the immune system to treat and manage a variety of cancers.

Still, the immune system frequently fails to enforce effective and sustained crowd control over cancer cells, as evidenced by the approximately 19.3 million new cases of cancer worldwide in 2021 and the fact that cancer results in 1 in 5 deaths

annually in the United States. Looking beyond these failures, in the next chapter we will see how the body's multi-layered immune system's diverse network of interacting defenses has been marshalled and manipulated to treat cancer, offering multiple opportunities for novel anti-cancer therapies.

Since the immune system has evolved to recognize and eliminate foreign agents from the body while leaving the body's own tissues unmolested, its purported ability to recognize and attack cancer cells long seemed implausible. As we have read repeatedly throughout this book, cancer cells are native to the body and are therefore, in so many respects, indistinguishable from the body's normal cells. In fact, considerable progress has been made toward determining precisely how the immune system distinguishes cancer cells as different from their normal counterparts and, as a consequence, recognizes these cells as appropriate targets of immune-mediated killing. This understanding has provided approaches for harnessing the immune system to effectively target cancer cells and given rise to the burgeoning field of cancer immunotherapy.

OceanofPDF.com

Glossary

self
: A constituent of the body that is native to the body's normal tissues and associated cells. *See also* **non-self**.

non-self
: Constituent or agent in the body that is of foreign, non-native origin. *See also* **self**.

immunosurveillance
: Process by which the immune system continuously monitors tissues for the presence of aberrant antigens or cells, including cancer cells, and in response, mounts responses to eliminate the antigens or cells expressing such antigens.

15.1 The immune system continuously conducts surveillance of tissues

Early insights in the area of tumor immunology research came from attempts to implant cells from a variety of sources into mouse hosts. Normal human cells were rapidly eliminated, and even normal cells from one strain of inbred mice were equally unable to gain a footing when implanted in the tissues of mice belonging to another inbred strain. Thus, these cells were rejected by the host tissues in which they were implanted, ostensibly by the immune systems of the hosts.

These now-ancient findings established a principle that is central to all that follows in this chapter: the immune system can recognize certain molecules displayed on the surface of certain implanted cells that somehow provide a clear and unambiguous signal that can provoke an attack on these cells, often leading to their elimination. As we will see, identification of the precise nature of these cell surface molecules and their recognition by the immune system required decades of research.

The observed rejections of implanted cells in mouse hosts were accompanied by the realization that the immune system usually tolerates the body's own cells, as well as implanted cells prepared from genetically identical mice, that is, cells from the same inbred strain of mice. Such tolerance implied an ability to recognize the "familiar," distinguishing it from the "unfamiliar and foreign." (Cells originating in mice of one inbred strain and implanted in mouse hosts of the same strain are said to be syngeneic with respect to these hosts.)

Thus, the major problem of anti-cancer immunosurveillance became clear: cancer cells originate from normal cells in the body's own familiar tissues. Given the immune system's ability to tolerate normal tissues (that is, the state of immunological tolerance), its ability to recognize the foreignness of

cancer cells became difficult to explain because it was widely assumed that cancer cells were essentially identical to normal cells in the body.

In fact, a small number of early studies in mice provided evidence that the immune system can indeed play a role in the immunosurveillance of tissues directed specifically toward the detection of aberrant cells including, notably, cancer cells. An important line of investigation relied on observations showing that certain chemically induced tumors (see Sections 2.9 and 11.11) in mice were immunogenic, that is, capable of provoking an immune response, and therefore could be recognized as foreign, making them vulnerable to elimination by the immune systems of the host mice bearing these tumors.

In one set of experiments outlined in **Figure 15.1**, cells from a 3-methylcholanthrene (3-MC)–induced tumor that arose in one strain of mice (see Section 11.11) were irradiated prior to implantation in mouse hosts of the same inbred strain. The irradiation served to prevent the proliferation of these cells and the resulting rapid outgrowth of life-threatening tumors in the hosts while, at the same time, permitting these cells to continue expressing certain immunogenic proteins. Because these cancer cells were prepared from tumors that had been induced in the same strain of mice as the recipient hosts, the implanted cancer cells did not elicit an immediate aggressive response.

An experiment on mice. The first step is to immunize the mice with irradiated tumor cells. Some of the mice are then injected with viable cells of the same tumor; in these mice, the host response rejects the tumor cells and prevents tumor formation. The other mice are injected with viable cells from a second, independently induced tumor; in these mice, the host response permits proliferation of cells and tumor growth.

Figure 15.1 Immunization of mice by exposure to killed cancer cells Mice from one strain were initially injected with irradiated, killed cancer cells (*red*) derived from a tumor that had been chemically induced in a mouse of the same strain (i.e., a syngeneic host). When these mice were subsequently injected with live cells prepared from the same tumor, the cells failed to grow (*lower left*). However, when these mice were injected with live cells from a second, independently induced tumor (*blue*), the cells proliferated and formed a tumor mass (*lower right*). The reciprocal experiment (*not shown*) yields the converse results, i.e., implantation of killed blue cancer cells subsequently rendered mice immune to the blue tumor but not to the red tumor. Because these experiments were all performed using tumor cells and mice from the same genetically defined strain, the rejection of these tumors could not be attributed to histoincompatibility, that is, to the rejection of allogeneic cells. Instead, these experiments demonstrated that the chemically induced tumor cells had developed distinctive antigens, apparently acquired during the chemical carcinogenesis (and associated intense mutagenesis) that led to their transformation. These results suggested, in turn, that cancer cells can express mutant proteins that may be recognized as foreign by the immune systems of tumor-bearing hosts.

Subsequently, mice previously implanted with the syngeneic, irradiated tumor cells received a second injection of live tumor cells originating from the same chemically induced tumor or, alternatively, from a different, independently induced 3-MC tumor. As before, all implanted cells were of syngeneic origin. As it turned out, the second set of implanted cancer cells originating from the original chemically induced tumor did not grow out and were ostensibly being attacked by the immune systems of these mouse hosts, that is, they were rejected. In contrast, the cells derived from another,

independently induced tumor could indeed grow and form new tumors in the recipients.

These experiments left two lessons. First, under certain conditions, implanted cancer cells could indeed evoke long-term immunity; this response appeared to be similar to the one achieved by vaccinating a host against one or another type of infectious agent, notably some type of virus. Second, somehow, tumor cells originating from one chemically induced tumor could be readily distinguished by the immune system from cells prepared from another independently induced tumor. Thus, the initial exposure to dead cancer cells from one tumor had immunized the mice against live cells originating from the same tumor, while failing to elicit some type of immunity against the second, independently arising tumor.

These observations led, in turn, to the notion that the neoplastic cells in different independently arising tumors exhibit distinct sets of antigens, that is, molecules with the potential to provoke an immune response. Exposure to a particular set of such antigens displayed by one type of cancer cell could apparently stimulate the immune system to remember a prior encounter with cells displaying that particular set of antigens, recognize these cells, and kill them. Conversely, such immune-mediated protection did not arise when the prior encounter involved cells from a different, independently formed tumor. As described below, these “antigens” are almost invariably different proteins.

OceanofPDF.com

Glossary

tolerance
: Physiological state that reflects the ability of the immune system to ignore or overlook the body's normal complement of antigens and the cells expressing such antigens.

syngeneic
: (1) Referring to two organisms that share the identical genetic background, such as two members of an inbred strain of mice. (2) Describing the relationship between two sets of cells or tissues, or between a set of cells and an organism, deriving from identical genetic backgrounds.

antigen
: (adj., **-genic**) Molecule or portion of a molecule, often an oligopeptide, that can be specifically recognized and bound by an antibody or a T-cell receptor or that provokes the production of an antibody. *See also* **immunogenic**.

rejection
: Process whereby the immune system of a host organism prevents the outgrowth of implanted donor cells or tissues, usually by the killing donor cells. *See also* **allograft rejection**.

immunogen
: (adj., **-genic**) A chemical structure that is capable of provoking some type of immune response, e.g., an antigen that can provoke the synthesis of antibody molecules capable of recognizing and binding it.

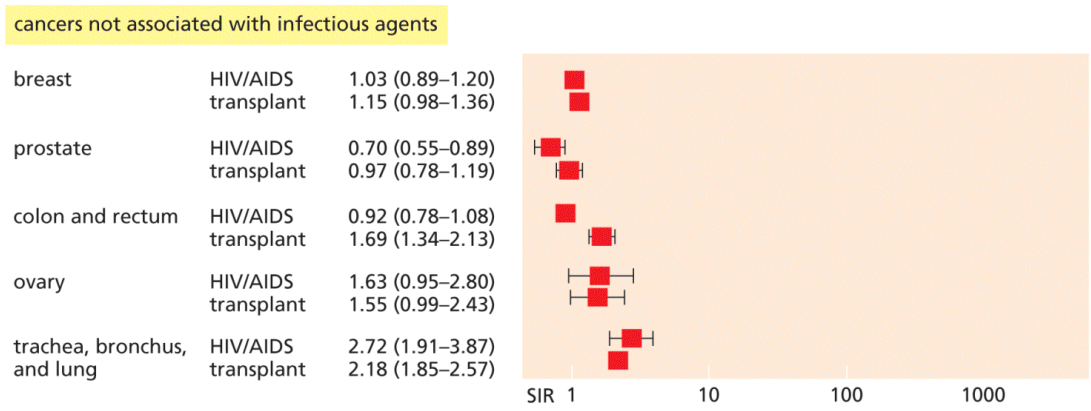
OceanofPDF.com

15.2 The human immune system plays a critical role in warding off various types of human cancer

Because the biology of mice and humans differs in so many respects, we need to interpret the results described above with caution when attempting to understand the role of the human immune system in defending us against cancer. In addition, it is possible that the chemical carcinogens used to induce mouse cancers may well create tumors that are far more capable of provoking a strong immune response than are provoked by spontaneously arising human tumors. In fact, there is compelling evidence that the human immune system can indeed recognize cancer cells arising in the body of an individual who has not been exposed to potent carcinogens and that the actions of our immune systems do indeed play an important role in warding off the outgrowth of some tumors. As we will see, this evidence is drawn from a diverse set of observations, including the elevated cancer risk borne by immunocompromised individuals, the presence of tumor-infiltrating lymphocytes across many different types of cancers, and the clinical successes achieved by targeting tumors with anti-cancer immune-based therapies that will be described in the next chapter.

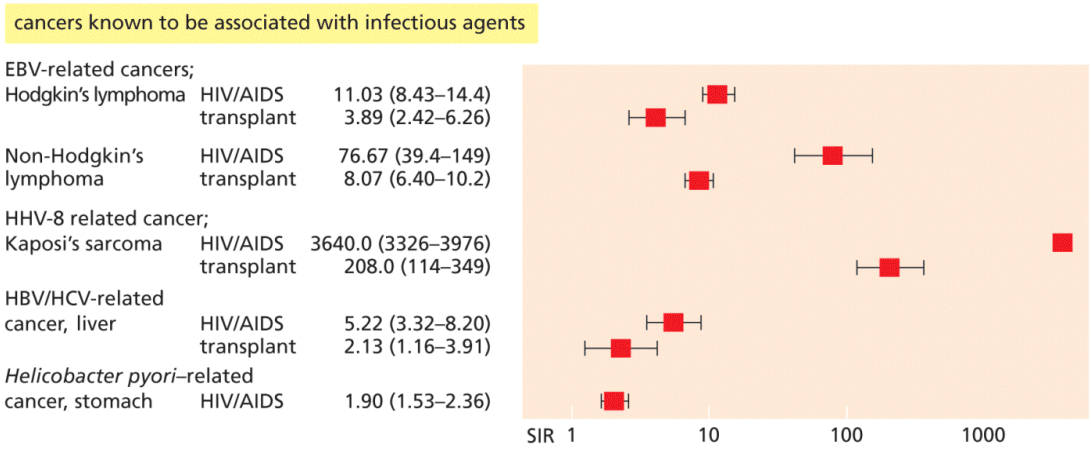
To begin, the study of cancer incidence in immunocompromised individuals reveals that dysfunctional or suppressed immune systems are indeed associated with an elevated risk for many types of cancer. Generally, the immunocompromised state responsible for this elevation arises from one of three sources. First, some individuals are born with certain germ-line mutations that render their immune systems dysfunctional. With improvements in hospital care, these immunocompromised individuals now live longer but still experience a reduced life expectancy. Second, in 2019, nearly 38 million people worldwide were infected by human immunodeficiency virus (HIV), which can lead to acquired immunodeficiency syndrome (AIDS). Those afflicted with AIDS have increased susceptibility to opportunistic infections by various tumor viruses, resulting in higher rates of cancer incidence. Third, organ transplantation, involving kidneys, hearts, and livers, has become common throughout the developed world. Because the transplanted organs are typically derived from donors who are genetically distinct from the transplant recipients (that is, allogeneic), the transplanted organs are recognized as foreign and thus subject to rejection by the immune systems of engrafted patients; such donor grafts are termed histoincompatible (literally, containing tissues that are incompatible with the tissues of graft recipients). To avoid rejection of the transplant by the recipients' immune systems, these patients are routinely rendered immunocompromised by treatment with several types of potent

immunosuppressive drugs and, as an unintended consequence, they experience markedly elevated rates of cancer incidence. This finding suggests that the mechanisms that allow the immune system to recognize implanted allogeneic cells (that is, cells derived from the tissues of genetically non-identical members of the same species) overlap with the mechanisms employed in the body to recognize incipient cancer cells (**Figure 15.2**).



Cancers not associated with infectious agents: breast; prostate; colon and rectum; ovary; trachea, bronchus, and lung. S I R values range from 0.7 for prostate cancer in H I V AIDS patients up to 2.72 for trachea, bronchus, and lung cancer in H I V AIDS patients.

(A)



Cancers known to be associated with infectious agents: E B V-related cancers and Hodgkin's lymphoma; non-Hodgkin's lymphoma; H H V-8 related cancer and Kaposi's sarcoma; H B V slash H C V-related cancer and liver cancer; and Helicobacter pylori–related cancer and stomach cancer. S I R values range from 1.90 for Helicobacter pylori–related cancer and stomach cancer in H I V

AIDS patients up to 3640 for Helicobacter pylori–related cancer and stomach cancer in H I V AIDS patients.
(B)

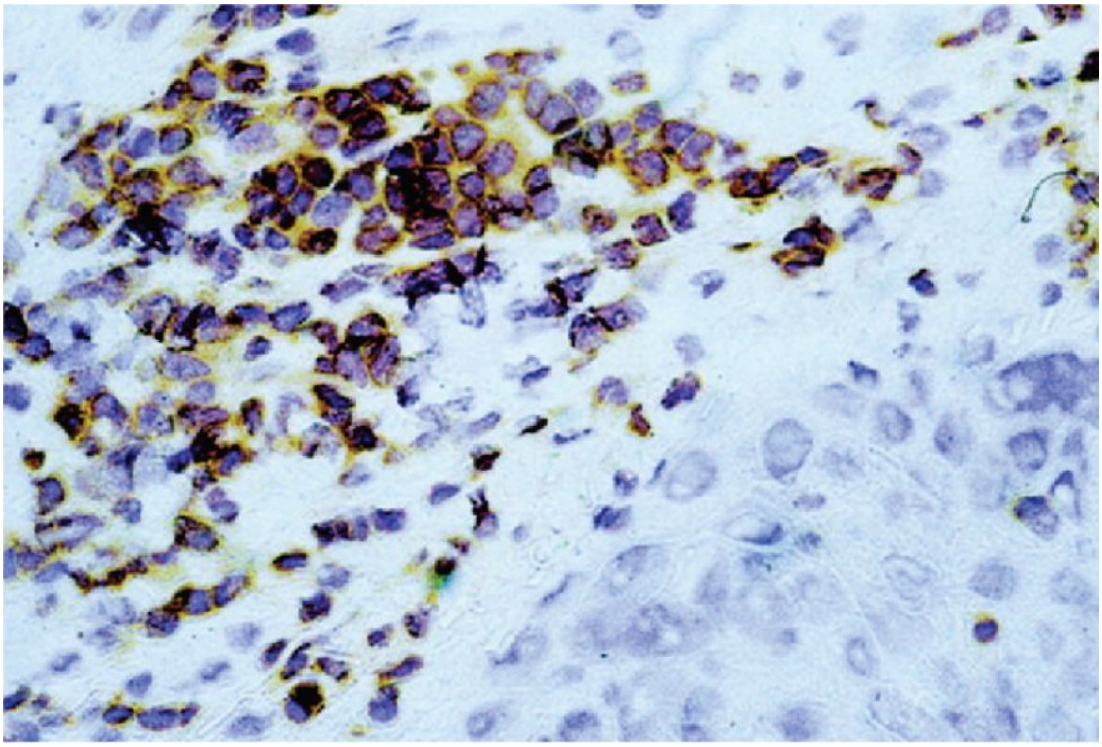
Figure 15.2 Effects of compromised immune systems on cancer incidence This meta-analysis pooled the conclusions of a group of epidemiologic studies in order to calculate the standardized incidence ratio (SIR)—the number of cancer cases actually observed in populations of HIV/AIDS patients and immunosuppressed individuals divided by the number expected in the age-matched general population. Note that the SIR values are plotted logarithmically on the abscissa. All patients in the transplant category were presumed to be subject to significant immunosuppression in order to prevent rejection of the transplanted organ. The numbers associated with each entry indicate the calculated mean SIR, followed by the confidence interval (which shows, with 95% probability, the interval within which the measured mean value will fall). Similarly, in these "box-and-whisker" plots (*right*), the filled boxes are centered on the median measurements, and the outer points of the whiskers indicate the bounds of the 95% confidence interval. (A) Among a group of five commonly occurring epithelial cancers, the incidence of breast, prostate, and colorectal carcinomas was not elevated in HIV-infected/AIDS patients relative to the general population, whereas carcinomas of the ovary and lungs were modestly elevated and at a statistically significant level. (B) Strikingly different values are seen, however, among a range of tumors that are known to be associated with either chronic viral or bacterial infections, where the lack of a fully functional immune system often leads to dramatic increases in tumor incidence. Included here are EBV-related cancers, non-Hodgkin lymphomas, HHV-8-induced Kaposi's sarcomas, HBV/HCV-related liver cancers, and *Helicobacter pylori*-associated stomach cancers. (EBV, Epstein–Barr virus; HHV-8, human herpesvirus-8; HBV and HCV, hepatitis viruses B and C.) (From A.E. Grulich et al., *Lancet* 370:59–67, 2007. With permission from Elsevier.)

At this stage in our discussion, the processes of anti-cancer immune surveillance must be divided into two classes: tumors that are of viral etiology and those that are not. Virus-induced malignancies (see Chapter 3) present clear biochemical evidence of their viral origin, because tumors that have been triggered by tumor virus infections (such as viruses of the herpesvirus and papillomavirus classes) almost always continue to express virus-encoded oncoproteins during the course of tumor outgrowth. These viral proteins are structurally distinct from normal host proteins and are therefore intrinsically capable of being recognized as foreign by the host immune system; the latter can readily respond by mounting immune responses against them, more specifically against the cancer cells that express them. These facts, on their own, explain how the cells of virus-induced malignancies can attract the attention of the immune system, which may in turn be able to control their outgrowth, and how failure

of this control accounts for the 20% of cancer mortality worldwide that derives from this class of human tumors.

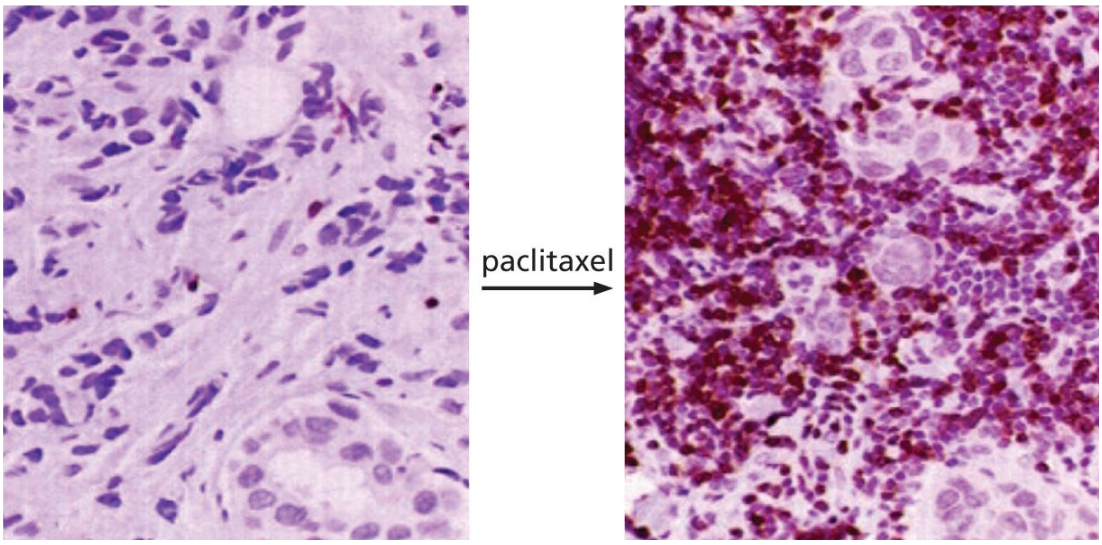
A more challenging task is understanding how the immune system can recognize and eliminate *nonviral* malignancies (that is, those not induced by infecting tumor viruses), and whether failure to do so results in the tumors responsible for nearly 80% of cancer-associated mortality. Here, the major difficulty derives from the phenomenon of tolerance described above—from the fact that the immune system's attentions are directed away from attacking the body's own tissues (that is, self) and thus away from the cancer cells that are, to a large extent, very similar to the cells in our normal tissues.

As we will see in more detail below, many of the actions of the immune system are mediated by a class of immune cells (immunocytes) collectively termed lymphocytes, which are responsible for organizing attacks against tumor cells. Much of the evidence supporting a role of lymphocyte-mediated immune surveillance in warding off non-virus-induced tumors comes from the histopathological studies of a broad spectrum of human tumors. These neoplasms often contain large numbers of tumor-infiltrating lymphocytes (TILs; **Figure 15.3**), providing a clear indication that immune recognition and associated recruitment of these immune cells into the interstices of tumors has occurred. Importantly, this recognition, on its own, does not guarantee a successful attack on and elimination of tumor cells. Instead, it only suggests that such recognition has taken place, setting the stage for possible attack on the associated tumor masses by the recruited immune cells.



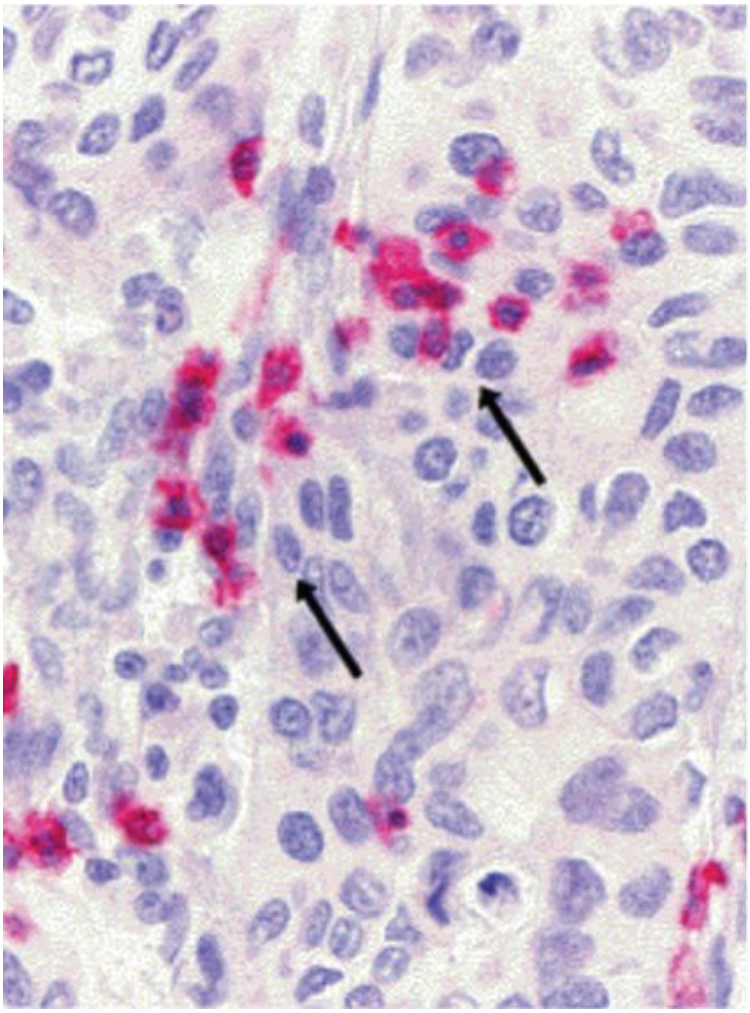
A histology stain image. The nuclei on the right side of the image are pale blue, while those on the left side are dark brown.

(A)



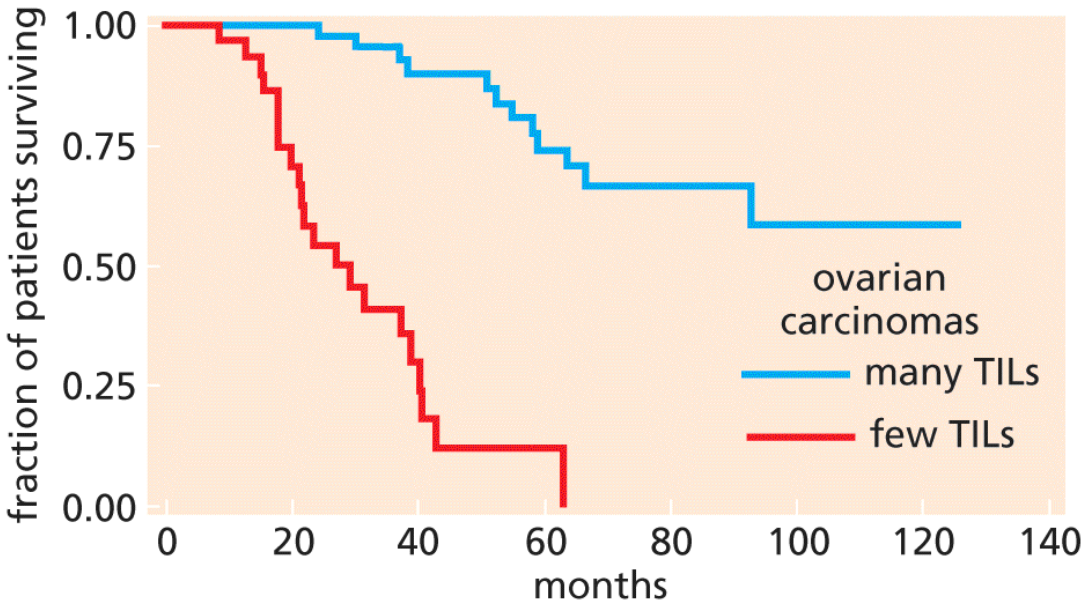
A before-and-after comparison of histology stain images. The before image is moderately dense with purple nuclei. The image after treatment with paclitaxel is thick with dark magenta nuclei.

(B)



A histology stain image. It mostly shows pale purple nuclei, but there are concentrations of bright pink smudges.

(C)



A line graph describing fraction of ovarian carcinoma patients surviving as a function of time. Of patients whose tumors contained many T I Ells, 70 percent survived at least 80 months after diagnosis. Of patients whose tumors contained few T I Ells, none survived to 65 months after diagnosis.

(D)

Figure 15.3 Tumor-infiltrating lymphocytes (A) This immunostaining of an oral carcinoma with an antibody that recognizes the CD3 antigen expressed by T lymphocytes reveals an abundance of tumor-infiltrating lymphocytes (TILs; *brown*) in certain areas of the tumor. More detailed characterizations revealed several T-lymphocyte subtypes among these cells (*not shown*). (B) This immunostaining demonstrates that TILs, detected once again with an anti-CD3 antibody (*dark purple*), are relatively rare in an untreated breast tumor (*left*) but become abundant in areas of the tumor following chemotherapy with the drug paclitaxel (*right*). The increased presence of TILs following chemotherapy is assumed to be indicative of an immune response mediated by the immigrant TILs. (C) TILs are also frequently found in invasive non-small-cell lung carcinomas (NSCLCs; *arrows*). The expression here of the CD8 antigen (*dark pink*) indicates that these cells are largely cytotoxic lymphocytes (CTL). (D) The clinical prognosis of a set of ovarian carcinoma patients was strongly correlated with the concentrations of TILs in their tumors. In this Kaplan–Meier plot, the proportion of patients surviving after initial diagnosis (*ordinate*) is plotted versus the months of survival (*abscissa*). Those patients whose tumors had high levels of TILs (*blue line*) fared significantly better than did those whose tumors lacked significant concentrations of TILs (*red line*). (A, from T.E. Reichert et al., *Clin. Cancer Res.*

In fact, the presence of TILs in a human tumor usually tells us more: it provides a strong indication that the immune system may be actively launching attacks against neoplastic cells. Such attacks may often succeed in constraining tumor outgrowth, but by definition, they fail to eliminate the tumor, as evidenced by the continued presence of a large, clinically detectable mass in a patient's body. As an example, clinical observations on ovarian carcinoma patients have demonstrated that the presence of large numbers of TILs in their tumors prior to debulking of the tumor through surgery and chemotherapy is associated with dramatically better survival outcomes compared to patients whose ovarian tumors lacked TILs (Figure 15.3D). Similar outcomes are associated with the clinical courses of melanoma and colorectal carcinoma patients whose tumors carry large numbers of TILs; in the case of melanomas, these patients live 1.5 to 3 times longer following diagnosis than do patients lacking comparable populations of TILs in their tumors. Similar correlations have been made between the presence of these infiltrating lymphocytes and the survival of patients bearing carcinomas of the breast, bladder, prostate, and rectum. Still, such observations, although striking, are only correlative, and therefore do not prove that these lymphocytes are actually important agents responsible for launching attacks on tumors, thereby constraining tumor growth and the progression to life-threatening cancers.

The identities of the immune cells that are attracted into a growing tumor mass are actually quite complex, involving multiple distinct types of immunocytes (**Figure 15.4**). The composition of these immunocytes differs greatly when comparing individual tumors with one another. Such heterogeneity complicates attempts at drawing generalizable conclusions about the role of the immune system in controlling all types of cancer. Moreover, each class of immunocytes may be represented by multiple subtypes that can play distinct, even conflicting roles in fostering or suppressing tumor growth. In some cases, the presence of specific subtypes of immune cells is closely associated with the stage of tumor progression, providing strong but still-correlative evidence of a causal role in controlling or failing to control clinical behavior (**Figure 15.5**).
